Paleontologists hypothesize, based on fossil evidence, that the first primates descended from small, shrewlike **placental mammals** that lived in trees and ate insects. (Placental mammals are the largest and most successful group of mammals. They possess a placenta, an organ that exchanges materials between the mother and the embryo/fetus developing in the uterus.) Many traits of the 233 living primate species are related to their **arboreal** (tree-dwelling) past. This chapter focuses on humans and their ancestors, who differ from most other primates because they did not remain in the trees but instead adapted to a terrestrial way of life. ■

PRIMATE ADAPTATIONS

Learning Objective

1 Describe the structural adaptations that primates have for life in treetops.

Humans and other **primates**—including lemurs, tarsiers, monkeys, and apes—are mammals that share such traits as flexible hands and feet with five digits, a strong social organization, and front-facing eyes, which permit depth perception. Mammals (class Mammalia) evolved from mammal-like reptiles known as *therapsids* more than 200 million years ago (mya), during the Mesozoic era (see Fig. 31-24). These early mammals remained a minor component of life on Earth for almost 150 million years and then rapidly diversified during the Cenozoic era (from 66 mya to the present).

Fossil evidence indicates that the first primates with traits characteristic of modern primates appeared by the Early Eocene epoch about 56 mya. These early primates had digits with nails, and their eyes were directed somewhat forward on the head.

Several novel adaptations evolved in early primates that allowed them to live in trees. One of the most significant primate features is each limb has five highly flexible digits: four lateral digits (fingers) plus a partially or fully opposable first digit (thumb and, in many primates, big toe; Fig. 22-1). An **opposable thumb** positions the fingers opposite the thumb, enabling primates to grasp objects such as tree branches with precision. Nails (instead of claws) provide a protective covering for the tips of the digits, and the fleshy pads at the ends of the digits are sensitive to touch. Another arboreal feature is long, slender limbs that rotate freely at the hips and shoulders, giving primates full mobility to climb and search for food in the treetops.

Having eyes located in the front of the head lets primates integrate visual information from both eyes simultaneously; they have *stereoscopic* (three-dimensional) vision important in judging distance and in depth perception. Stereoscopic vision is vital in an arboreal environment, especially for species that leap from branch to branch, because an error in depth perception may cause a fatal fall. In addition to having sharp sight, primates hear acutely.

Primates share several other characteristics, including a relatively large brain size. Biologists have suggested that the increased sensory input associated with primates' sharp vision and greater agility favored the evolution of larger brains. Primates are generally very social and intelligent animals that reach sexual maturity relatively late in life. They typically have long life spans. Females usually bear one offspring at a time; the baby is helpless and requires a long period of nurturing and protection.

Key Point

Primates have five grasping digits at the end of each limb, and the thumb or first toe is often partially or fully opposable.

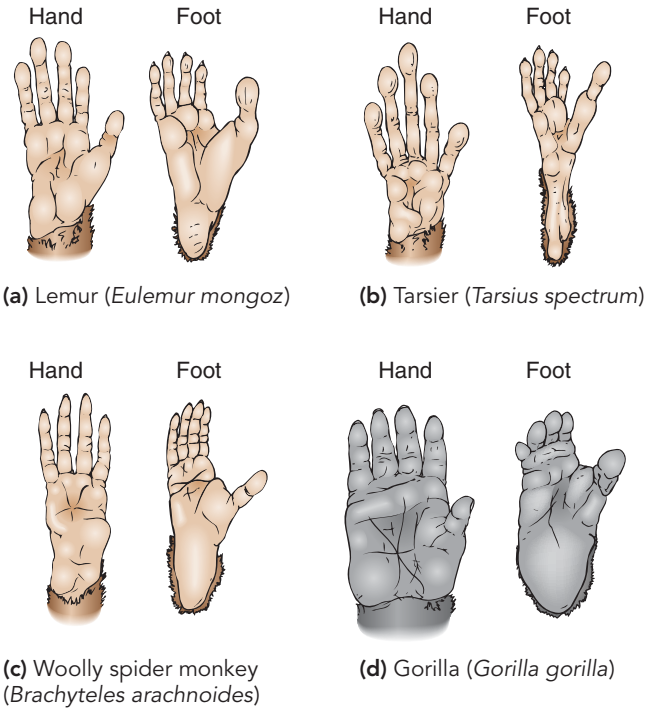

Figure 22-1 Right hands and feet of selected primates (*Figures not drawn to scale.*) (Adapted from A. H. Schultz, *The Life of Primates*, Weidenfeld & Nicholson, London, 1969.)

Review

- How are primate hands and feet adapted to an arboreal existence?
- Why is the location of primate eyes in the front of the head an important adaptation for an arboreal existence?

Key Point

Several kinds of data support the hypothesis that chimpanzees are the closest living relative of humans.

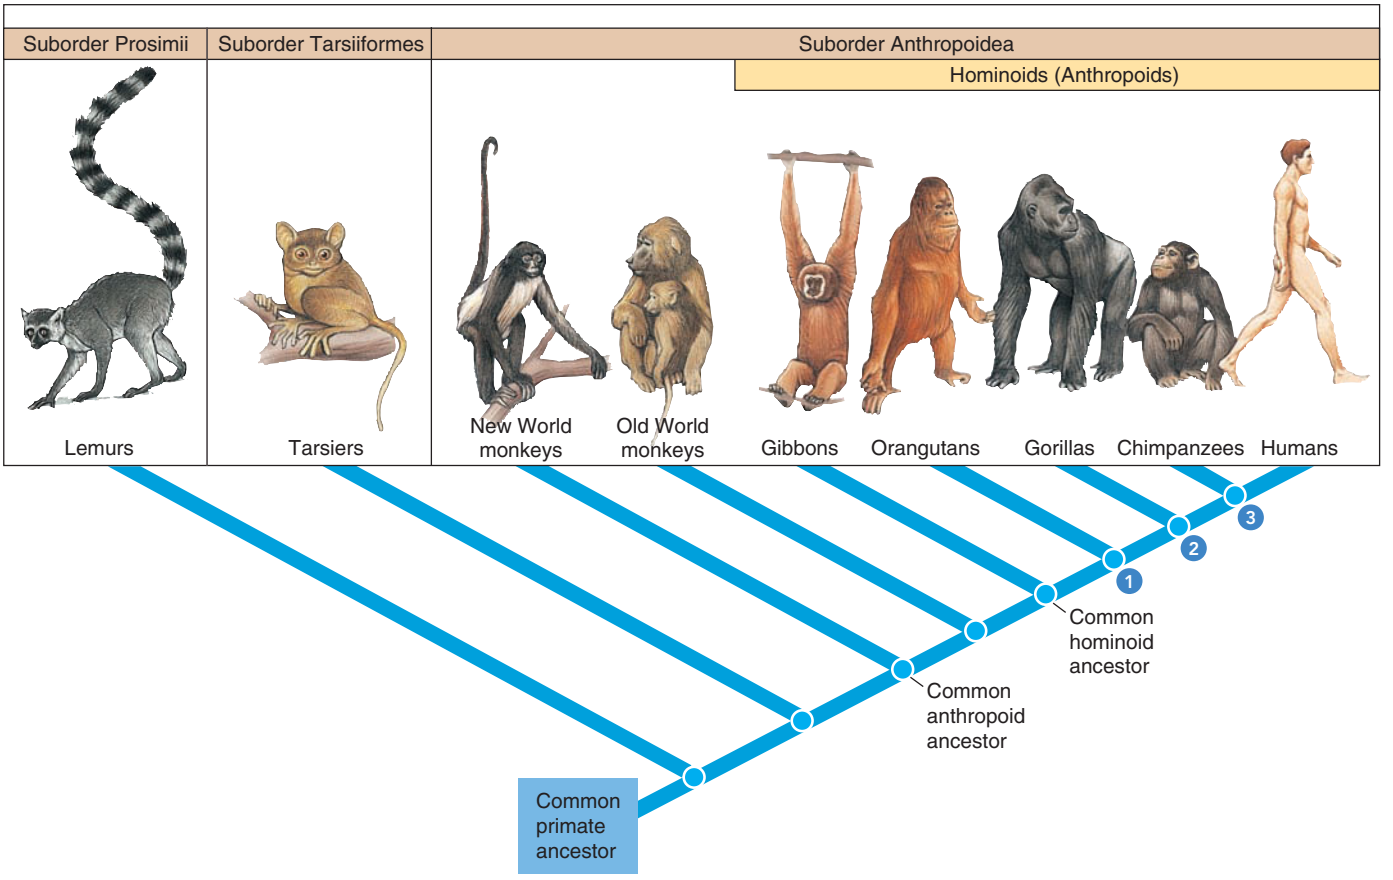

Figure 22-2 ***Animated*** Primate evolution

This branching diagram, called a cladogram, shows evolutionary relationships among living primates, based on current scientific evidence. The nodes (*circles*) represent branch points where a species splits into two or more lineages. 1 The divergence of orangutans from the ape/hominid line occurred some 12 mya to 16 mya. 2 Gorillas separated from the chimpanzee/hominid line an estimated 8 mya, and 3 the hominid (human) lineage diverged from that of chimpanzees about 6 mya. (*Figures not drawn to scale.*)

PRIMATE CLASSIFICATION

Learning Objectives

2 List the three suborders of primates, and give representative examples of each.

3 Distinguish among anthropoids, hominoids, and hominids.

Now that we have surveyed the general characteristics of primates, let us look at how they are classified. Many biologists currently divide the order Primates into three groups, or suborders (Fig. 22-2). The suborder Prosimii includes lemurs, galagos, and lorises; the suborder Tarsiiformes includes tarsiers; and the suborder Anthropoidea includes **anthropoids** (monkeys, apes, and humans).

All lemurs are restricted to the island of Madagascar off the coast of Africa. Because of extensive habitat destruction and hunting, they are very endangered. Lorises, which live in tropical areas of Southeast Asia and Africa, resemble lemurs in many respects, as do galagos, which live in sub-Saharan Africa. Lemurs, lorises, and galagos have retained several early mammalian features, such as elongated, pointed faces.

Tarsiers are found in rain forests of Indonesia and the Philippines (Fig. 22-3). They are small primates (about the size of a small rat) and are very adept leapers. These nocturnal primates resemble anthropoids in a number of ways, including their shortened snouts and forward-pointing eyes.

Suborder Anthropoidea includes monkeys, apes, and humans

Anthropoid primates arose during the Middle Eocene epoch, at least 45 mya. Several different fossil anthropoids have been identified, from Asia and North Africa, and there is a growing consensus about the relationships of these fossil groups to one another and to living anthropoids. Evidence indicates that anthropoids originated in Africa or Asia. The oldest known anthropoid fossils, such as 42-million-year-old *Eosimias,* have been found in China and Myanmar. Given details about their dentition and the few bones that have been discovered, scientists infer that *Eosimias* and other ancestral anthropoids were small, insect-eating arboreal primates that were active during the day. Once they evolved, anthropoids quickly spread throughout Europe, Asia, and Africa and arrived in South America much later. (Paleoanthropologists date the oldest known South American primate, *Branisella,* from Bolivia, at 26 million years old.)

One significant difference between anthropoids and other primates is the size of their brains. The cerebrum, in particular, is more developed in monkeys, apes, and humans, where it functions as a highly complex center for learning, voluntary movement, and interpretation of sensation.

Monkeys are generally diurnal (active during the day) tree dwellers. They tend to eat fruit and leaves, with nuts, seeds, buds, insects, spiders, birds' eggs, and even small vertebrates playing a smaller part in their diets. The two main groups of monkeys, New World monkeys and Old World monkeys, are named for the hemispheres where they diversified. Monkeys in South and Central America are called New World monkeys, whereas monkeys in Africa, Asia, and Europe are called Old World monkeys. New and Old World monkeys have been evolving separately for tens of millions of years.

One of the most important unanswered questions in anthropoid evolution concerns *how* monkeys arrived in South America. Africa and South America had already drifted apart (see Fig. 18-15), so the ancestors of New World monkeys may have rafted from Africa to South America on floating masses of vegetation. The South Atlantic Ocean would have been about half as wide as it is today, and islands could have provided "stepping stones." Alternatively, the ancestors of New World monkeys may have dispersed from Asia to North America to South America. Once established in the New World, these monkeys rapidly diversified.

New World monkeys are restricted to Central and South America and include marmosets, capuchins, howler monkeys, squirrel monkeys, and spider monkeys. New World monkeys are arboreal, and some have long, slender limbs that permit easy movement in the trees (Fig. 22-4a). A few have **prehensile tails** capable of wrapping around branches and serving as fifth limbs. Some New World monkeys have shorter thumbs, and in certain cases the thumbs are totally absent. Their facial anatomy differs from that of the Old World monkeys; New World monkeys have flattened noses with the nostrils opening to the side. They live in groups and engage in complex social behaviors.

Old World monkeys are distributed in tropical parts of Africa and Asia. In addition to baboons and macaques (pronounced "muh-kacks'"), the Old World group includes guenons, mangabeys, langurs, and colobus monkeys. Most Old World monkeys are arboreal, although some, such as baboons and macaques, spend much of their time on the ground (Fig. 22-4b). The ground dwellers, which are **quadrupedal** (four footed; they walk on all fours), arose from arboreal monkeys. None of the Old World monkeys has a prehensile tail, and some have extremely short tails. They have a fully opposable thumb, and unlike the New World monkeys, their nostrils are closer together and directed downward. Old World monkeys are intensely social animals.

Frans Lanting/Minden Pictures

Figure 22-3 A tarsier

The huge eyes of the tarsier (*Tarsius bancanus*) help it find insects, lizards, and other prey when it hunts at night. When a tarsier sees an insect, it pounces on it and grasps the prey with its hands. Tarsiers live in the rain forests of Indonesia and the Philippines.

Apes are our closest living relatives

Old World monkeys shared a common ancestor with the **hominoids,** a group composed of apes and **hominids** (humans and their ancestors). A fairly primitive anthropoid, discovered in Egypt, was named *Aegyptopithecus* (Fig. 22-5a). A cat-sized, forest-dwelling arboreal monkey with a few apelike characteristics, *Aegyptopithecus* lived during the Oligocene epoch, approximately 34 mya.

Fossil evidence indicates that apes and Old World monkeys had diverged between 23 mya and 25 mya, although a 2004 genetic analysis of living apes and monkeys suggests that this divergence may have occurred even earlier. During the Miocene epoch

as many as 100 species of apes lived in Africa, Asia, and Europe.

Paleoanthropologists have discovered the oldest fossils with hominoid features in East Africa, mostly in Kenya. *Proconsul,* for example, appeared early in the Miocene epoch, about 20 mya (Fig. 22-5b). It had a larger brain than that of monkeys, apelike teeth and diet (fruits), but a monkeylike body. At least 30 other early hominoid species lived during the Miocene epoch, but most of them became extinct and were not the common ancestor of modern apes and humans.

Miocene fossils of forest-dwelling, chimpanzee-sized apes called **dryopithecines,** which lived about 15 mya, are of special interest because this hominoid lineage may have given rise to modern apes as well as to humans (Fig. 22-5c). The dryopithecines, such as *Dryopithecus, Kenyapithecus,* and *Morotopithecus,* were distributed widely across Europe, Africa, and Asia. As the climate gradually cooled and became drier, their range became more limited. These apes had highly modified bodies for swinging through the branches of trees, although there is also evidence that some of them may have left the treetops for the ground as dense forest gradually changed into open woodland. Many questions about the relationships among the various early apes have been generated by the discovery of these and other Miocene hominoids. As future fossil finds are evaluated, they may lead to a rearrangement of ancestors in the hominoid family tree.

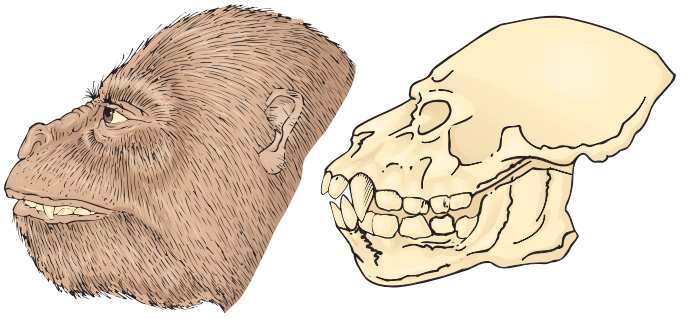
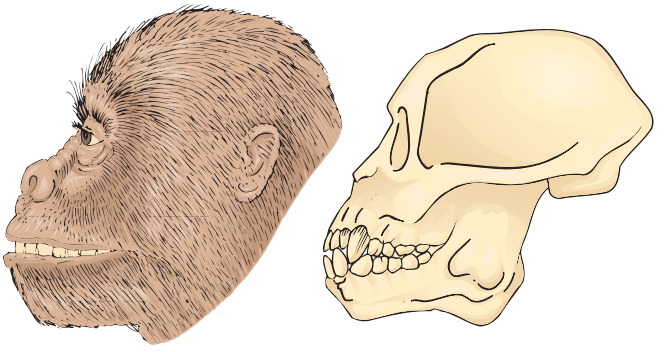
Figure 22-4 New World and Old World monkeys

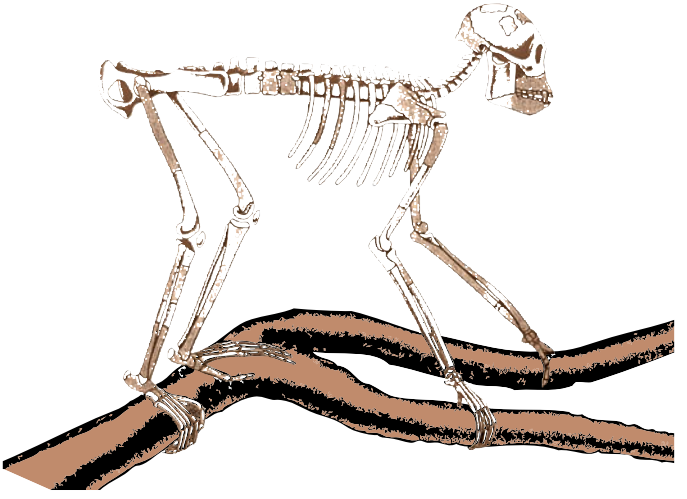
Five genera of hominoids exist today: gibbons (*Hylobates*), orangutans (*Pongo*), gorillas (*Gorilla*), chimpanzees (*Pan*), and humans (*Homo*). Gibbons are known informally as small apes; orangutans, gorillas, and chimpanzees are known as great apes. Molecular evidence indicates a close relationship between



(a) Fossils of *Aegyptopithecus*, a fairly primitive anthropoid, were discovered in Egypt.



(c) *Dryopithecus*, a more advanced ape, may have been ancestral to modern hominoids.



(b) Skeletal reconstruction of *Proconsul*. (The reconstructed parts are white.) This anthropoid had the limbs and body proportions of a monkey but lacked a tail, which is characteristic of apes.

Figure 22-5 Ape evolution

(*Figures not drawn to scale.*)

humans and the great apes, particularly chimpanzees.

Gibbons are natural acrobats that can **brachiate,** or arm-swing, with their weight supported by one arm at a time (Fig. 22-6a). Orangutans are also tree dwellers, but chimpanzees and especially gorillas have adapted to life on the ground (Fig. 22-6b–d). Gorillas and chimpanzees have retained long arms typical of brachiating primates but use these to assist in quadrupedal walking, sometimes known as **knuckle walking** because of the way they fold (flex) their digits when moving. Like humans, apes lack tails, a characteristic that makes them easy to distinguish from monkeys. They are generally much larger than monkeys, although gibbons are a notable exception.

Evidence of the close relatedness of orangutans, gorillas, chimpanzees, and humans is abundant at the molecular level. The amino acid sequence of the chimpanzee's hemoglobin is identical to that of the human; hemoglobin molecules of the gorilla and rhesus monkey differ from the human's by 2 and 15 amino acids, respectively. DNA sequence analyses indicate that chimpanzees are likely to be our nearest living relatives among the apes (see Table 18-1). Molecular evidence suggests that orangutans may have diverged from the gorilla, chimpanzee, and hominid lines about 12 mya to 16 mya. Gorillas may have diverged from the chimpanzee and hominid lines some 8 mya, whereas chimpanzee and hominid lines probably separated about 6 mya.

Review

- What are the three suborders of primates?
- How can you distinguish between anthropoids and hominoids?

HOMINID EVOLUTION

Learning Objectives

4 Describe skeletal and skull differences between apes and hominids.

5 Briefly describe the following early hominids: *Sahelanthropus, Orrorin, Ardipithecus ramidus,* and *Australopithecus anamensis, A. afarensis,* and *A. africanus.*

6 Distinguish among the following members of genus *Homo: H. habilis, H. ergaster, H. erectus, H. neanderthalensis,* and *H. sapiens.*

7 Discuss the origin of modern humans.

Joe McDonald/Visuals Unlimited

Figure 22-6 Apes

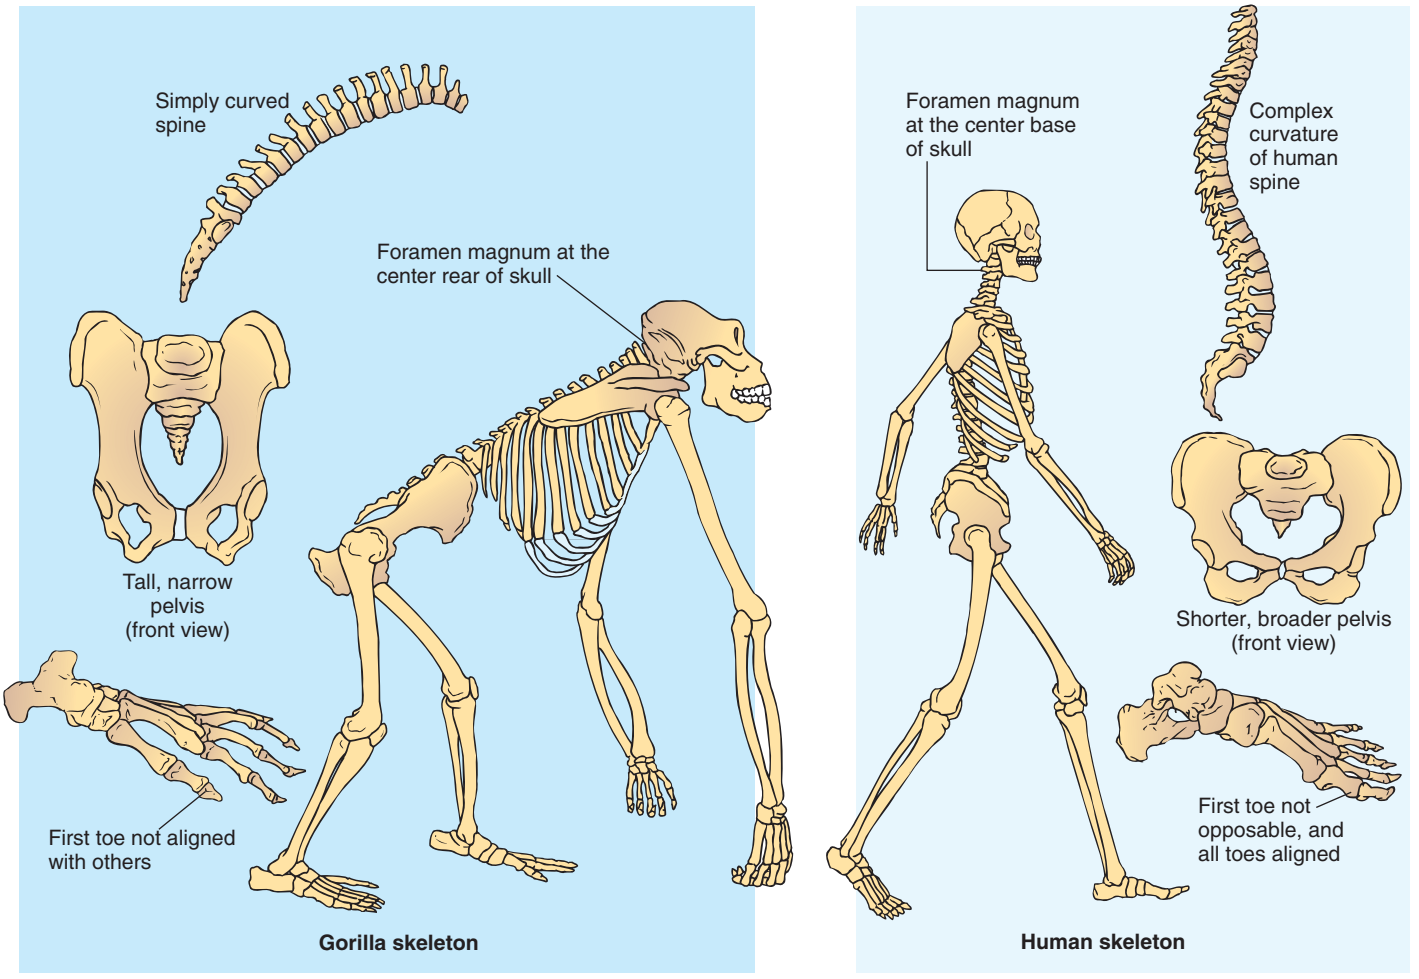

Figure 22-7 ***Animated*** Gorilla and human skeletons

When gorilla and human skeletons are compared, the skeletal adaptations for bipedalism in humans become apparent.

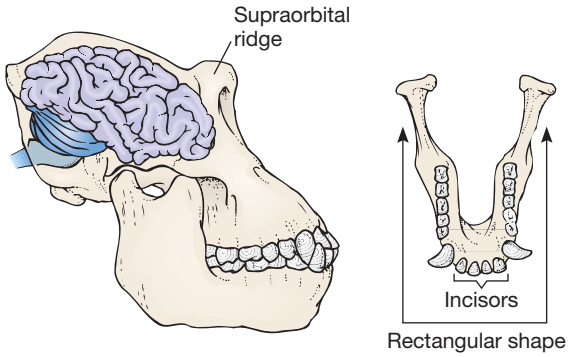
Scientists have a growing storehouse of hundreds of hominid fossils, which provide useful data about general trends in the body design, appearance, and behavior of ancestral humans. For example, before their brains enlarged, early hominids clearly adopted a **bipedal** (two-footed) posture. Despite the wealth of fossil evidence, scientists continue to vigorously debate interpretations of hominid characteristics, classification, and evolution, and new discoveries raise new questions. As in other scientific fields, ideas about hominid evolution are influenced by the different perspectives of the various workers studying it. The lack of scientific consensus regarding certain aspects of hominid evolution is, therefore, an expected part of the scientific process.

Evolutionary changes from the earliest hominids to modern humans are evident in some of the characteristics of the skeleton and skull. Compared with the ape skeleton, the human skeleton shows distinct differences that reflect humans' ability to stand erect and walk on two feet (Fig. 22-7). These differences also reflect the habitat change for early hominids, from an arboreal existence in the forest to a life spent at least partly on the ground.

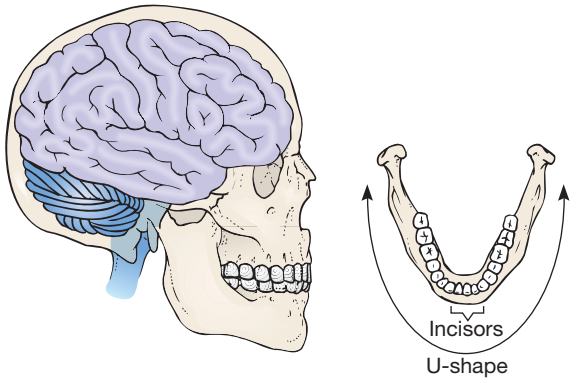
The curvature of the human spine provides better balance and weight distribution for bipedal locomotion. The human pelvis is shorter and broader than the ape pelvis, allowing better attachment of muscles used for upright walking. In apes the **foramen magnum,** the hole in the base of the skull for the spinal cord, is located in the rear of the skull. In contrast, the human foramen magnum is centered in the skull base, positioning the head for erect walking. An increase in the length of the legs relative to the arms, and alignment of the first toe with the rest of the toes, further adapted the early hominids for bipedalism.

Another major trend in hominid evolution was an increase in brain size relative to body size (Fig. 22-8). The ape skull has prominent **supraorbital ridges** above the eye sockets, whereas modern human skulls lack these ridges. Human faces are flatter than those of apes, and the jaws are different. The arrangement of teeth in the ape jaw is somewhat rectangular, compared with a rounded, or U-shaped, arrangement in humans. Apes have larger front teeth (canines and incisors) than do humans, and their canines are especially large. Gorillas and orangutans also have larger back teeth (premolars and molars) than do humans.

We now examine some of the increasing number of fossil hominids in the human lineage. As you read the following descriptions of human evolution, keep in mind that much of what



(a) The ape skull has a pronounced supraorbital ridge.



(b) The human skull is flatter in the front and has a pronounced chin. The human brain, particularly the cerebrum (*purple*), is larger than that of an ape, and the human jaw is structured so that the teeth are arranged in a U shape. Human canines and incisors are also smaller than those of apes.

Figure 22-8 Gorilla and human heads

is discussed is still open to interpretation and major revision as additional discoveries are made. It is also important to remember that although we present human evolution in a somewhat linear fashion, from ancient hominids to anatomically and behaviorally modern humans, the human family tree is not a single trunk but has several branches (Fig. 22-9). Perhaps it is most useful to think of the known hominid fossils as a sampling of human evolution instead of a continuous sequence.

Homo sapiens is the only species of hominid in existence today, but more than one hominid species coexisted at any given time for most of the past 4 million years. In addition, do not make the mistake of thinking that your smaller-brained ancestors were inferior to yourself. Ancestral hominids were evolutionarily successful in that they were well adapted to their environment and survived for millions of years.

The earliest hominids may have lived 6 mya to 7 mya

Hominid evolution began in Africa. Although most hominid fossils have been discovered in Ethiopia and Kenya, in 2002 French paleontologist Michel Brunet and an international team made a stunning discovery in a dry lake bed in Chad, which is in central

Key Point

Paleoanthropologists do not completely agree about certain specific details of the human family tree and hold many possible interpretations of classification lines of descent.

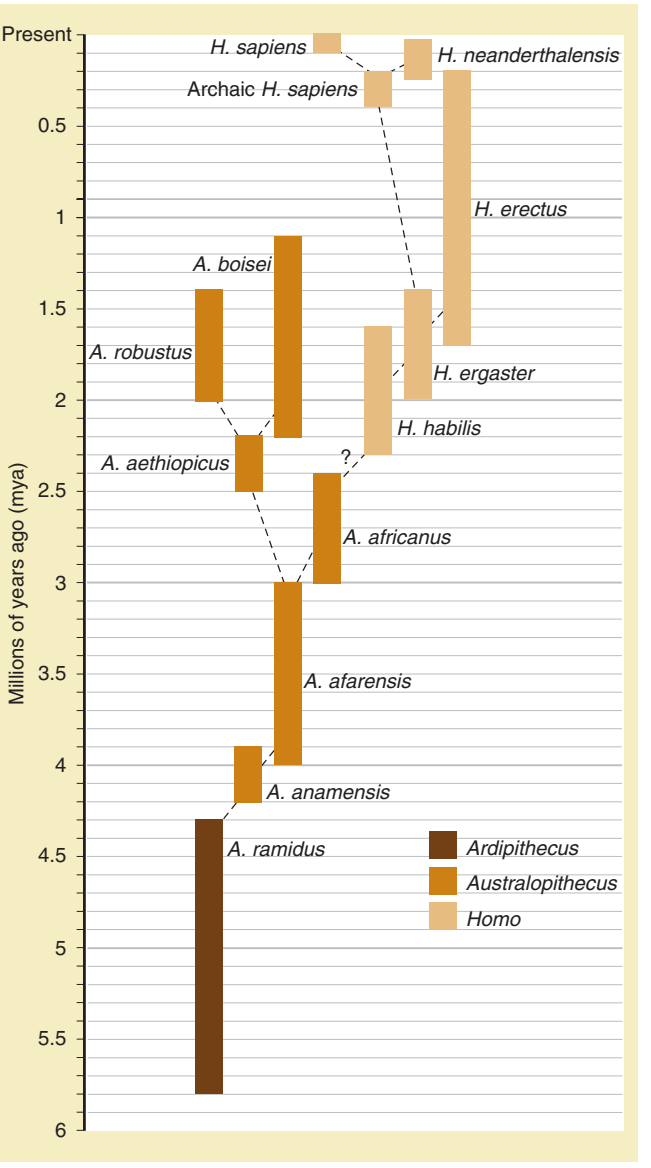


Figure 22-9 One interpretation of human evolution

This figure does not include hominid fossils earlier than *Ardipithecus*. Dashed lines show possible evolutionary relationships.

Africa. The fossil, which has been reliably dated at 6 million to 7 million years old, may be the earliest known hominid. Viewed from the back, the skull of ***Sahelanthropus,*** with its small braincase, resembles that of a chimpanzee. However, viewed from the front, the face and teeth have many characteristics of larger-brained human ancestors. Most paleoanthropologists place *Sahelanthropus* close to the base of the human family tree—that is, close to when genetic analyses suggest the last common ancestor of hominids and chimpanzees existed. The discovery of *Sahel-*

anthropus is important in its own right, but it is also significant because it shows that early hominids exhibited more variation and lived over a larger area of Africa than had been originally hypothesized.

Orrorin, discovered in 2001 in Kenya, may also represent one of the earliest known hominids. The sediments in which fossils of *Orrorin* were found have been reliably dated at 6 million years old. Researchers studying the fossil leg bones of *Orrorin* think that it walked upright and was bipedal.

As with many aspects of human evolution, scientists have widely differing interpretations of *Sahelanthropus* and *Orrorin.* For example, some paleoanthropologists hypothesize that *Sahelanthropus* was a forerunner of modern apes, specifically the gorilla, and not one of the earliest humans. Other researchers think the similar features of *Sahelanthropus, Orrorin,* and *Ardipithecus* (discussed in the next section) fossils mean that they are all members of the same genus, *Ardipithecus.* This point remains controversial, largely because there are currently no skeletal bones (leg, pelvis, and foot bones) to indicate if *Sahelanthropus* walked upright, a hallmark characteristic of hominids. (A 2005 reconstruction of the skull has features that strongly suggest *Sahelanthropus* was bipedal.) Future fossil discoveries and additional analyses of existing fossils should help clarify the evolutionary relationships among *Sahelanthropus, Orrorin,* and *Ardipithecus.*

Australopithecines are the immediate ancestors of genus *Homo*

After *Sahelanthropus* and *Orrorin,* the next-oldest hominid belongs to the genus ***Ardipithecus,*** which lived in eastern Africa more than 5 mya. Although not as primitive as *Sahelanthropus, Ardipithecus* is close to the "root" of the human family tree. The shape of the toe bones indicates that *Ardipithecus* walked upright.

Ardipithecus gave rise to ***Australopithecus,*** a genus that includes several species that lived between 4 mya and 1 mya. *Ardipithecus* and *Australopithecus* are referred to as **australopithecines,** or "southern man apes." Both had longer arms, shorter legs, and smaller brains relative to those of modern humans.

Hominids that existed between 4.2 mya and 3.9 mya are assigned to the species ***Australopithecus anamensis,*** first named by paleoanthropologist Meave Leakey and her coworkers in 1995 from fossils discovered in East Africa. This hominid species, which has a mixture of apelike and humanlike features, presumably evolved from *Ardipithecus ramidus.* A comparison of male and female *Australopithecus anamensis* body sizes and canine teeth reveals **sexual dimorphism,** marked phenotypic differences between the two sexes of the same species. (The modern-day gorilla is sexually dimorphic.) The back teeth and jaws of *A. anamensis* are larger than those of modern chimpanzees, whereas the front teeth are smaller and more like those of later hominids. A fossil leg bone, the tibia, indicates that *A. anamensis* had an upright posture and was bipedal, although it also may have foraged in the trees. Thus, bipedalism occurred early in human evolution and appears to have been the first human adaptation.

Australopithecus afarensis, another primitive hominid, probably evolved directly from *A. anamensis.* Many fossils of *A. afarensis* skeletal remains have been discovered in Africa, including a remarkably complete 3.2-million-year-old skeleton, nicknamed Lucy, found in Ethiopia in 1974 by a team led by U.S. paleoanthropologist Donald Johanson. In 1978, British paleoanthropologist Mary Leakey and coworkers discovered beautifully preserved fossil footprints of three *A. afarensis* individuals who walked more than 3.6 mya. In 1994, paleoanthropologists found the first adult skull of *A. afarensis.* The skull, characterized by a relatively small brain, pronounced supraorbital ridges, a jutting jaw, and large canine teeth, is an estimated 3 million years old. It is probable that *A. afarensis* did not construct tools or make fires, because no evidence of tools or fire has been found at fossil sites.

Many paleoanthropologists think that *A. afarensis* gave rise to several australopithecine species, including ***Australopithecus africanus,*** which may have appeared as early as 3 mya. The first *A. africanus* fossil was discovered in South Africa in 1924, and since then hundreds have been found. This hominid walked erect and possessed hands and teeth that were distinctly humanlike. Given the characteristics of the teeth, paleoanthropologists think that *A. africanus* ate both plants and animals. Like *A. afarensis,* it had a small brain, more like that of its primate ancestors than of present-day humans.

Three australopithecine species (*Australopithecus robustus* from South Africa, and *A. aethiopicus* and *A. boisei,* both from East Africa) were larger than *A. africanus* and had extremely large molars, very powerful jaws, relatively small brains, and bony skull crests. Most females lacked the skull crests and had substantially smaller jaws, another example of sexual dimorphism in early hominids. The teeth and jaws suggest a diet, perhaps of tough roots and tubers, that would require powerful grinding. These so-called *robust australopithecines* may or may not be closely related but are generally thought to represent evolutionary offshoots, or side branches, of human evolution. The first robust australopithecine, *A. aethiopicus,* appeared about 2.5 mya. Some researchers classify robust australopithecines in a separate genus, *Paranthropus.*

The actual number of australopithecine species for which fossil evidence has been found is under debate. In some cases, differences in the relatively few skeletal fragments could indicate either variation among individuals within a species or evidence of separate species. Most paleoanthropologists recognize at least six species of australopithecines.

Homo habilis is the oldest member of genus *Homo*

The first hominid to have enough uniquely human features to be placed in the same genus as modern humans is ***Homo habilis.*** It was first discovered in the early 1960s at Olduvai Gorge in Tanzania. Since then, paleoanthropologists have discovered other fossils of *H. habilis* in East and South Africa. *Homo habilis* was a small hominid with a larger brain and smaller premolars and molars than those of the australopithecines. This hominid appeared approximately 2.3 mya and persisted for about 0.75 million years. Fossils of *H. habilis* have been found in numerous areas in Africa. These sites contain primitive tools, stones that

had been chipped, cracked, or hammered to make sharp edges for cutting or scraping. *Oldowan* pebble choppers and flakes, for example, were probably used to cut through animal hides to obtain meat and to break bones for their nutritious marrow.

The relationship between the australopithecines and *H. habilis* is not clear. Using physical characteristics of their fossilized skeletons as evidence, many paleoanthropologists have inferred that the australopithecines were ancestors of *H. habilis.* Some researchers do not think that *H. habilis* belongs in the genus *Homo,* and they suggest it should be reclassified as *Australopithecus habilis.* Discoveries of additional fossils may help clarify these relationships.

Homo erectus apparently evolved from *Homo habilis*

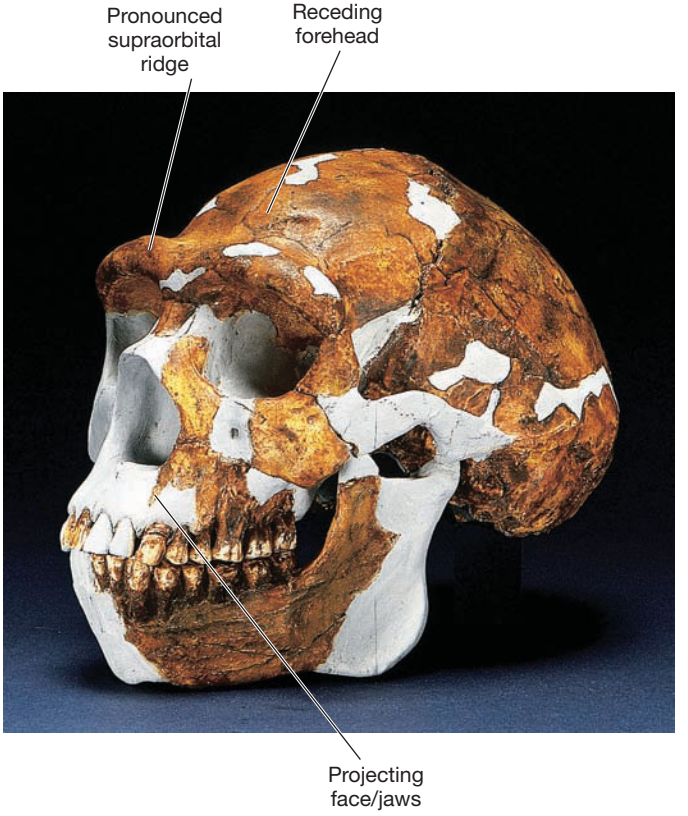
Investigators found the first fossil evidence of ***Homo erectus*** in Indonesia in the 1890s. Since then, searchers have found numerous fossils of *H. erectus* throughout Africa and Asia. Paleoanthropologists think that *H. erectus* originated in Africa about 1.7 mya and then spread to Europe and Asia. Peking man and Java man, discovered in Asia, were later examples of *H. erectus,* which existed until at least 200,000 years ago; some populations of *H. erectus* may have persisted more recently.

Homo erectus was taller than *H. habilis.* Its brain, which was larger than that of *H. habilis,* got progressively larger during the course of its evolution. Its skull, although larger, did not possess totally modern features, retaining the heavy supraorbital ridge and projecting face that are more characteristic of its ape ancestors (Fig. 22-10). *Homo erectus* is the first hominid to have fewer differences between the sexes.

The increased intelligence associated with an increased brain size enabled these early humans to make more advanced stone tools, known as *Acheulean* tools, including hand axes and other implements that scientists have interpreted as choppers, borers, and scrapers. Their intelligence also allowed these humans to survive in cold areas. *Homo erectus* obtained food by hunting or scavenging and may have worn clothing, built fires, and lived in caves or shelters. Evidence of weapons (spears) has been unearthed at *H. erectus* sites in Europe.

Ideas regarding *H. erectus,* like many other aspects of human evolution, are changing with each new fossil discovery. Some scientists hypothesize that the fossils classified as *H. erectus* really represent two species, ***Homo ergaster,*** an earlier African species, and *H. erectus,* a later East Asian offshoot. The best-known fossils of *H. ergaster* come from the Lake Turkana region in Kenya. Researchers who support this split speculate that *H. ergaster* may be the direct ancestor of later humans, whereas *H. erectus* may be an evolutionary dead end. (For the remarkable story of an evolutionary offshoot from *H. erectus,* see *Focus On: The Smallest Humans.*)

Other paleoanthropologists do not think that *H. erectus* should be split into two or more species. They cite evidence of a 1-million-year-old *H. erectus* fossil that was discovered in Africa in 2002. This fossil shares striking similarities with Asian *H. erectus* fossils and enables paleoanthropologists to compare *H. erectus* fossils from the same period but from two different continents. Scientists hope that further analysis of this fossil and of future fossil discoveries will clarify the status of *H. erectus.*



Ken Mowbray, AMNH

Figure 22-10 ***Animated*** *Homo erectus* skull from China

The reconstructed parts are white. Note the receding forehead, pronounced supraorbital ridge, and projecting face and jaws.

Archaic *Homo sapiens* appeared between 400,000 and 200,000 years ago

Archaic *Homo sapiens* are regionally diverse descendants of *H. erectus* or *H. ergaster* that lived in Africa, Asia, and Europe from about 400,000 to 200,000 years ago. The brains of archaic *H. sapiens* were essentially the same size as our brains, although their skulls retained some ancestral characters. Populations of archaic *H. sapiens* had rich and varied cultures (learned traditions) that included making many kinds of tools and objects with symbolic and ceremonial meaning. Some researchers classify European fossils of archaic *H. sapiens* as a separate species, ***Homo heidelbergensis,*** that existed until the appearance of the Neandertals.

Neandertals appeared approximately 230,000 years ago

Fossils of **Neandertals** were first discovered in the Neander Valley in Germany.[1] They lived throughout Europe and western Asia

[1] *Neandertal* was formerly spelled *Neanderthal.* The silent *h* has been dropped in modern German but not in the scientific name.

THE SMALLEST HUMANS

In 2004, paleoanthropologists reported a startling discovery—fossils of seven humans in a cave on the Indonesian island of Flores. The finding was completely unexpected, because the fossil bones and teeth were from adult humans that were about 1 m (about 3 ft) tall. The tiny humans, which represent a new species named *Homo floresiensis,* also had small, ape-sized brains. Yet sophisticated stone tools, fireplaces, and charred bones found with the fossils indicate that *H. floresiensis* was capable of complex thinking and activities. The charred bones were primarily from pygmy elephants (*Stegodon*) and Flores giant rats (*Papagomys*) and provide clues about the food that *H. floresiensis* hunted and killed (see figure). Based on several dating methods, *H. floresiensis* is thought to have existed from about 38,000 years ago to as recently as 13,000 years ago, when it went extinct.

Detailed studies of the *H. floresiensis* braincase, published in 2005, revealed that it was similar in many ways to the larger brain of *H. erectus,* which is known to have lived on nearby islands. Many researchers have concluded from this and other evidence that *H. floresiensis* was an evolutionary offshoot of *H. erectus.*

Why was *H. floresiensis* so small? Biologists have often observed two evolutionary trends of mammals living on remote islands: large mammals tend to evolve into much smaller species, and small mammals tend to evolve into much larger species. It is not unreasonable to assume that the small population of *H. erectus* ancestors that colonized Flores, perhaps by rafting to the island on a log, underwent natural selection and dwindled in size over the thousands of years they were isolated on Flores. (If *H. erectus* had been a frequent visitor to Flores, gene flow between the indigenous population and the visitors would have prevented the indigenous population from becoming measurably smaller.)

Not everyone agrees with the hypothesis that *H. floresiensis* is a separate species of tiny humans. Some researchers think the fossils have not been identified properly. In a study published in 2006, these researchers suggest that the fossils are from *H. sapiens* individuals suffering from a rare genetic defect (microcephaly) that causes small brains and bodies.

The research team that unearthed the fossils has returned to the cave and will continue excavations. It is anticipated that future discoveries will help scientists answer the many questions we have about Earth's smallest humans.

Peter Schouten/National Geographic Society/University of Wollongong

Homo floresiensis—or pygmy *H. sapiens*—carrying a giant rat

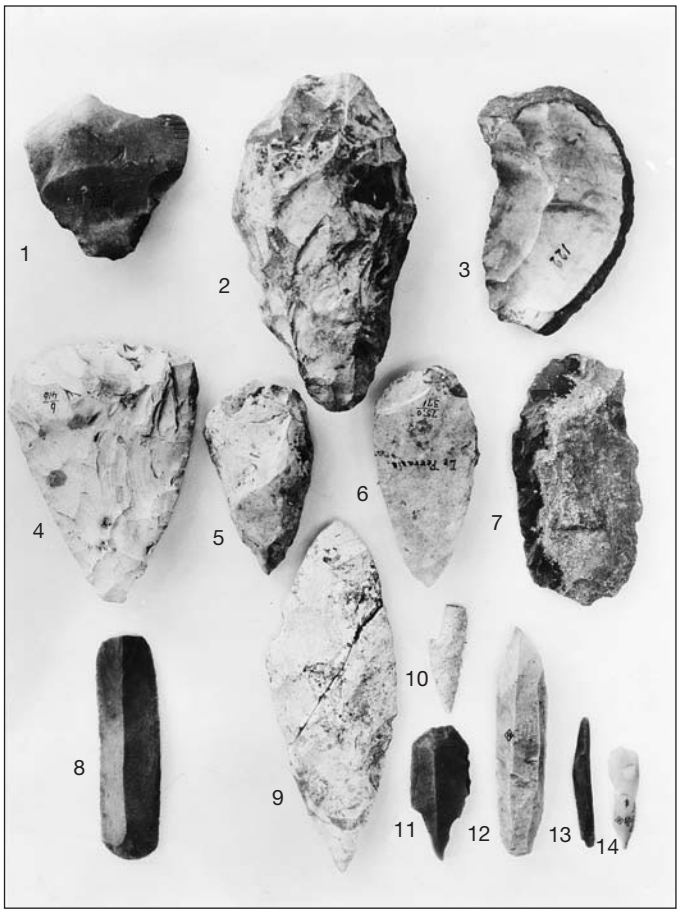
from about 230,000 to 30,000 years ago. These early humans had short, sturdy builds. Their faces projected slightly, their chins and foreheads receded, they had heavy supraorbital ridges and jawbones, and their brains and front teeth were larger than those of modern humans. They had large nasal cavities and receding cheekbones. Scientists have suggested that the large noses provided larger surface areas in Neandertal sinuses, enabling them to better warm the cold air of Ice Age Eurasia as inhaled air traveled through the head to the lungs.

Scientists have not reached a consensus about whether the Neandertals are a separate species from modern humans. Many think the anatomical differences between Neandertals and modern humans mean that they were separate species, ***Homo neanderthalensis*** and ***Homo sapiens.*** Other scientists disagree and think that Neandertals were a group of *H. sapiens.*

Neandertal tools, known as *Mousterian* tools, were more sophisticated than those of *H. erectus* (Fig. 22-11). Studies of Neandertal sites indicate that Neandertals hunted large animals. The existence of skeletons of elderly Neandertals and of some with healed fractures may demonstrate that Neandertals cared for the aged and the sick, an indication of advanced social cooperation. They apparently had rituals, possibly of religious significance, and sometimes buried their dead.

The disappearance of the Neandertals about 28,000 years ago is a mystery that has sparked debate among paleoanthropologists. Other groups of *H. sapiens* with more modern features coexisted with the Neandertals for several thousand years. Perhaps the other humans outcompeted or exterminated the Neandertals, leading to their extinction. It is also possible that the Neandertals interbred with these humans, diluting their features beyond recognition.

Analysis of **mitochondrial DNA (mtDNA)** contributes useful data for such controversies. Each of the several hundred mitochondria within a cell has about 10 copies of a small loop of DNA that codes for transfer RNAs, ribosomal RNAs, and certain respiratory enzymes. The mtDNA is transmitted only through the maternal line because eggs, not sperm, contribute mitochondria. Because mtDNA mutates more rapidly than nuclear DNA, mtDNA is a sensitive indicator of evolution. Researchers have extracted and evaluated the mtDNA from seven separate Neandertals. Its sequence differs significantly from all modern human mtDNA sequences, although it is more similar to human than



Omikron/Photo Researchers, Inc.

Figure 22-11 Mousterian tools

Paleoanthropologists named Mousterian tools after a Neandertal site in Le Moustier, France. Mousterian tools included a variety of skillfully made stone tools, such as hand axes, flakes, scrapers, borers, and spear points (*1* to *7* are earlier tools, and *8* to *14* are later tools).

Tom McHugh/Photo Researchers, Inc.

Figure 22-12 Cro-Magnon man painting an outline of his hand

to chimpanzee mtDNA. This finding suggests that Neandertals are an evolutionary dead end that did not interbreed appreciably with more modern humans. However, the amount of interbreeding that may have occurred between Neandertals and anatomically modern humans remains controversial.

Biologists debate the origin of modern *Homo sapiens*

Homo sapiens with anatomically modern features existed in Africa about 195,000 years ago. The *H. sapiens* skull lacked a heavy brow ridge and had a distinct chin. By about 30,000 years ago, anatomically modern humans were the only members of genus *Homo* remaining, excluding small, isolated populations.

Paleoanthropologists refer to European populations of these ancient people as **Cro-Magnons.** Their weapons and tools were complex and often made of materials other than stone, including bone, ivory, and wood. They made stone blades that were extremely sharp. Cro-Magnons developed art, including cave paintings, engravings, and sculpture, possibly for ritual purposes (Fig. 22-12). Their sophisticated tools and art indicate they may have possessed language, which they would have used to transmit their culture to younger generations.

Two opposing hypotheses have been suggested to explain the origin of these modern humans: the *out-of-Africa hypothesis* and the *multiregional hypothesis.* The out-of-Africa hypothesis holds that modern *H. sapiens* evolved from *H. erectus* in Africa sometime after 200,000 years ago and then migrated to Europe and Asia, displacing the Neandertals and other *Homo* species living there. The out-of-Africa hypothesis predicts that fossils of the earliest humans will be found in Africa.

According to the multiregional hypothesis, modern humans originated as separately evolving *H. erectus* populations living in several parts of Africa, Asia, and Europe. Each of these populations evolved in its own distinctive way but occasionally met and interbred with other populations, preventing complete reproductive isolation. The variation found today in different human populations therefore represents a continuation of this multiregional process. The multiregional hypothesis predicts that fossils of the earliest humans will be found scattered throughout Africa, Europe, and Asia.

Recent fossil finds and molecular analyses have promoted the out-of-Africa hypothesis as the main explanation for the origin of

modern humans. New data include the discovery of the earliest fossilized remains of modern *H. sapiens* in Africa and analyses of DNA from mitochondria and the Y chromosome. In 2005, fossils of the earliest known modern *H. sapiens* were reliably dated at 195,000 years old; these fossils were found in southern Ethiopia. No *H. sapiens* fossils of comparable age have been found in Europe or Asia. The earliest fossils of anatomically modern *H. sapiens* in Europe and most parts of Asia date to 45,000 to 40,000 years ago. One exception is in Israel, where *H. sapiens* fossils have been dated at 100,000 years before present.

Molecular anthropology, the comparison of biological molecules from present-day individuals of regional human populations, provides clues that help scientists unravel the origin of modern humans and trace human migrations. A series of recent genetic studies of both mtDNA and Y-chromosome DNA has strengthened the case for Africa as the birthplace of modern humans. These studies provide detailed comparisons of DNA in present-day populations around the world as well as ancient DNA extracted from Neandertal and early *H. sapiens* remains.

Based on the data, the ancestors common to all humans were probably ancient Khoisans, an indigenous group in southern Africa. This conclusion is based on separate analyses of DNA from both mitochondria and the Y chromosome. Both studies indicated that the Khoisan people are the most ancient of all human groups.

Review

- How does an ape skeleton differ from a human skeleton?
- How do australopithecines and *Homo* differ?
- How can you distinguish between *H. habilis* and *H. erectus*?
- How do *H. neanderthalensis* and *H. sapiens* differ?
- What two hypotheses have been proposed to explain where modern humans originated? Which hypothesis is strongly supported by fossil and molecular evidence?

CULTURAL CHANGE

Learning Objective

8 Describe the impact of human culture on the biosphere.

Genetically speaking, humans are not very different from other primates. At the level of our DNA sequences, we are roughly 98% identical to gorillas and 99% identical to chimpanzees. Our relatively few genetic differences, however, give rise to several important distinguishing features, such as greater intelligence and the ability to capitalize on it by transmitting knowledge from one generation to the next. Human culture is not inherited in the biological sense but instead is learned, largely through the medium of language.[2] Human culture is dynamic and is modified as people obtain new knowledge. Human culture is generally divided into three stages: (1) the development of hunter–gatherer societies, (2) the development of agriculture, and (3) the Industrial Revolution.

Early humans were hunters and gatherers who relied on what was available in their immediate environment. They were nomadic, and as the resources in a given area were exhausted or as the population increased, they migrated to a different area. These societies required a division of labor and the ability to make tools and weapons, which were needed to kill game, scrape hides, dig up roots and tubers, and cook food. Although scientists are not certain when hunting was incorporated into human society, they do know it declined in importance approximately 15,000 years ago. This may have been due to a decrease in the abundance of large animals, triggered in part by overhunting. A few isolated groups of hunter–gatherer societies, such as the Inuit of the northern polar region and the Mbuti of Africa, survived into the 21st century.

Development of agriculture resulted in a more dependable food supply

Evidence that humans had begun to cultivate crops approximately 10,000 years ago includes the presence of agricultural tools and plant material at archaeological sites. Agriculture resulted in a more dependable food supply. Archaeological evidence suggests that agriculture arose in several steps. Although there is variation from one site to another, plant cultivation, in combination with hunting, usually occurred first. Animal domestication generally followed later, although in some areas, such as Australia, early humans did not domesticate animals.

Agriculture, in turn, often led to more permanent dwellings, because considerable time was invested in growing crops in one area. Villages and cities often grew up around the farmlands, but the connection between agriculture and the establishment of villages and towns is complicated by certain discoveries. For example, Abu Hureyra in Syria was a village founded *before* agriculture arose. The villagers subsisted on the rich plant life of the area and the migrating herds of gazelle. Once people turned to agriculture, however, they seldom went back to hunting and gathering to obtain food.

Other advances in agriculture include the domestication of animals, which people kept to supply food, milk, and hides. Archaeological evidence indicates that wild goats and sheep were probably the first animals to be domesticated in southwestern Turkey, northern Iraq, and Iran. In the Old World, people also used animals to prepare fields for planting. Another major advance in agriculture was irrigation, which began more than 5000 years ago in Egypt.

Producing food agriculturally was more time-consuming than hunting and gathering, but it was also more productive. In hunter–gatherer societies, everyone shares the responsibility for obtaining food. In agricultural societies, fewer people are needed to provide food for everyone. Thus, agriculture freed some people to pursue other endeavors, including religion, art, and various crafts.

[2]Humans are not the only animals to have culture. Chimpanzees have primitive cultures that include tool-using techniques, hunting methods, and social behaviors that vary from one population to another. These cultural traditions are passed to the next generation by teaching and imitation; see Chapter 51.

Cultural evolution has had a profound impact on the biosphere

Cultural evolution has had far-reaching effects on both human society and on other organisms. The Industrial Revolution, which began in the 18th century, drew populations to concentrate in urban areas near centers of manufacturing. Advances in agriculture encouraged urbanization, because fewer and fewer people were needed in rural areas to produce food for everyone. The spread of industrialization increased the demand for natural resources to supply the raw materials for industry.

Cultural evolution has permitted the human population, which reached 6.5 billion in 2006, to expand so dramatically that there are serious questions about Earth's ability to support so many people indefinitely (see Chapter 52). According to the United Nations (UN) Food and Agricultural Organization, more than 800 million people lack access to the food needed to be healthy and lead productive lives. To further compound the problem, the UN projects that 2.8 billion *additional* people will be added to the world population by the year 2050.

Cultural evolution has resulted in large-scale disruption and degradation of the environment. Tropical rain forests and other natural environments are rapidly being eliminated. Soil, water, and air pollution occur in many places. Since World War II, soil degradation caused by poor agricultural practices, overgrazing, and deforestation has occurred in an area equal to 17% of Earth's total vegetated surface area. Many species cannot adapt to the rapid environmental changes caused by humans and thus are becoming extinct. The decrease in biological diversity from species extinction is alarming (see Chapter 56).

On a positive note, people are aware of the damage we are causing and have the intelligence to modify behavior to improve these conditions. Education, including the study of biology, may help future generations develop environmental sensitivity, making cultural evolution our salvation rather than our destruction.

Review

- What is cultural evolution?
- How has cultural evolution affected planet Earth?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Describe the structural adaptations that primates have for life in treetops (page 467).

- **Primates** are **placental mammals** that arose from small, **arboreal** (tree-dwelling), shrewlike mammals. Primates possess five grasping digits, including an **opposable thumb** or toe; long, slender limbs that move freely at the hips and shoulders; and eyes located in front of the head.

2 List the three suborders of primates, and give representative examples of each (page 468).

- Primates are divided into three suborders. The suborder Prosimii includes lemurs, galagos, and lorises. The suborder Tarsiiformes includes tarsiers. The suborder Anthropoidea includes anthropoids—monkeys, apes, and humans.

ThomsonNOW™ **Learn more about primate evolution by clicking on the figure in ThomsonNOW.**

3 Distinguish among anthropoids, hominoids, and hominids (page 468).

- Anthropoids include monkeys, apes, and humans. Early anthropoids branched into two groups: New World monkeys and Old World monkeys.
- **Hominoids** include apes and humans. Hominoids arose from the Old World monkey lineage. There are four modern genera of apes: gibbons, orangutans, gorillas, and chimpanzees.
- The **hominid** line consists of humans and their ancestors.

4 Describe skeletal and skull differences between apes and hominids (page 471).

- Unlike ape skeletons, hominid skeletons have adaptations that reflect the ability to stand erect and walk on two feet. These adaptations include a complex curvature of the spine; a shorter, broader pelvis; repositioning of the **foramen magnum** to the base of the skull; and a first toe that is aligned with the other toes.
- The human skull lacks a pronounced **supraorbital ridge,** is flatter than ape skulls in the front, and has a pronounced chin. The human brain is larger than ape brains, and the jaw is structured so that the teeth are arranged in a U shape.

ThomsonNOW™ **Learn more about monkey, gorilla, and human skeletons by clicking on the figure in ThomsonNOW.**

5 Briefly describe the following early hominids: *Sahelanthropus, Orrorin, Ardipithecus ramidus,* and *Australopithecus anamensis, A. afarensis,* and *A. africanus* (page 471).

- Hominid evolution began in Africa. The earliest known hominids, dated at 6 to 7 million years old, belong to ***Sahelanthropus.*** Although *Sahelanthropus* had a small brain, its face and teeth had many characteristics of larger-brained human ancestors.
- ***Orrorin*** is an early hominid that arose about 6 mya. Researchers studying the fossil leg bones of *Orrorin* think that it walked upright and was bipedal.
- *Ardipithecus* and *Australopithecus* species are often referred to as **australopithecines.** *Australopithecus* species were **bipedal** (walked on two feet), a hominid feature. ***Ardipithecus ramidus,*** which appeared about 5.8 mya to 5.2 mya, presumably gave rise to ***Australopithecus anamensis,*** which in turn may have given rise to another primitive hominid, ***Australopithecus afarensis.*** Many paleoanthropologists think that *A. afarensis* gave rise to several australopithecine species, including ***Australopithecus africanus.***
- The genus *Australopithecus* contains the immediate ancestors of the genus *Homo.*

6 Distinguish among the following members of genus *Homo: H. habilis, H. ergaster, H. erectus, H. neanderthalensis,* and *H. sapiens* (page 471).

- ***Homo habilis*** was the earliest known hominid with some of the human features lacking in the australopithecines,

including a slightly larger brain. *H. habilis* fashioned crude tools from stone.

- ***Homo erectus*** had a larger brain than *H. habilis;* made more sophisticated tools; and may have worn clothing, built fires, and lived in caves or shelters. Some scientists hypothesize that fossils identified as *H. erectus* represent two different species, ***Homo ergaster,*** an earlier African species that gave rise to archaic *H. sapiens*, and *H. erectus,* a later Asian offshoot that may be an evolutionary dead end.
- **Archaic *Homo sapiens*** are regionally diverse descendants of *H. erectus* or *H. ergaster* that lived in Africa, Asia, and Europe from about 400,000 to 200,000 years ago. The brains of archaic *H. sapiens* were essentially the same size as our brains, although their skulls retained some ancestral characters, and they had rich and varied cultures.
- **Neandertals** lived from about 230,000 to 30,000 years ago. Neandertals had short, sturdy builds; receding chins and foreheads; heavy supraorbital ridges and jawbones; larger front teeth; and nasal cavities with unusual triangular bony projections. Many scientists think that Neandertals were a separate species, ***Homo neanderthalensis,*** whereas some scientists think that Neandertals were a type of modern human.
- ***Homo sapiens,*** anatomically modern humans, existed in Africa about 195,000 years ago. By about 30,000 years ago, anatomically modern humans were the only members of genus *Homo* remaining, excluding small, isolated populations. European remains of these ancient people are referred to as **Cro-Magnons.**

ThomsonNOW™ Learn more about *Homo* skulls by clicking on the figure in ThomsonNOW.

7 Discuss the origin of modern humans (page 471).

- Two hypotheses purport to explain the origin of modern humans. The out-of-Africa hypothesis holds that modern *H. sapiens* arose in Africa and migrated to Europe and Asia, displacing the more primitive humans living there. According to the multiregional hypothesis, modern humans originated as separately evolving populations of *H. erectus* living in several parts of Africa, Asia, and Europe. Each of these populations occasionally met and interbred with other populations, thereby preventing complete reproductive isolation. Recent fossil discoveries and molecular data support the out-of-Africa hypothesis as the main explanation for the origin of modern humans.

8 Describe the impact of human culture on the biosphere (page 478).

- Large human brain size makes possible the transmission of knowledge from one generation to the next. Two significant advances in human culture were the development of agriculture and the Industrial Revolution.

TEST YOUR UNDERSTANDING

1. The first primates evolved about 56 mya from (a) shrewlike monotremes (b) therapsids (c) shrewlike placental mammals (d) tarsiers (e) shrewlike marsupials
2. The anthropoids are more closely related to _____ than to _____. (a) tarsiers; lemurs (b) lemurs; monkeys (c) tree shrews; tarsiers (d) lemurs; tarsiers (e) tree shrews; monkeys
3. Unlike Old World monkeys, some New World monkeys have (a) body hair (b) five grasping digits (c) a well-developed cerebrum (d) a bipedal walk (e) a prehensile tail
4. Apes and humans are collectively called (a) mammals (b) primates (c) anthropoids (d) hominoids (e) hominids
5. With what group do hominoids share the most recent common ancestor? (a) Old World monkeys (b) New World monkeys (c) tarsiers (d) lemurs (e) lorises and galagos
6. The _____ in humans is centered at the base of the skull, positioning the head for erect walking. (a) supraorbital ridge (b) foramen magnum (c) pelvis (d) bony skull crest (e) femur
7. Scientists collectively call humans and their *immediate* ancestors (a) mammals (b) primates (c) anthropoids (d) hominoids (e) hominids
8. The earliest hominid fossil found so far belongs to the genus (a) *Aegyptopithecus* (b) *Dryopithecus* (c) *Sahelanthropus* (d) *Homo* (e) *Australopithecus*
9. The earliest hominid that scientists placed in the genus *Homo* is (a) *H. habilis* (b) *H. ergaster* (c) *H. erectus* (d) *H. heidelbergensis* (e) *H. neanderthalensis*
10. Some scientists now think that fossils identified as *Homo erectus* represent which two different species? (a) *H. habilis* and *H. erectus* (b) *H. ergaster* and *H. erectus* (c) *H. heidelbergensis* and *H. ergaster* (d) *H. neanderthalensis* and *H. erectus* (e) *H. neanderthalensis* and *H. sapiens*
11. Archaic *Homo sapiens* appeared as early as _____ years ago. (a) 5 million (b) 400,000 (c) 230,000 (d) 100,000 (e) 5000
12. _____ were an early group of humans with short, sturdy builds and heavy supraorbital ridges that lived throughout Europe and western Asia from about 230,000 to 30,000 years ago. (a) Australopithecines (b) Dryopithecines (c) Archaic *Homo sapiens* (d) Neandertals (e) Cro-Magnons
13. The modern human skull *lacks* (a) small canines (b) a foramen magnum centered in the base of the skull (c) pronounced supraorbital ridges (d) a U-shaped arrangement of teeth on the jaw (e) a large cranium (braincase)
14. The comparison of genetic material from individuals of regional populations of humans, used to help unravel the origin and migration of modern humans, is known as (a) paleoarchaeology (b) cultural anthropology (c) molecular anthropology (d) cytogenetics (e) genetic dimorphism
15. Place the following hominids in chronological order of appearance in the fossil record, beginning with the earliest:

    1. *H. habilis* 2. *modern H. sapiens* 3. *H. neanderthalensis* 4. *H. erectus*

    (a) 1, 4, 2, 3 (b) 4, 1, 2, 3 (c) 4, 1, 3, 2 (d) 3, 1, 4, 2 (e) 1, 4, 3, 2

CRITICAL THINKING

1. What types of as-yet-undiscovered scientific evidence might help explain how monkeys got to South America from the Old World?
2. If you were evaluating whether other early humans exterminated the Neandertals, what kinds of archaeological evidence might you look for?
3. The remains of Cro-Magnons have been found in southern Europe alongside reindeer bones, but reindeer currently exist only in northern Europe and Asia. Explain the apparent discrepancy.
4. **Evolution Link.** What was the common ancestor of chimpanzees and humans—a chimpanzee, a human, or neither? Explain your answer.
5. **Evolution Link.** Some scientists say that modern medicine and better sanitation are slowing down or altering the course of human evolution in highly developed countries today. As a result, evolution in humans today has gone from survival of the fittest to survival of almost everyone. Do you think this is a valid idea? Why or why not?
6. **Analyzing Data.** If you were to add *H. floresiensis* to Figure 22-9, where would you put it? Justify your answer.
7. **Analyzing Data.** Using the information in Figure 22-9, draw a simple cladogram that represents a reasonable hypothesis of human evolution at the genus level. (*Hint:* Your diagram will have three branches.)

23

Understanding Diversity: Systematics

KEY CONCEPTS

Traditionally, biologists have named organisms using a binomial system (in which each species has a genus name followed by a specific epithet) and have classified organisms in taxonomic categories arranged in a hierarchy from most inclusive (domain) to least inclusive (species).

Based on current knowledge, the tree of life consists of three domains: Bacteria, Archaea, and Eukarya.

Phylogeny (evolutionary history) is based on common ancestry inferred from shared characters, including structural, developmental, behavioral, and molecular similarities, as well as from fossil evidence.

Phylogenetic trees are diagrams of hypothetical evolutionary relationships; cladograms are phylogenetic trees constructed by analyzing shared derived characters.

The total number of living species is estimated to be between 4 million and 100 million, but only about 1.7 million species have been described. Biologists estimate that to date they have identified less than 10% of bacteria, about 5% of fungi species, only about 2% of nematode (roundworm) species, and less than 20% of insect species. Thousands of new species are discovered each year, and even new primates are found. For example, in 2003 and 2004 two independent research teams discovered a monkey, now known as kipunji (*Rungwecebus kipunji*), at two sites in southern Tanzania (see photo). Whether or not the monkey remains classified in this genus will depend on DNA analysis.

The variety of living organisms and the variety of ecosystems they form are referred to as **biological diversity,** or **biodiversity.** The totality of life on Earth represents our biological heritage, and the quality of life for all organisms depends on the health and balance of this worldwide web of life-forms. For example, we depend on organisms to maintain the life-sustaining composition of gases in the atmosphere, form soil, break down wastes, recycle nutri-

ents, and provide food for one another. We humans exploit many species for economic benefit. One very anthropocentric (human-centered) example of the practical importance of biodiversity is that more than 40% of the prescriptions that pharmacists dispense in the United States derive from living organisms. Investigators are just learning how to effectively screen organisms for potential drugs. Unfortunately, human activity is seriously reducing biodiversity, and species are becoming extinct faster than researchers can study them (see the discussion on declining biodiversity in Chapter 56).

Alarmed by these extinctions, biologists are mobilizing to more rapidly identify new species and to conserve biodiversity. Many biologists agree that describing and classifying all the surviving species of the world should be a major scientific goal of the 21st century. An important step toward that goal is the Catalogue of Life, the work of a collaborative international research team that manages a comprehensive global database made available on the Internet. The Catalogue of Life categorizes and lists all of the world's known species.

In this chapter, we explore some of the approaches and methods used by biologists to classify organisms and to infer their evolutionary history and relationships. Information comes from many sources, including fossils, biogeography, patterns of development, structural and behavioral characteristics, and molecular similarities and differences. Researchers organize this information into large databases and manipulate it using computer algorithms to generate hypotheses regarding relationships. From these data, biologists are constructing the "tree of life." However, as more sophisticated molecular methods and discovery of new fossils provide new data, old data must be reinterpreted. As we gain greater understanding of how organisms are related, we revise the way we classify organisms, and the structure of the tree of life changes. ■

CLASSIFYING ORGANISMS

Learning Objectives

1 State at least two justifications for the use of scientific names and classifications of organisms.
2 Describe the binomial system of naming organisms, and arrange the Linnaean categories in hierarchical fashion, from most inclusive to least inclusive.

The scientific study of the diversity of organisms and their evolutionary relationships is called **systematics.** An important aspect of systematics is **taxonomy,** the science of naming, describing, and classifying organisms. The term **classification** means arranging organisms into groups based on similarities that reflect evolutionary relationships among lineages.

Organisms are named using a binomial system

Because there are millions of kinds of organisms, scientists need a system for accurately identifying them. Imagine that you were going to develop a classification system. How would you use what you already know about living things to assign them to categories? Would you place insects, bats, and birds in one category because they all have wings and fly? And would you, perhaps, place squid, whales, fish, penguins, and Olympic backstroke champions in another category because they all swim? Or would you classify organisms according to a culinary scheme, placing lobsters and tuna in the same part of the menu, perhaps identifying them as "seafood"? Any of these schemes might be valid, depending on your purpose. Similar methods have been used throughout history. St. Augustine in the fourth century classified animals as useful, harmful, or superfluous—to humans. During the Renaissance, scholars began to develop categories based on the characteristics of the organisms themselves.

Of the many classification systems that were developed, the one designed by Carolus Linnaeus in the mid-18th century (described briefly in Chapter 1) has survived with some modification to the present day. Linnaeus grouped organisms according to their similarities, mainly structural similarities.

Before the mid-18th century, each species had a lengthy descriptive name, sometimes consisting of 10 or more Latin words! Linnaeus simplified scientific classification, developing a **binomial system of nomenclature** in which each species is assigned a unique two-part name. The first part of a binomial scientific name designates the **genus** (pl., *genera*), and the second part is called the **specific epithet.**

The genus name is always capitalized, whereas the specific epithet is usually not. Both names are underlined or italicized. The genus, or generic, name can be used alone to designate all species in the genus (for example, the genus *Quercus* includes all oak species). Note that the specific epithet alone is *not* the species' name. In fact, the same specific epithet can be used as the second name of species in different genera. For example, *Quercus alba* is the scientific species name for the white oak, and *Salix alba* is the species name for the white willow (*alba* comes from a Latin word meaning "white"). Thus, both parts of the name must be used to accurately identify the species. However, the specific epithet is never used alone; it must always follow the full or abbreviated genus name, such as *Quercus alba* or *Q. alba.*

Scientific names are generally derived from Greek or Latin roots or from latinized versions of the names of persons, places, or characteristics. For example, the generic name for the bacterium *Escherichia coli* is based on the name of the scientist, Theodor Escherich, who first described it. The specific epithet *coli* reminds us that *E. coli* lives in the colon (large intestine).

Most areas of biology depend on scientific names and classification. To study the effects of pollution on an aquatic community, biologists must be able to accurately record the relative

numbers of each type of organism present and changes in their populations over time. This requires that all investigators identify each species accurately by name.

Scientific names permit biology to be a truly international science. Even though the common names of an organism may vary in different locations and languages, an organism can be universally identified by its scientific name. A researcher in Puerto Rico knows exactly which organisms were used in a study published by a Russian scientist and therefore can repeat or extend the Russian's experiments using the same species.

Each taxonomic level is more general than the one below it

Linnaeus devised a system for assigning species to a hierarchy of increasingly broader groups. As you move up the hierarchy, each group is more inclusive, that is, it includes the groups below it. When he set up his system, Linnaeus did not have a theory of evolution in mind. Nor did he have any idea of the vast number of extant (living) and extinct organisms that would later be discovered. Yet his system has proved remarkably flexible and adaptable to new biological knowledge and theory. Very few other 18th-century inventions survive today in a form that would still be recognizable to their originators.

The range of taxonomic categories from species to domain forms a hierarchy (Fig. 23-1 and Table 23-1). Closely related species are assigned to the same genus, and closely related genera are grouped in a single **family.** Families are grouped into **orders,** orders into **classes,** classes into **phyla,** phyla into **kingdoms,** and kingdoms into **domains.** A species is considered a true biological entity, but taxonomic categories above the species level are artificial constructs used for cataloguing the diverse life-forms on Earth.

A **taxon** (pl., *taxa*) is a formal grouping of organisms at any given level, such as species, genus, or phylum. For example, class Mammalia is a taxon that includes many different orders. A taxon can be separated into subgroupings, such as subphyla or superclasses. Subphylum Vertebrata, a subgroup of phylum Chordata, is a taxon that contains several classes, including Amphibia and Mammalia.

Biologists are moving away from Linnaean categories

Biologists are finding it difficult to name new species as quickly as they are being discovered. They are also working hard to reclassify organisms as they adjust hypotheses about relationships among organisms. Many systematists are moving away from the hierarchical Linnaean categories because these categories are limiting and do not fit well with recent findings.

One group of biologists has proposed a very different approach to classification known as **PhyloCode,** which is based on evolutionary relationships. In this system, taxonomic ranks are not used. A species is defined as a segment of a population lineage. Organisms are grouped into clades; a **clade** is defined as a group of organisms with a common ancestor. Advocates of PhyloCode argue that this system avoids the problem of changing names when discoveries of new species require shifts in ranks. The system also makes it easier to name clades one at a time as they are discovered.

A new approach to identifying organisms is based on recently developed molecular methods. In 2003, Paul Hebert, of the University of Guelph in Canada, and his colleagues proposed in the British *Proceedings of the Royal Society* that we identify all living things by DNA rather than by their physical structure. Hebert holds that each organism has a DNA **bar code** (much like grocery store products). Biologists can use bar codes to identify the species of an organism in any stage of life, even as an egg or seed. Another advantage of bar coding is that this method can be used to distinguish among species that look alike.

Hebert has used a segment of mitochondrial DNA consisting of only 648 base pairs. This short sequence of DNA, part of the gene that codes for the enzyme cytochrome *c* oxidase, can be used as a label for the genome of a species. When applied to bird species, results from bar coding were strikingly consistent with relationships inferred from traditional taxonomic methods. For example, differences between members of closely related species were about 18 times as great as differences among birds within a single species. Information gained suggested that four bird species should each be divided into two new species.

Hebert's bar code does not work with all groups. Some groups, such as bacteria, will require different bar code markers. A component of ribosomes is being used as a bar code to identify bacteria. The sequence used is a small subunit ribosomal RNA (SSU rRNA), specifically the 16S rRNA nucleotide sequence.[1] The gene that codes SSU rRNA is highly conserved; it is present in all known organisms, and its function has remained the same through time.

Review

- What are the key features of the binomial system of nomenclature?
- Why is it important to use scientific, rather than common, names for organisms?
- Classify the domestic cat, using taxa from domain to species.

DETERMINING THE MAJOR BRANCHES IN THE TREE OF LIFE

Learning Objectives

3 Describe the six kingdoms and three domains of organisms, and give the rationales for and against this system of classification.

4 Given its distinguishing characters, classify an organism in the appropriate domain and kingdom.

The history of taxonomy at the kingdom level is a good example of the process of science. From the time of Aristotle to the mid-19th century, biologists divided organisms into two kingdoms: **Plantae** and **Animalia.** After the development of microscopes,

[1]The number *16S* refers to the sedimentation coefficient (a measure of relative size) when centrifuged.

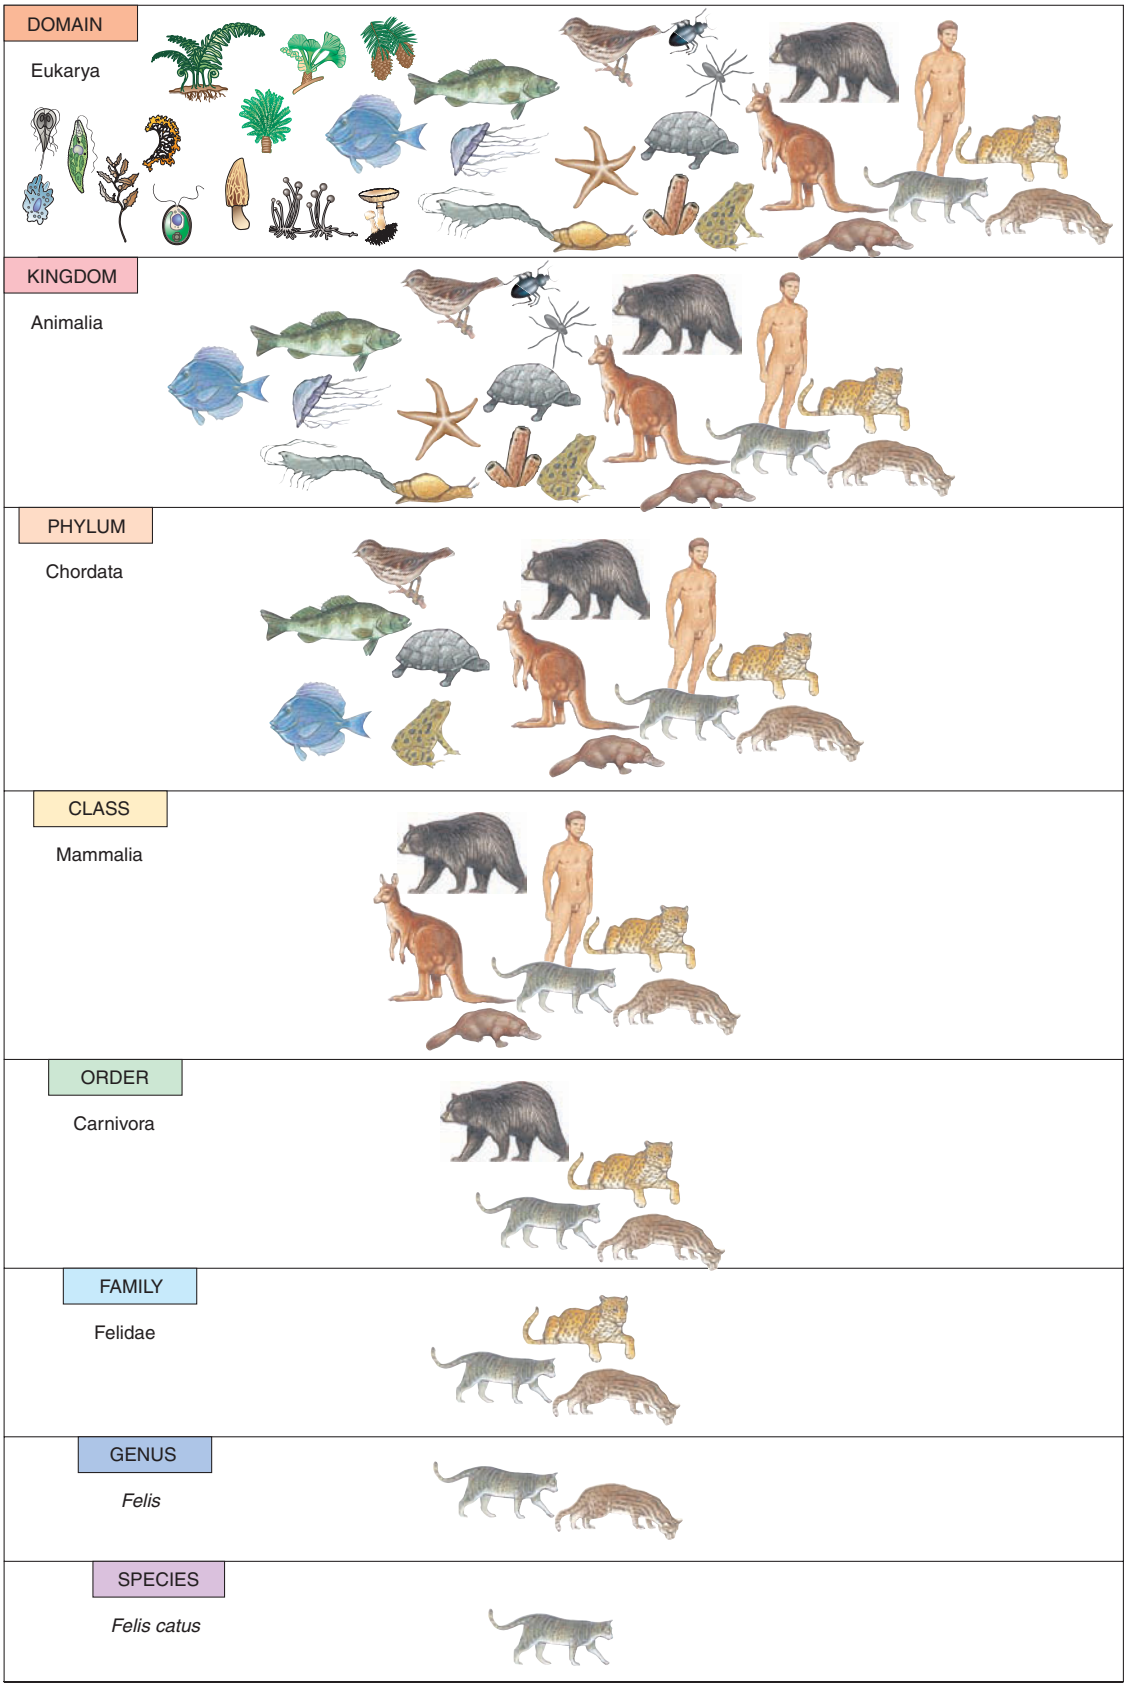

Figure 23-1 The principal categories used in classification

The domestic cat (*Felis catus*) is classified here to illustrate the hierarchical organization of our taxonomic system. Each level is more inclusive than the one below it, meaning that it includes more groups of organisms.

TABLE 23-1

Classification of Corn

Domain	**Eukarya** Organisms that have nuclei and other membrane-enclosed organelles
Kingdom	**Plantae** Terrestrial, multicellular, photosynthetic organisms
Phylum	**Anthophyta** Vascular plants with flowers, fruits, and seeds
Class	**Monocotyledones** Monocots: Flowering plants with one seed leaf (cotyledon) and flower parts in threes
Order	**Commelinales** Monocots with reduced flower parts, elongated leaves, and dry 1-seeded fruits
Family	**Poaceae** Grasses with hollow stems; fruit is a grain; and abundant endosperm in seed
Genus	***Zea*** Tall annual grass with separate female and male flowers
Species	***Zea mays*** Only one species in genus—corn

it became increasingly obvious that many organisms could not be easily assigned to either the plant or the animal kingdom. For example, the unicellular organism *Euglena,* which has been classified at various times in the plant kingdom and in the animal kingdom, carries on photosynthesis in the light but in the dark uses its flagellum to move about in search of food (see Fig. 25-6). In 1866, a German biologist, Ernst Haeckel, proposed that a third kingdom, **Protista,** be established to accommodate bacteria and other microorganisms, such as *Euglena,* that did not seem to fit into the plant or animal kingdoms. Today, many biologists place algae (including multicellular forms), protozoa, water molds, and slime molds in kingdom Protista. Thus, protists are a diverse group of mainly unicellular, mainly aquatic eukaryotic organisms.

In 1937, the French marine biologist Edouard Chatton suggested the term *procariotique* ("before nucleus") to describe bacteria, and the term *eucariotique* ("true nucleus") to describe all other cells. This dichotomy between prokaryotes and eukaryotes is now universally accepted by biologists as a fundamental evolutionary divergence. In the 1960s, advances in electron microscopy and biochemical techniques revealed further cell differences that inspired many new proposals for classifying organisms.

In 1969, R. H. Whittaker proposed a five-kingdom classification based mainly on cell structure and the way that organisms derive nutrition from their environment. Whittaker suggested that the fungi (which include the mushrooms, molds, and yeasts) be removed from the plant kingdom and classified in their own kingdom, **Fungi.** After all, fungi are not photosynthetic and must absorb nutrients produced by other organisms. Fungi also differ from plants in the composition of their cell walls, in their body structures, and in their modes of reproduction. Kingdom **Prokaryotae** was established to accommodate the bacteria, which are fundamentally different from all other organisms in that they do not have distinct nuclei and other membranous organelles and do not undergo mitotic division (see Fig. 4-6).

In the late 1970s, Carl Woese (pronounced "woes"), of the University of Illinois, and his colleagues began to study the evolutionary relationships among organisms by analyzing their 16S rRNA. Using sequence analysis, Woese used variations in this universal molecule to challenge the long-held view that all prokaryotes were closely related and very similar to one another. He showed that there are two fundamentally different groups of prokaryotes, archaea and bacteria. He proposed that the prokaryotes account for two of the three major branches of organisms.

Woese's hypothesis gained support in 1996 when Carol J. Bult of the Institute for Genomic Research in Rockville, Maryland, reported in the journal *Science* that she and her colleagues had sequenced the complete genome of a methane-producing archaea, *Methanococcus jannaschii.* When these researchers compared gene sequences with those of two previously sequenced bacteria, they found that fewer than half of the genes matched. Given this molecular evidence, most biologists now divide the prokaryotes into kingdom **Bacteria** and kingdom **Archaea.**

In this eighth edition of *Biology,* we classify organisms into six kingdoms: Bacteria, Archaea, Protista, Fungi, Plantae, and Animalia (Table 23-2). As we discuss in Chapter 25, the Protista are quite diverse, and biologists will likely divide this group into several kingdoms.

Systematists construct **phylogenetic trees** to graphically represent the evolutionary history of a group of species. We can construct a type of phylogenetic tree called a **cladogram** to illustrate the evolutionary relationships among groups of organisms (Fig. 23-2).

Most systematists use a level of classification above the kingdom, called a **domain,** based on fundamental molecular differences among the bacteria, archaea, and eukaryotes. They classify organisms in three domains: **Archaea** (which corresponds to kingdom Archaea), **Bacteria** (which corresponds to kingdom Bacteria), and **Eukarya** (eukaryotes) (Fig. 23-3). As we will discuss in Chapter 24, the viruses are a special case and are not classified in any of the three domains. Biologists have inferred that the three domains are the three main branches of the tree of life.

An important character that distinguishes the archaea from the bacteria is the absence of the compound peptidoglycan in the cell walls of the archaea (discussed in Chapter 24). Neither do the archaea have the simple RNA polymerase characteristic of bacteria. Gene sequencing indicates that the archaea have a combination of bacteria-like and eukaryote-like genes.

As biologists continue to investigate the origin and relationships of the domains, they have discovered that evolution is not always linear. During the course of evolution, genes not only were passed down "vertically" from one generation to the next but were also exchanged laterally. Such gene swapping between organisms in one taxon and related organisms in another taxon is called **horizontal gene transfer,** or *lateral gene transfer.* This pro-

TABLE 23-2

Domains and Kingdoms

Domain	Kingdom	Characteristics	Ecological Role and Comments
Bacteria	Bacteria	Prokaryotes (lack distinct nuclei and other membranous organelles); unicellular; microscopic; cell walls generally composed of peptidoglycan.	Most are decomposers; some parasitic (and pathogenic); some chemosynthetic autotrophs; some photosynthetic; important in recycling nitrogen and other elements; some used in industrial processes.
Archaea	Archaea	Prokaryotes; unicellular; microscopic; peptidoglycan absent in cell walls; differ biochemically from bacteria.	Methanogens are anaerobes that inhabit sewage, swamps, and animal digestive tracts; extreme halophiles inhabit salty environments; extreme thermophiles inhabit hot, sometimes acidic environments.
Eukarya	Protista	Eukaryotes; mainly unicellular or simple multicellular. Three informal groups (not taxa) include protozoa, algae, and slime molds and water molds.	Protozoa are an important part of zooplankton. Algae are important producers, especially in marine and freshwater ecosystems; important oxygen source.
	Fungi	Eukaryotes; heterotrophic; absorb nutrients; do not photosynthesize; body composed of threadlike hyphae that form tangled masses that infiltrate food or habitat; cell walls of chitin.	Decomposers; some parasitic (and pathogenic); some form important symbiotic relationships with plant roots (mycorrhizae) or algae (lichens); some used as food; yeast used in making bread and alcoholic beverages; some used to make industrial chemicals or antibiotics; responsible for much spoilage and crop loss.
	Plantae	Eukaryotes; multicellular; photosynthetic; possess multicellular reproductive organs; alternation of generations; cell walls of cellulose.	Terrestrial biosphere depends on plants in their role as primary producers; important source of oxygen in Earth's atmosphere.
	Animalia	Eukaryotes; multicellular heterotrophs; many exhibit tissue differentiation and complex organ systems; most able to move about by muscular contraction; nervous tissue coordinates responses to stimuli.	Consumers; some specialized as herbivores, carnivores, or detritus feeders.

cess is apparently common and can occur in several ways, such as by exchange of DNA among different populations or species of bacteria or by interbreeding between closely related groups. Indeed, the common ancestor of all living things may have been a *community* of species that traded their genes. Horizontal gene transfer appears to be a continuous process between members of the three domains.

Eukaryotic cells most likely evolved from prokaryotic cells that lived symbiotically within one another. Recall that mitochondria and chloroplasts are thought to have originated from prokaryotes that lived as endosymbionts inside other cells (see Chapter 21). Based on what is now known about horizontal gene transfer, some systematists argue that there is no simple tree of life and have suggested alternative hypotheses. One group hypothesizes a complex bush with many connecting branches (Fig. 23-4a). James A. Lake and Maria C. Rivera, of the University of California at Los Angeles, have recently proposed another approach—that the tree of life is actually a ring of life (Fig. 23-4b). These systematists hypothesize, based on their analysis of hundreds of genes, that horizontal gene transfer between bacteria and archaea gave rise to the eukaryotes.

The evolution of systematics reflects the creative and dynamic process of science. Systematists are very responsive to new data, and consequently, classification of organisms at all levels is a continuously changing process. Although many biologists are moving away from a hierarchical system, some suggest adding new groups so that the classical approach keeps up with new findings. Whatever approach is used, the goal of systematics is to base classification on evolutionary change and relationships.

Review

- What are some of the defining characteristics of each of the six kingdoms and three domains?
- What are the advantages of a "six-kingdom" system over a "two-kingdom" system?
- In which domain and kingdom would you classify each of the following: *Salix alba*, amoeba, *Escherichia coli*, tapeworm, and black bread mold?
- Why do representations of the structure of the tree of life constantly change?

RECONSTRUCTING PHYLOGENY

Learning Objectives

5 Critically review the difficulties encountered in choosing taxonomic criteria.
6 Apply the concept of shared derived characters to the classification of organisms.
7 Describe how molecular homologies contribute to the science of systematics.
8 Contrast monophyletic, paraphyletic, and polyphyletic taxa.

Key Point

Many biologists classify organisms in categories called kingdoms.

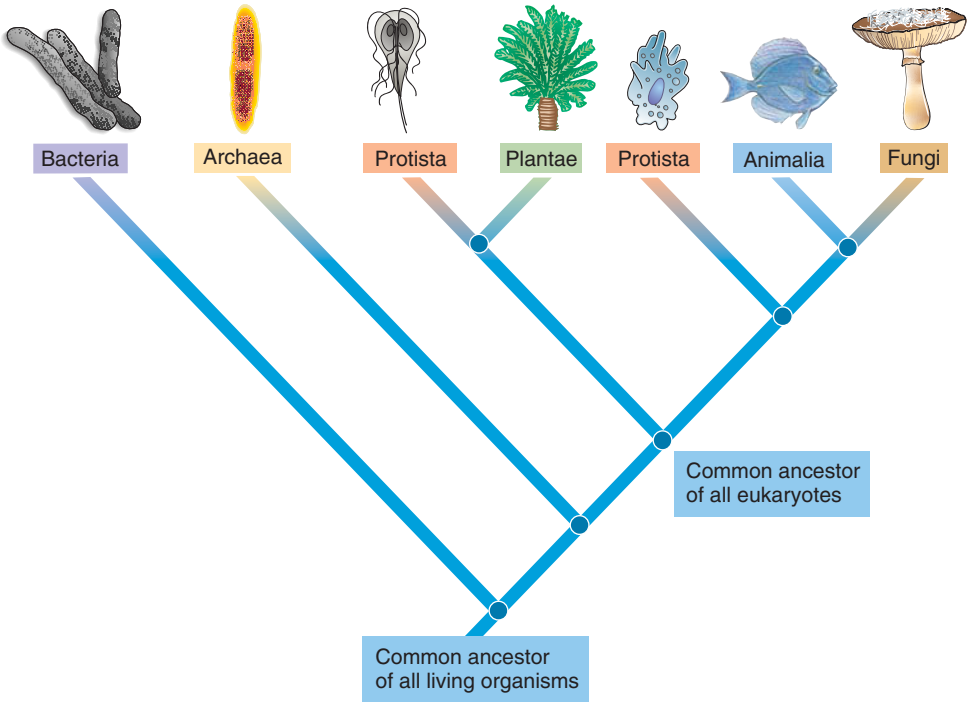

Figure 23-2 ***Animated*** The six-kingdom system of classification

This cladogram illustrates the evolutionary relationships among organisms in the six kingdoms. The branches portray ancestral populations of each group through time. Each node (*circle*) represents the point when two groups diverged from each other.

Modern biologists link classification with evolution. Their goal is to reconstruct **phylogeny** (literally, "production of phyla"), the evolutionary history of a group of organisms from a common ancestor. As they determine evolutionary relationships among and between species and higher taxa, systematists build classifications based on common ancestry. Consequently, systematics reflects the integration of all evolutionary processes and evolutionary evidence and thus is at the center of how we understand and explain the nonrandom occurrence and relationships of lifeforms on Earth.

Once phylogenies are established, they help answer other questions in biology. For example, phylogenies help us understand evolutionary patterns that might provide clues to the origin and spread of HIV and other pathogens. Phylogenies also help biologists identify new species and predict their characteristics. Systematists may classify a new species based on specific characters that it shares with other organisms in a particular taxon. They may then infer that the new species shares other characters with organisms in that group.

As you read the following sections, remember that phylogenies are testable hypotheses. They are supported or falsified by the available data. Systematics proceeds by constantly re-evaluating data, hypotheses, and theoretical constructs. As new data are discovered and old data are reinterpreted, the ideas of system-

Key Point

Many biologists classify organisms in three major categories called domains.

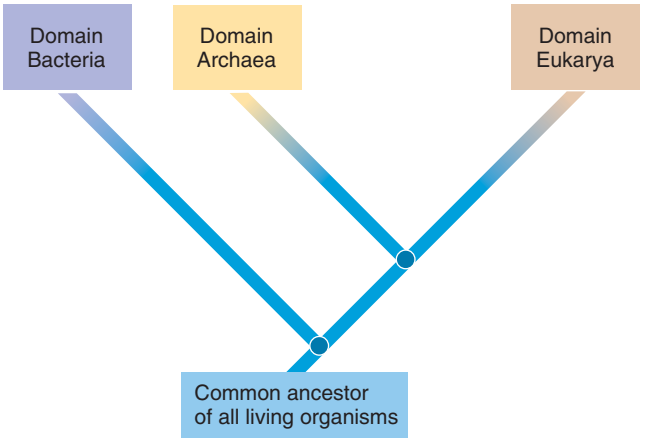

Figure 23-3 ***Animated*** The three domains

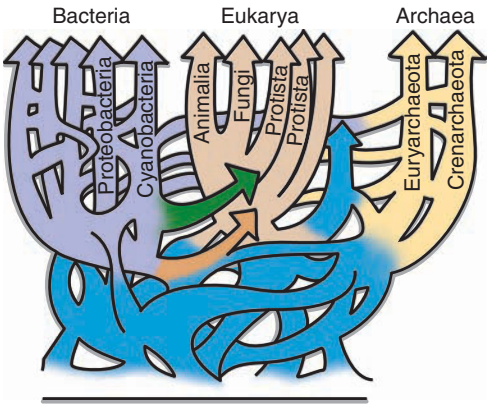
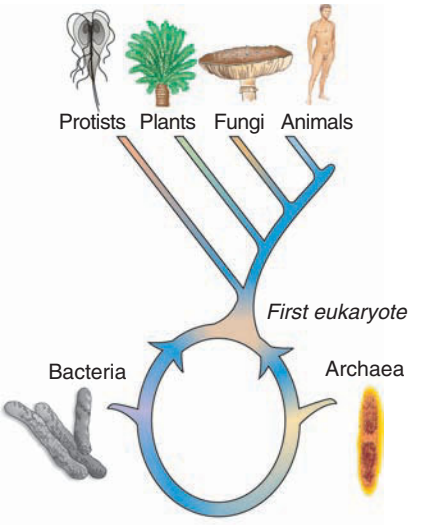
This cladogram illustrates the evolutionary relationships among organisms in the three domains. Kingdoms Protista, Plantae, Animalia, and Fungi are assigned to domain Eukarya.



a The three-domain approach drawn to show horizontal gene transfer as a continuous process between domains and also among groups within each domain. Only some of the branches are labeled. The diagonal brown arrow represents mitochondrial endosymbiosis; the diagonal green arrow represents chloroplast endosymbiosis.



b The ring of life is based on the hypothesis that lateral gene transfer between bacteria and archaea gave rise to the eukaryotes.

Figure 23-4 Other ways to represent the tree of life

[**(a)** based on W. F. Doolittle, *Science,* Vol. 284, pp. 2124–2128, 1999; **(b)** based on M. C. Rivera and J. A. Lake, *Nature,* Vol. 431, pp. 152–155, Sept. 9, 2004.]

atists change. As a result, our understanding of how organisms are related and the way we classify organisms are continuously being revised. Systematics is a dynamic science that changes as biologists discover new species and use ever more sophisticated techniques to investigate the evolutionary relationships among organisms.

You learned in Chapter 18 that evolution is the accumulation of inherited changes within populations over time. Recall that a **population** is made up of all the individuals of the same species that live in a particular area. A population has a dimension in space—its geographic range—and also a dimension in time. Each population extends backward in time. Somewhat like branches of a tree, a population may diverge from other populations enough to become a new species (which may be depicted by a new tree branch; see Chapters 19 and 20). Species have various degrees of evolutionary relationships with one another, depending on the degree of genetic divergence since their populations branched from a common ancestor.

Homologous structures are important in determining evolutionary relationships

Just how to determine phylogeny and how to group species into higher taxa—genera, families, orders, classes, or phyla—can be difficult decisions. Biologists base their judgments about the degree of relationship on the extent of similarity among species. They examine structural, physiological, developmental, behavioral, and molecular traits, as well as fossil evidence. When examining these traits, they look for homologies among different organisms. Recall from Chapter 18 that **homology** refers to the presence, in two or more species, of a structure derived from a recent common ancestor. For example, the bones in the wings of a bird and a bat are homologous. As we will discuss, identifying homologous traits is very important in inferring phylogeny.

It is often difficult to determine whether traits are similar as a result of homology. Although the wings of a butterfly are adapted for flight, their structure is different from bird wings, and these animals do not share a common winged ancestor. Similar structures sometimes evolve when unrelated or distantly related species become adapted to similar environmental conditions. Thus, wings may occur in two or more species not derived from a recent common ancestor. Recall from Chapter 18 that independent evolution of similar structures in distantly related organisms is known as **convergent evolution.** Sharks and dolphins have similar, but independently derived, body forms because they have become adapted to similar environments (aquatic) and lifestyles (predatory).

Another challenge in deciding on homology is **reversal,** in which a trait reverts to its ancestral state. A reversal removes a similarity that had evolved. A characteristic that superficially appears homologous but is actually independently acquired by convergent evolution or reversal is described as exhibiting **homoplasy.**

Shared derived characters provide clues about phylogeny

Organisms sharing many homologous structures are considered closely related, whereas organisms sharing few homologous characters are presumed less closely related. However, distinguishing

between homology and homoplasy is not always straightforward. Determining traits that indicate evolutionary relationships is extremely important.

How does a systematist interpret the significance of these similarities? In making decisions about taxonomic relationships, the systematist first examines the characteristics in the largest group (such as phylum or class) of organisms being studied and interprets them as indicating the most *remote* common ancestry. These **shared ancestral characters,** or **plesiomorphies,** are features that were present in an ancestral species and remain present in all groups descended from that ancestor. For example, the vertebral column, present in all vertebrates, is an ancestral character for study of classes within the subphylum Vertebrata. Studying the presence or absence of the vertebral column does not help us discriminate among various classes of vertebrates: we could not distinguish between amphibians and mammals, because all individuals in these classes have a vertebral column.

When two populations become separated and begin to evolve independently, some of their homologous traits change as a result of mutation, natural selection, and genetic drift. The novel traits that evolve are referred to as **shared derived characters,** or **synapomorphies.** Note that shared derived characters originate in a *recent* common ancestor and are present in its descendants. Species that share derived characters form a clade. Systematists use shared derived characters to identify points where groups diverged from one another. A trait viewed as a *derived character* in a more inclusive (broader) taxon may also be considered an *ancestral character* in a less inclusive (narrower) taxon.

More recent common ancestry is indicated by classification into less and less inclusive taxonomic groups with more and more specific shared derived characters. For example, the three small bones in the middle ear are useful in identifying a branch point between reptiles and mammals. The evolution of this derived character was a unique event, and only mammals have these bones. However, if we compare mammals with one another, the three ear bones are a shared ancestral character, because all mammals have them. Consequently, they have no value in distinguishing among mammalian taxa. Other characters must be used to establish branch points among the mammals.

If we compare dogs, goats, and dolphins (all of which are mammals), we find that dogs and goats have abundant hair whereas dolphins do not. Hair is an ancestral trait in mammals and therefore cannot be used as evidence that dogs and goats share a more recent common ancestor. In contrast, the virtual absence of hair in mature dolphins is a derived character within mammals. When we compare dogs, dolphins, and whales, we find that dolphins and whales share this derived character, providing evidence that these animals evolved from a common ancestor not shared by dogs.

Biologists carefully choose taxonomic criteria

Both fishes and dolphins have streamlined body forms, but this characteristic is homoplastic and does not indicate close evolutionary relationships. The dolphin shares important homologous derived characters (synapomorphies) with mammals such as humans: mammary glands, which produce milk for the young; three small bones in the middle ear; and a muscular diaphragm that helps move air into and out of the lungs. Thus, the dolphin is classified as a mammal.

© Jean Philippe Varin / Jacana / Photo Researchers, Inc.

Figure 23-5 Is this animal a bird?

A few mammals, such as the duck-billed platypus, lay eggs, have beaks, and lack teeth. However, the platypus does not have feathers, and it nourishes its young with milk secreted from mammary glands.

Although dolphins have more shared derived characters in common with humans than with fishes, some characters are shared by all three. Among these shared ancestral characters are a dorsal tubular nerve cord, and during embryonic development, a notochord (skeletal rod) and rudimentary gill slits. These shared ancestral characters (plesiomorphies) indicate a common ancestry and serve as a basis for classification. The ancestry is more remote between the dolphin and the fish than between the dolphin and the human. Therefore, although fishes, humans, and dolphins are grouped in a more inclusive taxon, the phylum Chordata, humans and dolphins are also classified in class Mammalia, a less inclusive taxon within phylum Chordata, indicating that they are more closely related.

Determining which traits best illustrate evolutionary relationships can be challenging. What, for example, are the most important taxonomic characteristics of a bird? We might list feathers, beak, wings, absence of teeth, egg laying, and endothermy (an endothermic animal uses metabolic heat to maintain a constant body temperature despite variations in surrounding temperature). The duck-billed platypus and a few other mammals (members of a group called monotremes) have many of these same characteristics: beaks, endothermy, absence of teeth, and egg laying. Yet we do not classify them as birds (Fig. 23-5). No mammal, however, has feathers. Is this trait absolutely diagnostic of birds? According to the conventional taxonomic wisdom, the presence or absence of feathers determines what is and is not a bird. This criterion was not always valid, however. A number of dinosaur fossils bear impressions of feathers!

Organisms are typically classified on the basis of a combination of traits rather than on any single trait. The significance of these combinations is determined inductively, that is, by integrating and interpreting the data. Such induction is a necessary part of the process of science. Systematists may hypothesize that all birds should have beaks, feathers, no teeth, and so forth. Then they re-examine the living world and observe whether any organisms might reasonably be called birds that do not fit the current definition of "birdness." If not, the definition stands. If too many exceptions emerge, the definition may be modified or abandoned. Sometimes the systematist determines that an apparent exception—the bat, for instance—resembles a bird only superficially and should not be considered one. The bat has all the basic characteristics of a mammal, such as hair and mammary glands that produce milk for the young.

Molecular homologies help clarify phylogeny

When a new species evolves, it does not always exhibit obvious phenotypic differences when compared to closely related species. For example, two distinct species of fruit flies may appear identical. Some of their DNA, proteins, and other molecules, however, are different. Such variations in the structure of specific macromolecules among species, just like differences in anatomical structure, result from mutations. Macromolecules that are functionally similar in two different types of organisms are considered homologous if their subunit sequence is similar. Advances in molecular biology have provided the tools for biologists to compare the macromolecules of various organisms.

The science of **molecular systematics** focuses on molecular structure to clarify evolutionary relationships. DNA, RNA, and amino acid sequencing are used to compare the macromolecules of organisms being studied. Such comparisons provide systematists with valuable information about the degree of relatedness among organisms. The more that subunit sequences of two species correspond, the more closely related the species are considered to be. The number of differences in certain DNA or RNA nucleotide sequences or in amino acid sequences in two groups of organisms may reflect how much time has passed since the groups branched from a common ancestor. (This can be true only if the rates of change have remained constant.) Thus, specific macromolecules can be used as **molecular clocks** (see Chapter 18).

Many systematists look to ribosomal RNA structure to help determine phylogenies. All known organisms have ribosomes that function in protein synthesis, and certain ribosomal RNA nucleotide sequences have been highly conserved in evolution. Recall that the division of organisms into three domains was based, in large part, on the comparison of ribosomal RNA by Carl Woese and his research team. All prokaryotic ribosomes contain three types of RNA, named in order of increasing size: 5S, 16S, and 23S. The 5S and 16S RNAs have been extensively used to determine evolutionary relationships among bacteria because the number of base pairs is manageable and because these molecules are transcribed from highly conserved regions of DNA.

The very precise tools provided by molecular biology have put systematics on the cutting edge of biological research. Biologists are no longer limited by subjective decisions regarding anatomical similarities among organisms. For example, until recently the African elephant and the Indian elephant were the only two species of living elephants recognized. Using molecular methods, biologists have demonstrated that there are at least two distinct species of African elephants. Each species has its own distinctive DNA bar code.

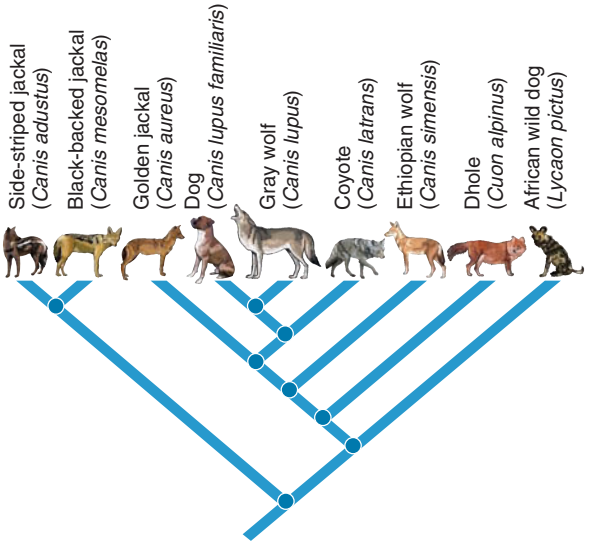
Kerstin Lindblad-Toh, codirector of Broad's Genome Sequencing and Analysis program at MIT and Harvard, and her colleagues recently provided another example of applied molecular systematics (Fig. 23-6). They sequenced the genome of the domestic dog and compared coding regions of more than 13,000

Key Experiment

QUESTION: How is the dog related to other canids?

HYPOTHESIS: Analysis of molecular data from a variety of canids will clarify the evolutionary relationships of canids.

EXPERIMENT: Researcher Kerstin Lindblad-Toh and her colleagues sequenced the genome of the domestic dog. They compared coding regions of more than 13,000 dog genes with corresponding human and mouse genes. Then, they selected 12 exons and 4 introns and sequenced them in 30 out of 34 living canids.



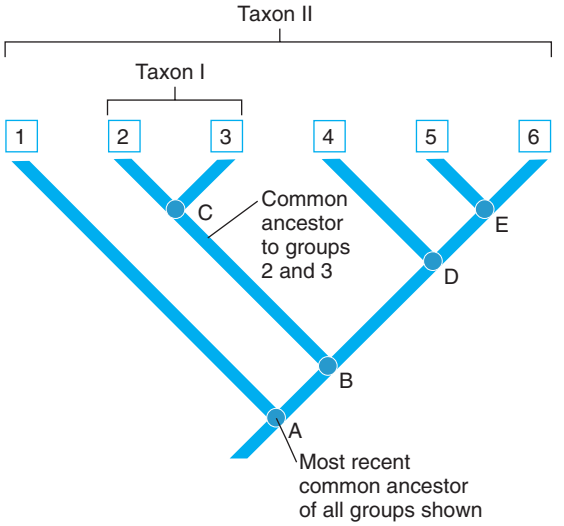
RESULTS AND CONCLUSION: Analysis of the comparisons of exon and intron nucleotide sequences allowed these researchers to build a cladogram of Canidae species. The data indicated that the dog is most closely related to the gray wolf. (Sequence divergence of nuclear exon and intron sequences is 0.04% and 0.21, respectively.) The two African jackals are the most basal members of this clade (branch at left), suggesting an African origin for the canids.

Figure 23-6 Molecular phylogeny

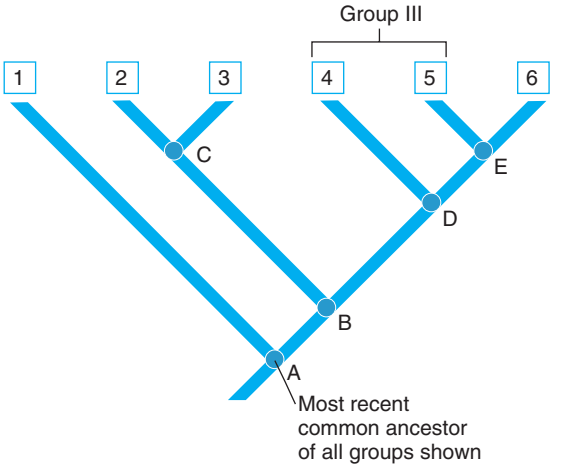
Molecular similarities indicate that the dog is closely related to the gray wolf. Note that some biologists list the scientific name for the domestic dog as *Canis familiaris* and others, including the *Smithsonian Institution* and the *American Society of Mammalogists*, consider the dog a subspecies of the gray wolf and list its name as *Canis lupus familiaris*.

Key Point

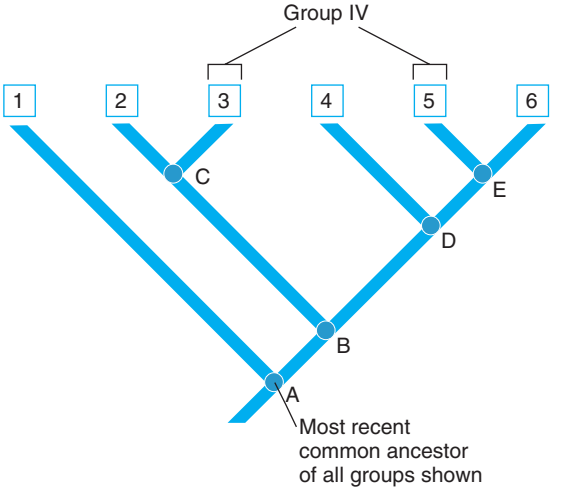
Groups of organisms can be monophyletic, paraphyletic, or polyphyletic. Most systematists recognize only monophyletic groups.



(a) Taxon I and taxon II are monophyletic groups, or clades. Each includes a common ancestor and all its descendants.



(b) Group III is paraphyletic. It includes some, but not all of the descendants of a common ancestor.



(c) Group IV is polyphyletic. Members of this group do not share the same recent common ancestor.

Figure 23-7 ***Animated*** Evolutionary relationships

In all three figures, node A represents the branch point from the common ancestor of all groups shown. Node B represents the branch point from the common ancestor of groups 2 through 6. Node C represents the branch point from the common ancestor of groups 2 and 3. Node D represents the branch point from the common ancestor of groups 4, 5, and 6. Node E represents the branch point from the common ancestor of groups 5 and 6.

dog genes with human and mouse genes. Then, they selected exons and introns and compared their nucleotide sequences in 30 living canids (members of the family Canidae to which the dog belongs). The data they gathered enabled these investigators to construct a cladogram of the phylogenetic relationships of canids. They confirmed earlier research showing that the dog's closest relative is the gray wolf. Lindblad-Toh is using her nucleotide data to identify genes responsible for specific diseases and will apply her findings to the human genome in an effort to better understand the many diseases that canids have in common with humans.

Comparison of ribosomal RNA sequences has also been used to challenge the once widely accepted idea that fungi are closely related to plants. According to ribosomal RNA analysis, fungi are more closely related to animals than to plants; that is, animals and fungi share a more recent common ancestor, perhaps a flagellate protist.

Taxa are grouped based on their evolutionary relationships

Systematists recognize three kinds of taxonomic groupings based on structural similarities, molecular data, and other criteria: monophyletic, paraphyletic, and polyphyletic. A **monophyletic taxon** includes an ancestral species and all its descendants (Fig. 23-7a). Mammals, for example, form a monophyletic taxon because all mammals are thought to have evolved from a common ancestral mammal and all descendants of this ancestor are mammals. Monophyletic taxa are natural groupings, because they represent true evolutionary relationships and include all close relatives. **Sister taxa,** or sister groups, share a more recent common ancestor with one another than either taxon does with any other group shown on a cladogram. In Figure 23-7a, taxa 2 and 3 are sister taxa; taxa 5 and 6 are also sister taxa.

A **paraphyletic taxon** is a group that contains a common ancestor and some, but not all, of its descendants (Fig. 23-7b). As discussed later in this chapter, the class Reptilia is paraphyletic

because it does not include all descendants of the most recent common ancestor of reptiles. Birds are thought to share a recent common ancestor with reptiles.

A **polyphyletic group** consists of several evolutionary lines that do not share the same recent common ancestor (Fig. 23-7c). Biologists might have mistakenly classified the members of such a group together because these organisms share similar (homoplastic) features arising from convergent evolution (see Chapter 18). Systematists avoid constructing polyphyletic taxa, because they are unnatural and misrepresent evolutionary relationships. Polyphyletic taxa are sometimes accepted temporarily until research provides additional data.

Review

- How are shared ancestral characters and shared derived characters different?
- Why don't shared ancestral characters provide evidence for relationships between organisms within a taxon that has those traits? Give an example.
- How is molecular biology contributing to the science of systematics?
- Why do systematists prefer monophyletic taxa to polyphyletic taxa?

CONSTRUCTING PHYLOGENETIC TREES

Learning Objectives

9 Contrast the classification of reptiles and birds by an evolutionary systematist and a cladist.

10 Describe the construction of a cladogram by using outgroup analysis.

In determining the relationships among organisms, systematists use a variety of data and methods. How data are analyzed and interpreted depends on the systematist's approach. In the **phenetic approach,** relationships are based on the number of shared characteristics. Phylogenetic relationships are defined by statistics, such as genetic distances, which summarize overall similarities among taxa based on collected data. For example, a researcher can compare the base sequences of a given gene or coding region to arrive at an average percentage of difference between the taxa being analyzed. A computer program then compares these values and generates trees that cluster similar taxa and place divergent taxa on more distant branches.

Phenetic techniques are currently used with molecular data. For example, if each amino acid in a protein is considered a character, amino acid sequences of various animals can be determined in the laboratory and compared by computer. The information about differences in amino acid sequences can be used to construct phylogenetic diagrams. Species are placed at relative distances from one another, reflecting the extent of difference in amino acid sequence.

Cladistics, also known as **phylogenetic systematics,** is an approach in which shared derived characters are analyzed and used to infer evolutionary relationships. Cladists emphasize common ancestry rather than phenotypic similarity as the basis for classification. They base their assessment on shared derived characters that can be structural, behavioral, physiological, or molecular. The characters must be homologous. According to cladistics, dolphins are classified with mammals rather than with fishes, because dolphins and mammals share derived characters not present in fishes, indicating that dolphins and mammals share a more recent common ancestor.

Cladists use shared derived characters to reconstruct evolutionary relationships of organisms and express them in *cladograms.* In a cladogram, the **branches** depict the evolutionary history of each group. Each branch point, referred to as a **node,** represents the divergence, or splitting, of two or more new groups from a common ancestor. The most recent common ancestor of each monophyletic group would be found at the node. Thus, a cladogram uses the positions of branch points to illustrate the evolutionary relationships among taxa. Shared derived characters can be indicated by labels or by bars across the branches. Cladograms may be rooted. The **root** indicates the most recent common ancestor of the clade depicted.

Consider the evolutionary grouping of mammals, lizards, snakes, crocodiles, dinosaurs, and birds (Fig. 23-8a). Birds, along with dinosaurs, are thought to share a common ancestor with modern crocodiles and alligators (node D in Fig. 23-8b). Crocodiles, dinosaurs, and birds, then, constitute a monophyletic group, or clade. Similarly, snakes and lizards form a clade that is the closest group to birds, dinosaurs, and crocodiles. Mammals form an additional clade.

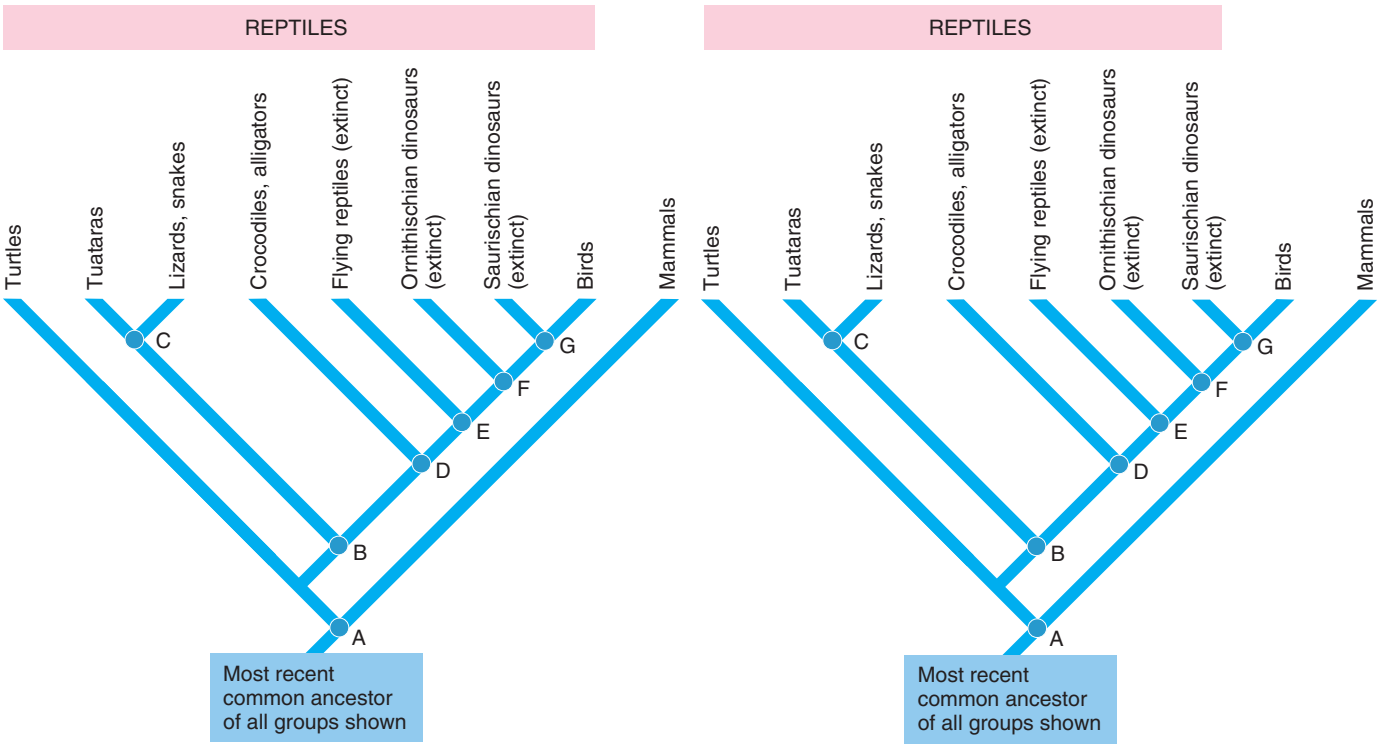
Evolutionary systematists use phenotypic similarity and a combination of shared ancestral characters and shared derived characters to establish evolutionary relationships and build classifications. Although evolutionary systematists recognize paraphyletic taxa, groups that include some, but not all, subgroups of organisms that share the same most recent common ancestor, most of the taxa that they currently recognize are monophyletic. These biologists recognize class Reptilia as a valid group containing snakes, lizards, crocodiles, dinosaurs, and turtles, even though this class is paraphyletic; it does not include all subgroups, such as birds, that evolved from the ancestral reptile (see Fig. 23-8b). Evolutionary systematists assign birds to a separate class because birds have diverged markedly from the reptiles. As we have discussed, cladists do not recognize reptiles as a natural grouping because reptiles do not form a monophyletic group.

Outgroup analysis is used in constructing and interpreting cladograms

A crucial step in most cladistic analyses is **outgroup analysis,** a method for estimating which attributes are shared derived characters in a given group of organisms. An **outgroup** is a taxon that is considered to have diverged earlier than the taxa under investigation, the **ingroups.** Therefore, the outgroup represents an approximation of the ancestral condition. An ideal outgroup is the closest relative of the group being studied, its sister taxon, and has not been highly modified since its origin. Recall that sister taxa evolved from the same recent common ancestor. Systematists argue that an outgroup is likely to retain the ancestral state

Key Point

The cladistic approach, shown in (a), is preferred because it recognizes reptiles and birds as a monophyletic group.



(a) Cladists classify birds and reptiles together because they have a recent common ancestor and are a monophyletic group. The cladogram shows the branching points in the evolution of the major groups of reptiles. Node F represents the branching of two clades of dinosaurs and of birds from a common ancestor, and the subsequent branching of birds from the dinosaurs.

(b) The evolutionary systematics approach considers both common ancestry and extent of divergence that has occurred since two taxa split. Reptiles are a paraphyletic group. Lizards, snakes, and crocodiles are phenotypically most similar, but crocodiles, dinosaurs, and birds are most closely related because they evolved most recently from a common ancestor.

Figure 23-8 Two approaches to the classification of reptiles, birds, and mammals

for characters being used in the analysis, allowing the biologists to identify the evolutionary changes leading to derived characters. To help you understand outgroup analysis, we now consider a specific example.

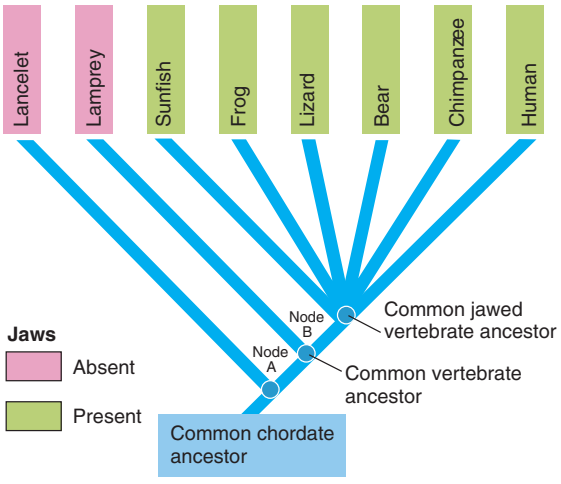
The first step in constructing a cladogram is to select the taxa, which may consist of individuals, species, genera, or other taxonomic levels. Here we use a representative group of eight chordates: the lancelet, lamprey, sunfish, frog, lizard, bear, chimpanzee, and human (Fig. 23-9). The next step is to select the homologous characters to be analyzed. In our example, we use seven characters. For each character, we must define all the different conditions, or states, as they exist in our taxa. For simplicity, we consider our characters to have only two different states: *present* or *absent*. Keep in mind that many characters used in cladistics have more than two states. For example, black, brown, yellow, and red may be only a few of the many possible states for the character of hair color.

The last, and often the most difficult, step in preparing the data is to organize the character states into their correct evolutionary order. For this step, we use outgroup analysis. In our example, the lancelet, a small marine chordate with a fishlike appearance, is the chosen outgroup. It belongs to a taxon that is considered to have diverged earlier than any of the other taxa under investigation but to be closely related to vertebrates; thus, the lancelet represents an approximation of the ancestral condition for vertebrates. Therefore, the character state "absent" for a particular character state such as vertebrae is the ancestral (plesiomorphic) condition, and the character state "present" is the derived condition for the characters in Figure 23-9.

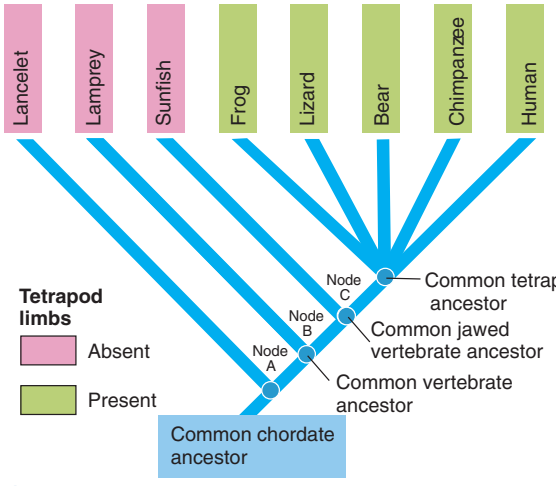
A cladogram is constructed by considering shared derived characters

Our objective is to construct a cladogram that requires the fewest number of evolutionary changes in the characters. Taxa are grouped by the presence of shared derived characters. To form a valid monophyletic group, all members must share at least one derived character. Membership in a clade cannot be established by shared ancestral characters (plesiomorphies).

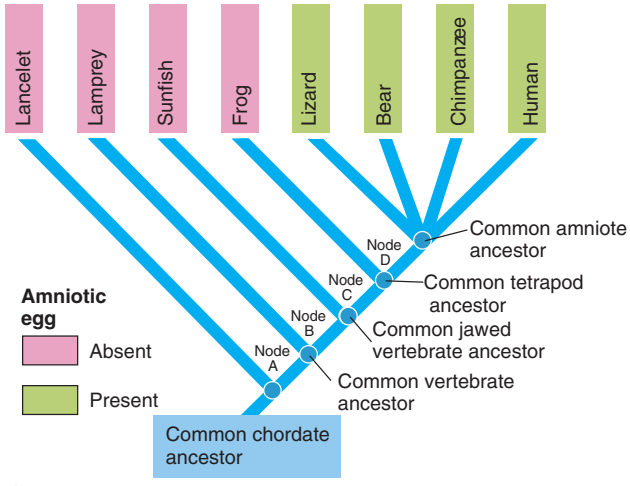
A = Absent, B = Present	CHARACTERS						
TAXA	Vertebrae (backbones)	Jaws	Tetrapod (4 limbs)	Amniotic egg	Mammary glands	Opposable thumb	Upright posture
Lancelet (outgroup)	A	A	A	A	A	A	A
Lamprey	P	A	A	A	A	A	A
Sunfish	P	P	A	A	A	A	A
Frog	P	P	P	A	A	A	A
Lizard	P	P	P	P	A	A	A
Bear	P	P	P	P	P	A	A
Chimpanzee	P	P	P	P	P	P	A
Human	P	P	P	P	P	P	P



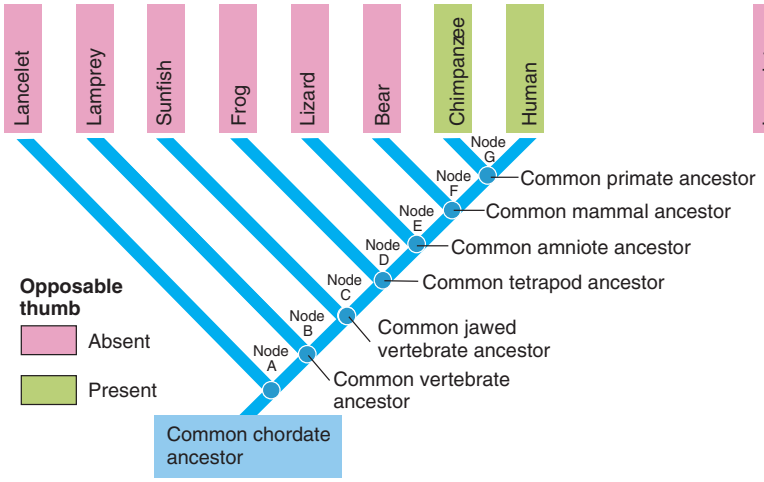
1 All of the seven vertebrate taxa shown here have jaws, except the lamprey. Jaws are a shared derived character for these six taxa.



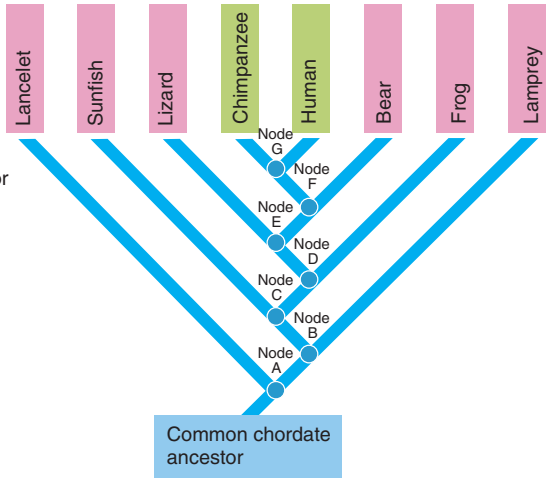
2 Tetrapod limbs are a shared derived character for all vertebrate taxa shown here except the lamprey and sunfish.



3 The taxa represented by lizard, bear, chimpanzee, and human are amniotes. They share the derived character amniotic egg.



4 Of the vertebrate taxa shown here, only the chimpanzee and human share the derived character opposable thumb.



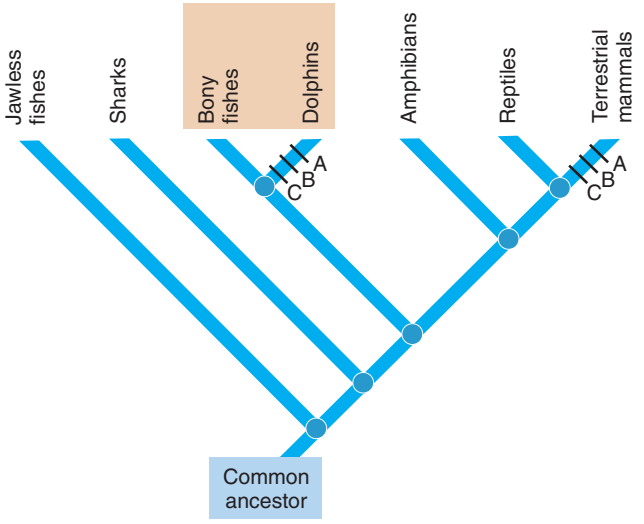
5 Another way to depict the relationships shown in 4.

Figure 23-9 ***Animated*** Building a cladogram

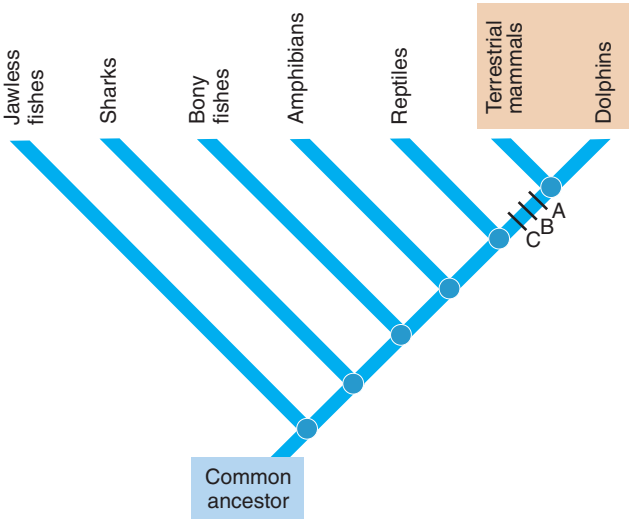
In this example, the lancelet is the chosen outgroup that represents an approximation of the ancestral condition. Refer to the table as you follow the steps in 1 through 4 to build a cladogram. In 5 we illustrate another way to build a cladogram showing the same relationships as in 4.

Key Point

Biologists use the principle of parsimony to choose between alternative hypotheses of evolutionary relationships.



(a) Hypothesis 1: Dolphins and bony fishes are close relatives.



(b) Hypothesis 2: Dolphins and terrestrial mammals are close relatives.

Figure 23-10 Applying parsimony to cladogram construction

Are dolphins more closely related to bony fishes or to terrestrial mammals? Three characters are examined: character A = hair; B = mammary glands; C = middle-ear bones. In hypothesis 1, all three characters examined had to evolve independently twice. Hypothesis 2 is chosen because it requires that each character evolve only once.

In our example, notice that all taxa, except the outgroup lancelet, have vertebrae. We can therefore conclude that these seven vertebrate taxa form a valid clade. Next, among the seven vertebrate taxa, note that jaws are present in all groups except lampreys (a group of jawless vertebrates). Using these data, we construct a preliminary cladogram (Fig. 23-9 1).

The base, or root, of the cladogram represents the common ancestor for all taxa being analyzed. In Figure 23-9 1, node A represents the common chordate ancestor from which the outgroup (lancelet) and the seven vertebrate taxa evolved. Similarly, node B represents the common ancestor of the vertebrates; and node C, the common ancestor of the jawed vertebrates. Continuing with this procedure, notice that among the six-jawed taxa, all but sunfish are tetrapods (animals with four limbs) (Fig. 23-9 2). Among the five tetrapods, all but frogs have amniotic eggs (Fig. 23-9 3). (In an amniotic egg, the embryo is surrounded by a fluid-filled sac, called an *amnion*.) The branching process is continued, using the data in the table in the upper left-hand corner of the figure, until all clades are established (Fig. 23-9 4).

In a cladogram each branch point represents a major evolutionary step

Notice that humans and chimpanzees share a recent common ancestor at node G in Figure 23-9 4. This hypothesis is supported by the derived characters they share (synapomorphies). In the same way, bears are more closely related to the human–chimpanzee clade than to any other clade considered in our example, as indicated by the common ancestor at node F.

Note that shared derived characters are nested. As you trace the tree from its root to its tips, each branch reflects the addition of one or more shared derived characters. When we compare the nodes, the order of divergence (branching) is indicated by distance from the base of the diagram. The farther a node is located up the cladogram, the more recently the group diverged. In our example, node G represents the most recent divergence, and node A represents the most ancient divergence. Thus, in our example, humans are closely related to chimpanzees (through node G) but more distantly related to bears (through node F). Therefore, humans and chimpanzees are collectively assigned to a less inclusive taxon (order Primates), whereas humans, chimpanzees, and bears are assigned to a broader, more inclusive taxon (class Mammalia). In addition, the cladogram reveals that lizards are more closely related to the mammal clade than to frog, sunfish, or any other clade. Can you explain why?

Two important concepts guide interpretation of cladograms. First, the relationships among taxa are determined only by tracing along the branches back to the most recent common ancestor and not by the relative placement of the branches along the horizontal axis. It is possible to represent the same relationships with many different types of branching diagrams. For example, the cladogram in Figure 23-9 5 is equivalent to the one in Figure 23-9 4. (Verify this by comparing the numbered nodes and by checking the relationships described earlier.)

A second important concept is that the cladogram tells us which taxa shared a common ancestor and how recently they shared a common ancestor. The ancestor itself remains unspecified. The cladogram does not establish direct ancestor–descendant relationships among taxa. In other words, a cladogram does not suggest that a taxon gave rise to any other taxon.

A cladogram illustrates the pattern of evolutionary relationships but does not indicate time. The lengths of the branches in a cladogram do not give us information. A **phylogram** provides information about the relative number of mutations that have occurred within each lineage. This information is depicted by the length of the branches. An **ultrametric tree** is rooted, and the tips are all equally distant from the root. The branch points of an ultrametric tree indicate when in geologic time critical events took place.

Systematists use the principle of parsimony to make decisions

When systematists consider the evolutionary relationships of organisms, they must choose between multiple, competing cladograms. How do they choose the most accurate branching pattern? The most common criterion is the principle of **parsimony**—they choose the simplest explanation to interpret the data. Parsimony, a guiding principle in many areas of research, is based on the experience that the simplest explanation is probably the correct one. Applied to choice of cladograms, parsimony requires that the cladogram with the fewest changes in characters (the one with the fewest homoplasies) be accepted as most probable (▮ Fig. 23-10). In actual practice it is often possible to generate several cladograms that are equally parsimonious. The excluded choices are those with more homoplasies, because shared derived characters are more likely than homoplasies.

Systematists also use **maximum likelihood,** especially when analyzing molecular data. This method depends on the probability that nucleotide sequences in DNA and RNA change at a constant rate over time. Complex computer programs analyze large data sets and report the probability of a particular tree.

Many evolutionary questions remain. New hypotheses about how organisms are related suggest new taxonomic schemes. Systematics offers tools to help us test these hypotheses. In Chapters 24 through 31, we explore many evolutionary puzzles and discuss current hypotheses about relationships and classifications of organisms.

Review

- In what way are shared derived characters important to cladists?
- What does a node represent in a cladogram?
- What is outgroup analysis?
- How do systematists apply the principle of parsimony?

SUMMARY WITH KEY TERMS

Learning Objectives

1 State at least two justifications for the use of scientific names and classifications of organisms (page 483).

- **Systematics** is the scientific study of the diversity of organisms and their evolutionary relationships. **Taxonomy** is the branch of systematics devoted to naming, describing, and classifying organisms. The process of assigning organisms into groups based on their similarities or relationships is **classification.**
- Scientific names are important because they allow biologists from different countries with different languages to communicate about organisms. Biologists in distant locations must know with certainty that they are studying the same (or different) organisms.
- Classifications help biologists organize their knowledge.

2 Describe the binomial system of naming organisms, and arrange the Linnaean categories in hierarchical fashion, from most inclusive to least inclusive (page 483).

- Biologists name organisms using the **binomial system of nomenclature** developed by Linnaeus in the mid-18th century. In this system the basic unit of classification is the **species.**
- The name of each species has two parts: the **genus** name followed by the **specific epithet.**
- The hierarchical system of classification used in this book includes **domain, kingdom, phylum, class, order, family, genus,** and **species.** Each formal grouping at any given level is a **taxon.**

3 Describe the six kingdoms and three domains of organisms, and give the rationales for and against this system of classification (page 484).

- The six-kingdom classification recognizes the kingdoms **Archaea, Bacteria, Protista, Fungi, Plantae,** and **Animalia.** Members of Archaea and Bacteria are prokaryotes. Kingdom Protista consists of a diverse group of mainly unicellular, mainly aquatic eukaryotic organisms. The fungi, which include molds, yeasts, and mushrooms, absorb nutrients produced by other organisms. Kingdoms Plantae and Animalia both consist of multicellular eukaryotes. For additional characteristics of the six kingdoms, refer to Table 23-2.
- The three-domain classification system assigns organisms to domains **Archaea, Bacteria,** or **Eukarya.** Domain Bacteria is distinguished by the presence of the compound peptidoglycan in cell walls. Peptidoglycan is absent in the cell walls of the Archaea.
- Domain Eukarya includes the protists, fungi, plants, and animals.

ThomsonNOW™ Explore the tree of life by clicking on the figures in ThomsonNOW.

4 Given its distinguishing characters, classify an organism in the appropriate domain and kingdom (page 484).

- To classify an organism in a domain, first determine whether it is a prokaryote or eukaryote. If it is a prokary-

ote, decide whether it should be assigned to domain Archaea or domain Bacteria by learning about its characters, such as presence or absence of peptidoglycan in its cell wall. If it is not a prokaryote, it should be assigned to domain Eukarya. Check the characteristics in Table 23-2 to determine the appropriate kingdom.

5 Critically review the difficulties encountered in choosing taxonomic criteria (page 487).
- The goal of systematics is to determine evolutionary relationships, or **phylogeny,** based on shared characteristics. Historically, scientists have depended mainly on structural similarities to make decisions about phylogeny. **Homology,** the presence in two or more species of a trait derived from a recent common ancestor, implies evolution from a common ancestor.
- It can be challenging to decide if a character is homologous. Some seemingly homologous characters are acquired independently by **convergent evolution,** independent evolution of similar structures in distantly related organisms, or by **reversal,** reversion of a trait to its ancestral state. The term **homoplasy** refers to such superficially similar characters that are not homologous.

6 Apply the concept of shared derived characters to the classification of organisms (page 487).
- **Shared ancestral characters (plesiomorphies)** suggest a distant common ancestor.
- **Shared derived characters (synapomorphies)** indicate a more recent common ancestor. Systematists carefully consider shared derived characters in choosing taxonomic criteria.

7 Describe how molecular homologies contribute to the science of systematics (page 487).
- **Molecular systematics** depends on molecular structure to clarify phylogeny. Comparisons of nucleotide sequences in DNA and RNA, and of amino acid sequences in proteins, provide important information about how closely organisms are related. For example, comparison of nucleotide sequences in ribosomal RNA has led to important taxonomic decisions regarding domains, kingdoms, and species.

8 Contrast monophyletic, paraphyletic, and polyphyletic taxa (page 487).
- A **monophyletic taxon** includes all the descendants of the most recent common ancestor. A **paraphyletic taxon** consists of a common ancestor and some, but not all, of its descendants. The organisms in a **polyphyletic group** evolved from different recent ancestors.

9 Contrast the classification of reptiles and birds by an evolutionary systematist and a cladist (page 493).
- Scientists applying the principles of **cladistics** insist that taxa be monophyletic. Each monophyletic taxon, or **clade,** consists of a common ancestor and all its descendants. Cladists use shared derived characters to determine these relationships. Cladists classify reptiles and birds in a single clade.
- Scientists using an **evolutionary systematics** approach classify reptiles and birds in separate classes even though they are paraphyletic groups. Evolutionary systematics is based on shared ancestral characters as well as shared derived characters.

10 Describe the construction of a cladogram by using outgroup analysis (page 493).
- Cladists use shared derived characters to reconstruct evolutionary relationships and diagram these relationships in phylogenetic trees called **cladograms.** The cladogram indicates which taxa shared a common ancestor and how recently they shared that ancestor.
- Each branch point, referred to as a **node,** represents the divergence, or splitting, of two or more new groups from a common ancestor. The most recent common ancestor of each monophyletic group would be found at the node. In interpreting cladograms, cladists determine the relationships among taxa by tracing along the branches back to the nodes.
- Cladists use **outgroup analysis** to determine which characters in a given group of taxa are ancestral and which are derived. An **outgroup** is a taxon that represents the ancestral condition because it diverged earlier than any of the other taxa being investigated.
- Cladists use the principle of **parsimony:** They choose the simplest explanation to interpret the data.

TEST YOUR UNDERSTANDING

1. The science of describing, naming, and classifying organisms is (a) systematics (b) taxonomy (c) cladistics (phylogenetic systematics) (d) phenetics (e) evolutionary systematics
2. In the binomial system of nomenclature, the scientific name of each species consists of which two parts? (a) class, specific epithet (b) family, genus (c) genus, specific epithet (d) family, species (e) genus, species
3. The mold that produces penicillin is *Penicillium notatum*. *Penicillium* is the name of its (a) genus (b) order (c) family (d) species (e) specific epithet
4. Closely related genera may be grouped together in a single (a) phylum (b) domain (c) species (d) family (e) kingdom
5. Related classes are grouped in the same (a) genus (b) phylum (c) order (d) paraphyletic taxon (e) family
6. In the six-kingdom system, the kingdom that includes the protozoa is (a) Plantae (b) Protista (c) Archaea (d) Eukarya (e) Fungi
7. Decomposers such as molds and mushrooms belong to which domain and kingdom? (a) Eukarya, Plantae (b) Bacteria, Protista (c) Archaea, Fungi (d) Eukarya, Protista (e) Eukarya, Fungi
8. A group of organisms that contains a recent common ancestor and all its descendants is (a) polyphyletic (b) paraphyletic (c) monophyletic (d) an example of horizontal gene transfer (e) plesiomorphic
9. The presence of homologous structures in two different groups of organisms suggests that (a) the organisms evolved from a common ancestor (b) convergent evolution has oc-

curred (c) they belong to a polyphyletic group (d) homoplasy has occurred (e) independently acquired characters may evolve when organisms inhabit similar environments

10. The dolphin and the human both have the ability to nurse their young, whereas the less closely related fish does not. The ability to nurse their young is a (a) shared derived character of mammals (b) shared ancestral character of all vertebrates (c) plesiomorphy (d) homologous behavior (e) homoplasy
11. Relative constancy in the rates of DNA and protein evolution permits biologists to use these macromolecules as (a) molecular clocks (b) polymerase chains (c) clades (d) paraphyletic clues (e) outgroups
12. Using DNA as a molecular bar code (a) is effective only with bacteria (b) is possible because of similarities in sugars (c) could cause major mistakes in distinguishing among closely related species (d) is an effective way to identify vertical gene transfer (e) could help taxonomists identify and describe new species
13. The conclusion that fungi are more closely related to animals than to plants was based in large part on comparing (a) molecular clocks (b) polymerase chains (c) nucleotides in DNA (d) ribosomal RNA sequences (e) amino acid sequences
14. Phenetics (a) is a systematic approach based on phenotypic similarities (b) emphasizes common ancestry (c) emphasizes polyphyletic groups (d) focuses on ancestral characters (e) strives to differentiate between homology and homoplasy
15. Some systematists classify crocodiles and birds in the same taxon because they are contained within a monophyletic group. These systematists follow which approach? (a) phyletic (b) cladistic (c) evolutionary systematic (d) polyphyletic (e) both cladistic and evolutionary systematic
16. In cladistic analysis (a) ancestral characters are used to reconstruct phylogenies (b) characters must be homoplastic (c) polyphyletic groups are preferred (d) the method called maximum likelihood is rarely used (e) outgroup analysis is used to determine a taxon that diverged earlier than the other taxa being studied
17. When cladists use the principle of parsimony, they (a) choose the simplest explanation to interpret the data (b) select multiple hypotheses to explain each relationship (c) do not use outgroups (d) typically use a polyphyletic approach (e) hypothesize that the most complex explanation is most probably the correct one

CRITICAL THINKING

1. What are the advantages of PhyloCode? Of bar-coding organisms?
2. **Evolution Link.** Are members of a genus similar because they share a common ancestor, or do they belong to the same genus because they are similar? How might your answer vary depending on which approach to systematics you are following?
3. **Evolution Link.** The TATA-binding protein (TBP) is thought to be necessary for transcription in all eukaryotic cell nuclei. Studies show that archaea, but not bacteria, have a protein structurally and functionally similar to TBP. What does this similarity suggest regarding the evolution of archaea and eukaryotes? How might knowledge of this similarity affect how systematists classify these organisms?
4. **Analyzing Data.** Construct a cladogram based on the following data. Mosses are plants with no vascular tissue. Horsetails, ferns, gymnosperms (pines and other plants with naked seeds), and angiosperms (flowering plants) are all vascular plants. Seeds are absent in all but the gymnosperms and angiosperms.
5. **Analyzing Data.** In the illustration, what kind of grouping is represented by the bracketed area? What type of group is formed by 2 and 3? What type of group is formed by 2, 4, and 6?

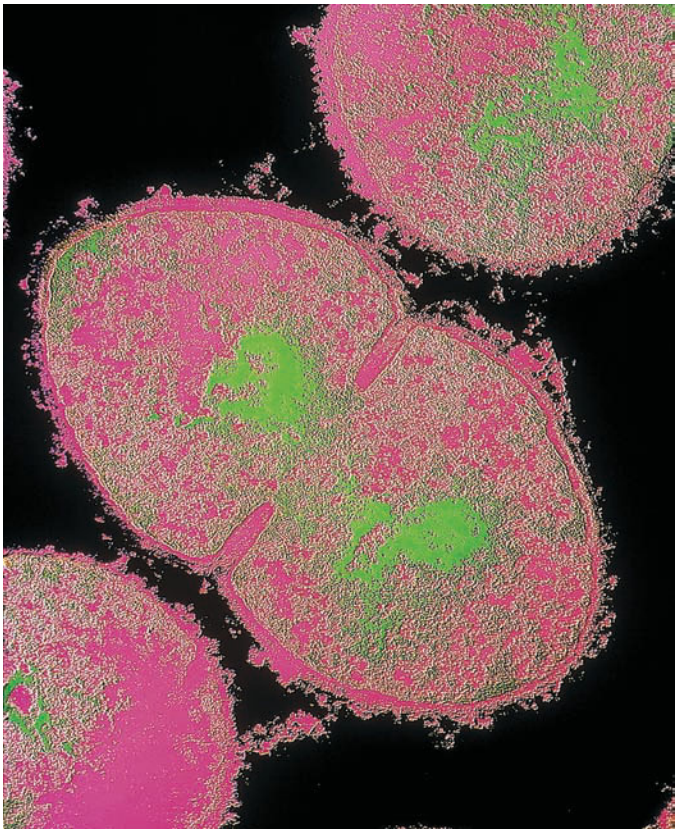
Viruses and Prokaryotes



Dr. Kari Lounatmaa/Science Photo Library/Photo Researchers, Inc.

Color-enhanced TEM of a bacterium (*Streptococcus pyogenes*) dividing by binary fission. This bacterium, a pathogen that inhabits the human nose and throat, can cause scarlet fever and inflammation of the heart tissue. The strain shown here is resistant to antibiotics, and infection can be fatal.

KEY CONCEPTS

A virus is a small particle consisting of a DNA or RNA genome surrounded by a protein coat.

Viroids and prions are smaller than viruses; a prion consists only of proteins.

In contrast to eukaryotic cells, prokaryotic cells do not have membrane-enclosed organelles such as nuclei and mitochondria.

Prokaryotes make up two of the three domains: Bacteria and Archaea.

Evolution occurs rapidly in prokaryotes; natural selection acts on the genetic variation provided by mutations and genetic recombination and is facilitated by rapid reproduction.

Great diversity has evolved in the mode of nutrition, the metabolism, and the ecological roles of prokaryotes.

Prokaryotes (bacteria and archaea) have inhabited our planet for more than 3.5 billion years—much longer than eukaryotes, which evolved about 1.5 billion to 1.6 billion years ago. Although prokaryotes are microscopic, they are so numerous that they, together with the fungi, account for approximately half of Earth's biomass, the mass of living material. In contrast, plants account for about 35% and animals for about 15% of the biomass of our planet.

The Dutch microscopist Anton van Leeuwenhoek discovered bacteria and other microorganisms in 1674 when he looked at a drop of lake water through a glass lens. During the late 1800s, many microorganisms, including bacteria, fungi, and protozoa, were identified as **pathogens,** agents that cause disease (see photograph). Although bacteria cause many diseases, for example, respiratory infections and food poisoning in humans, only a small minority of bacterial species are pathogens. In fact, bacteria play an essential role in the biosphere as decomposers, breaking down organic molecules into their components. Along with fungi, prokaryotes are nature's chief recyclers. Without these microorganisms, elements such as carbon, nitrogen, phosphorus, and sulfur would remain locked up in the wastes and dead bodies of plants, animals, and other organisms and would be unavailable for the synthesis of new cells and organisms.

Some prokaryotes are producers that carry on photosynthesis. Others convert atmospheric nitrogen to ammonia and then to nitrates, forms that are used by plants (see Fig. 54-8). This conversion enables plants and animals (because they eat plants) to manufacture essential nitrogen-containing compounds such as proteins and nucleic acids.

In contrast to prokaryotes, viruses are acellular. Biologists long considered them nonliving particles, but some biologists now view them as life-forms. Viruses contain the nucleic acids necessary to make copies of themselves, and they reproduce by invading living cells and commandeering their metabolic machinery. These tiny, but potent, particles infect cells and produce a wide variety of diseases in plants and animals. Viruses influence the biodiversity of prokaryotes and algae, as well as many ecological processes, including the recycling of nutrients.

This chapter examines the diversity and characteristics of viruses, prokaryotes, and the smaller viroids and prions. They are not a natural group of closely related organisms, and we discuss them in a single chapter only for convenience, not to reflect shared ancestry. ■

VIRUSES

Learning Objectives

1. Describe the structure of a virus, and contrast a virus with a living cell.
2. Trace the evolutionary origin of viruses according to current hypotheses.
3. Characterize bacteriophages, and contrast a lytic cycle with a lysogenic cycle.
4. Compare viral infection of animals and plants, and identify specific diseases caused by animal viruses.
5. Describe the reproductive cycle of a retrovirus, such as human immunodeficiency virus (HIV).

During the late 1800s, botanists searched for the cause of tobacco mosaic disease, which stunts the growth of tobacco plants and gives the infected tobacco leaves a spotted, mosaic appearance. They found they could transmit the disease to healthy plants by daubing their leaves with the sap of diseased plants. In 1892, Dmitri Ivanowsky, a Russian botanist, showed that the sap was still infective after it had been passed through porcelain filters designed to filter out all known bacteria. A few years later, in 1898, Martinus Beijerinck, a Dutch microbiologist, provided evidence that the agent that caused tobacco mosaic disease had many characteristics of a living organism. He hypothesized that the infective agent could reproduce only within a living cell and named it *virus* (from the Latin word *virus,* which means "poison").

Early in the 20th century, scientists discovered infective agents, like those responsible for tobacco mosaic disease, that could cause disease in animals or kill bacteria. These pathogens were so small that they could not be seen with the light microscope. They also passed through filters that removed all known bacteria. Curiously, they could not be grown in laboratory cultures unless living cells were present.

Further studies of viruses have confirmed that they are indeed small. The poliovirus is about 30 nm in diameter (about the size of a ribosome). Almost a million of them lined up end to end would span only an inch. A larger virus, such as the poxvirus that causes smallpox, can measure up to 300 nm long and 200 nm wide. The largest known virus is the Mimivirus, with a diameter of at least 400 nm, the size of a small bacterium (mycoplasma). Mimivirus infects amoebae (which are protists).

A virus consists of nucleic acid surrounded by a protein coat

Sir Peter Medawar, 1960 Nobel laureate in Medicine, defined a virus as "a piece of bad news wrapped in protein." We now know that most known viruses are not pathogens, that is, they do not cause disease. A **virus,** or **virion,** is a tiny, infectious particle consisting of a nucleic acid core (its genetic material) surrounded by a protein coat called a **capsid.**

Viruses are not made of cells and cannot independently perform metabolic activities. They do not have the components necessary to carry on cellular respiration or to synthesize proteins and other molecules. Viruses reproduce, but only within the complex environment of the living **host cells** they infect. Viruses use their genetic information to force the host cell to replicate the viral nucleic acid. They take over the transcriptional and translational mechanisms of the host cell. Viruses are **obligate intracellular parasites,** which means that they survive only by using the resources of a host cell.

A virus may contain either DNA or RNA

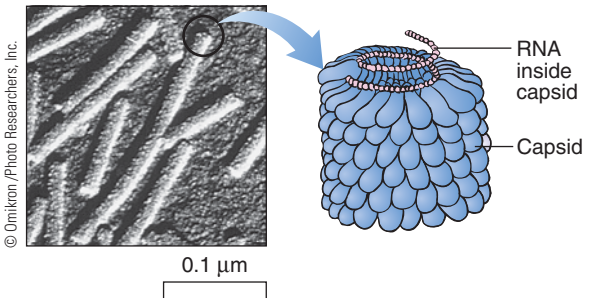
Until recently, biologists thought that whereas other living organisms contain both deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), a virus contains *either* DNA or RNA, not both. However, investigators recently sequenced the genome of Mimivirus and reported that this large DNA virus also has six transfer RNAs. Viruses typically have single-stranded (ss) DNA, double-stranded (ds) DNA, ssRNA, or dsRNA. As we will discuss, the type of nucleic acid is important in classifying viruses.

The capsid is a protective protein coat

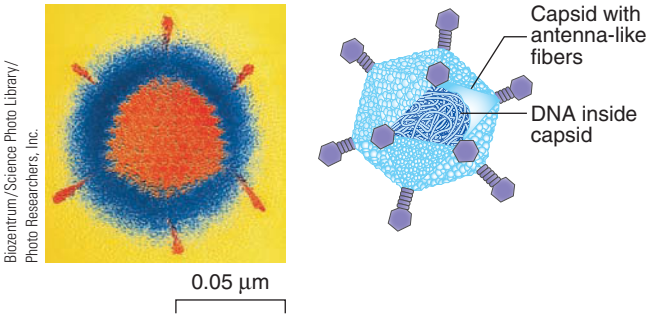
After viruses take over the metabolic machinery of a cell, the host synthesizes capsids for the viruses. Some viruses are surrounded by an outer membranous envelope, and the host cell also produces these envelopes.

Capsids consist of protein subunits, called *capsomeres.* The capsomeres determine the shape of a virus. Viral capsids generally are either helical or polyhedral, or a combination of both shapes. Helical viruses, such as the tobacco mosaic virus (TMV), appear as long rods or threads (Fig. 24-1a). The capsid is a hollow cylinder made up of proteins that form a groove into which the RNA fits.

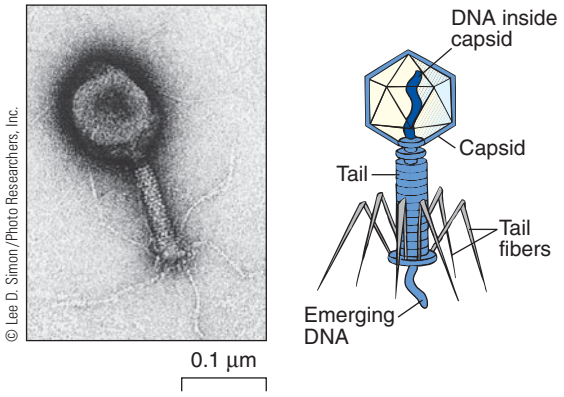
Polyhedral viruses, such as the adenoviruses (which cause a number of human illnesses, including some respiratory infections), appear somewhat spherical (Fig. 24-1b). The capsomeres are organized in equilateral triangles. The capsid of a large virus can consist of several hundred capsomeres. The most common polyhedral structure is an *icosahedron,* a structure with 20 identical surface faces (each face is a triangle).



(a) TEM of tobacco mosaic virus, a rod-shaped virus with a helical arrangement of capsid proteins.



(b) Color-enhanced TEM of an adenovirus, which has a capsid composed of 252 subunits (visible as tiny ovals) arranged into a 20-sided polyhedron. Twelve of the subunits have projecting protein spikes that permit the virus to recognize host cells.



(c) TEM of T4, a bacteriophage that has a polyhedral head and a helical tail.

Figure 24-1 ***Animated*** Virus structure

Some viruses have both helical and polyhedral components. Viruses that infect bacteria are called **bacteriophages** ("bacteria eaters"), or **phages** (Fig. 24-1c). The T4 phage that infects the bacterium *Escherichia coli* consists of a polyhedral "head" attached to a helical "tail," a shape commonly found in bacteriophages. Many phages have tail fibers that attach to the host cell.

Viruses surrounded by an outer membranous envelope are referred to as *enveloped viruses.* Typically, the virus acquires the envelope, which is a part of the host cell's plasma membrane, as it leaves the host cell. Interestingly, while in the host cell, the virus synthesizes certain proteins and inserts them into the host's plasma membrane. Thus, the viral envelope consists of phospholipids and proteins of the host's plasma membrane, as well as distinctive proteins produced by the virus itself. Some viruses produce envelope proteins that extend out from the envelope as spikes. As we will discuss, these spikes can be very important in the virus's interaction with the host cell.

Viruses may have evolved from cells

Where did viruses come from? The most widely held hypothesis is that viruses derive from bits of nucleic acid that "escaped" from cellular organisms. Viruses may have originated as mobile genetic elements such as *transposons* (see Chapter 13) or *plasmids* (small, circular DNA fragments discussed in Chapter 15 and later in this chapter). Such fragments could have moved from one cell and entered another through damaged cell membranes.

According to this *escaped gene hypothesis,* some viruses may trace their origin to animal cells, others to plant cells or to bacterial cells. Their multiple origins may explain why many viruses are species specific; perhaps they infect only those species that are closely related to the organisms from which they originated. This hypothesis is supported by the genetic similarity between some viruses and their host cells—a closer similarity than exists between one type of virus and another.

A very different hypothesis suggests that viruses arose early in the history of life, even before the three domains diverged. Evidence for this hypothesis comes from similarities found in the protein structures of some viral capsids and in genetic similarities between some viruses that infect archaea and some that infect bacteria. Molecular biologists studying this hypothesis consider it improbable that these similarities evolved independently. This evidence suggests that viruses diverged very early. However, viruses are parasites, dependent on their hosts. How could they have existed before their hosts evolved?

Several investigators have suggested that DNA viruses have a common origin and that they evolved before the evolution of the three domains. According to this hypothesis, ancestral DNA viruses were important in the evolution of eukaryotes. The investigators who sequenced the Mimivirus genome reported that its genome is larger than the genomes of 20 different bacteria and archaea. Also unlike other viruses, Mimivirus has genes that encode components for protein translation. These researchers suggest that this giant virus evolved from a more complex ancestor and gradually lost some of the genes necessary for protein synthesis. This hypothesis explains how viruses could have existed before their hosts evolved.

No matter how viruses came to be, they are here in large numbers and are important players in evolution. They mutate constantly, producing many new alleles. They replicate rapidly, and some of their genes are incorporated into the genomes of host cells. In fact, viruses may be a major source of new genes for their host cells.

The International Committee on Taxonomy of Viruses classifies viruses

Viruses present a taxonomic challenge to biologists because they do not show the characteristics that define living organisms (see Chapter 1). They are acellular, do not carry on metabolic activi-

ties, and reproduce only by taking over the reproductive machinery of other cells. Viruses do not manufacture ribosomes so do not have distinctive rRNA. For these reasons, viruses cannot be classified in any of the three domains.

Viruses can be classified based on their **host range,** the types of organisms they infect. Host ranges include bacteria, algae, protozoa, fungi, plants, invertebrates, and vertebrates. Viruses are further classified based on their characteristics. Two major defining traits are what type of nucleic acid the virus contains and whether the nucleic acid is single or double stranded. Other traits considered are the presence of an envelope, the size and shape of the virus, and the method by which it is transmitted from host to host.

The International Committee on Taxonomy of Viruses (ICTV), a group of virologists, decides on the criteria for classifying and naming viruses. The ICTV has classified viruses into approximately 56 families and 233 genera based on host range and characteristics. Note that this classification system is not a traditional Linnaean system and does not assign viruses to domains, kingdoms, or phyla.

Bacteriophages are viruses that attack bacteria

Much of our knowledge of viruses has come from studying bacteriophages, because they can be cultured easily within living bacteria in the laboratory. Researchers have identified more than 2000 phages. Bacteriophages are among the most complex viruses (see Fig. 24-1c). Their most common structure consists of a long nucleic acid molecule (usually dsDNA) coiled within a polyhedral head.

Before the age of sulfa drugs and antibiotics, phages were used clinically to treat infection. In the 1940s, they were abandoned (at least in Western countries) in favor of antibiotics, which were more dependable and easier to use. Now, with the widespread and growing problem of bacterial resistance to antibiotics, these bacteria-killing viruses are once again the focus of research. With new knowledge of phages and sophisticated technology, several research groups are investigating phages to determine which ones kill which species of bacteria. Scientists are genetically engineering phages so that bacteria will be slower to evolve resistance to them.

Phages can also be used to improve food safety. For example, certain phages can kill deadly strains of *E. coli* in cattle. These bacteria do not appear to make cattle ill but can cause illness and death in people who eat contaminated, undercooked hamburgers.

Viruses reproduce only inside host cells

The reproductive cycle of viruses begins with a virus coming into contact with a host cell. The virus typically attaches to the surface of the host cell. The viral nucleic acid must enter the host cell and synthesize the components it needs to reproduce itself. Then, viral components are assembled and viruses are released from the cell—ready to invade other cells. Two types of reproduction among viruses are lytic and lysogenic cycles.

Lytic reproductive cycles destroy host cells

In a **lytic cycle,** the virus lyses (destroys) the host cell. When the virus infects a susceptible host cell, it forces the host to use its metabolic machinery to replicate viral particles. Viruses that have only a lytic cycle are described as **virulent,** which means that they cause disease, and often death.

Five steps are typical in lytic viral reproduction (Fig. 24-2):

1. **Attachment (or absorption).** The virus attaches to receptors on the host cell. This process ensures that the virus infects only its specific host.
2. **Penetration.** The virus penetrates the host plasma membrane and moves into the cytoplasm. Many viruses that infect animal cells enter the host cell intact. Some phages inject only their nucleic acid into the cytoplasm of the host cell; the capsid remains on the outside.
3. **Replication and synthesis.** The viral genome contains all the information necessary to produce new viruses. Once inside, the virus degrades the host cell nucleic acid and uses the molecular machinery of the host cell to replicate its own nucleic acid. Many antiviral drugs interfere with replication of viral nucleic acid. After replication, capsid proteins and other needed molecules are synthesized.
4. **Assembly.** The newly synthesized viral components are assembled into new viruses.
5. **Release.** Assembled viruses are released from the cell. Generally, lytic enzymes, produced by the phage late in the replication process, destroy the host plasma membrane. Phage release typically occurs all at once and results in rapid cell lysis. Animal viruses are often released slowly or bud off from the plasma membrane.

Once released, the viruses infect other cells, and the process begins anew. The time required for viral reproduction, from attachment to the bacterium to the release of new viruses, varies from less than 20 minutes to more than an hour.

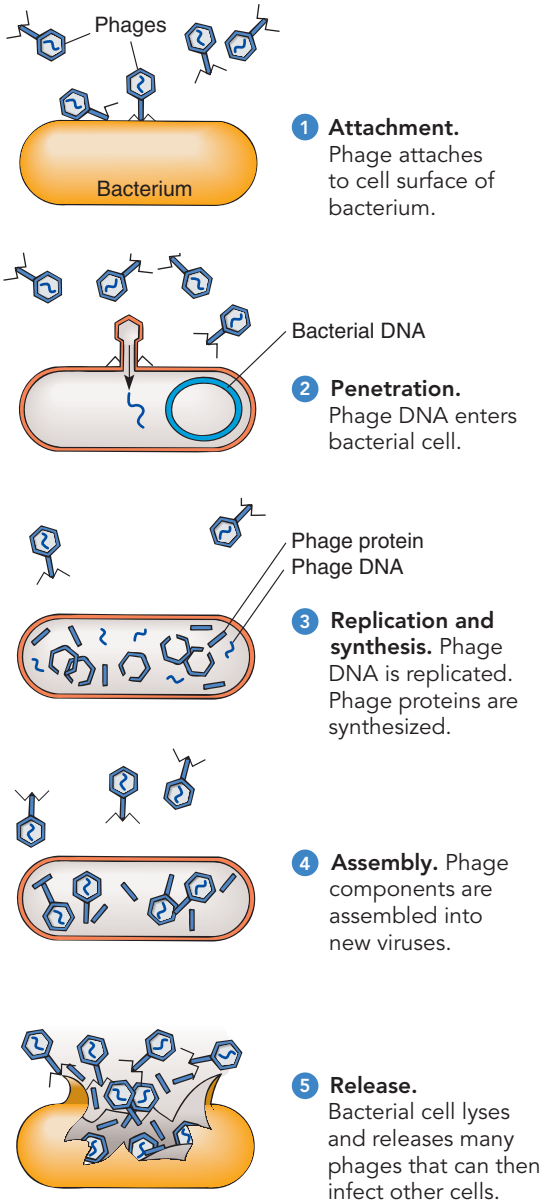
How do bacteria protect themselves from phage infection? You may recall from Chapter 15 that bacteria produce **restriction enzymes,** enzymes that cut up the foreign DNA of the phage. The bacterial cell protects its own DNA by slightly modifying it after replication so that the restriction enzyme does not recognize the sites it would cut.

Temperate viruses integrate their DNA into the host DNA

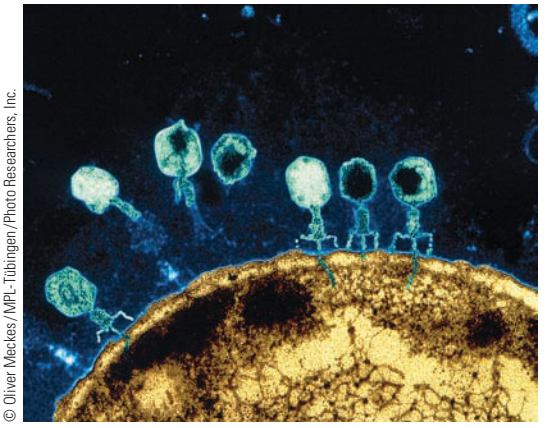
Temperate viruses do not always destroy their hosts. In a **lysogenic cycle,** the viral genome usually becomes integrated into the host bacterial DNA and is then referred to as a **provirus,** or **prophage.** When the bacterial DNA replicates, the provirus also replicates (Fig. 24-3). The viral genes that code for viral structural proteins may be repressed indefinitely. Bacterial cells carrying proviruses are called *lysogenic cells.* Certain external conditions (such as ultraviolet light and X-rays) cause temperate viruses to revert to a lytic cycle and then destroy their host. Sometimes temperate viruses become lytic spontaneously.

Key Point

Viruses reproduce by seizing control of the metabolic machinery of a host cell. The host cell is destroyed in a lytic infection.



(a) The sequence of events in a lytic infection.



(b) Color-enhanced TEM of phages infecting a bacterium, *Escherichia coli*.

Figure 24-2 ***Animated*** Lytic cycle

Bacterial cells containing certain temperate viruses may exhibit new properties. This change is called **lysogenic conversion.** An interesting example involves the bacterium *Corynebacterium diphtheriae,* which causes diphtheria. Two strains of this species exist, one that produces a toxin (and causes diphtheria) and one that does not. The only difference between these two strains is that the toxin-producing bacteria are infected by a specific temperate phage. The phage DNA codes for the powerful toxin that causes the symptoms of diphtheria. Similarly, the bacterium

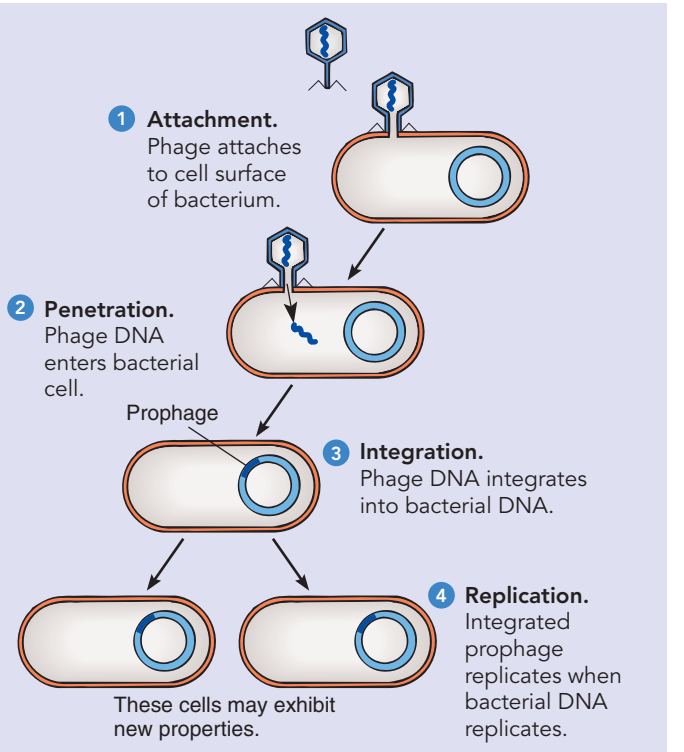


Figure 24-3 ***Animated*** Lysogenic cycle

Temperate phages integrate their nucleic acid into the host cell DNA, making it a lysogenic cell.

TABLE 24-1

Some Viruses That Infect Vertebrates

Group	Diseases Caused	Characteristics
DNA Viruses with Envelope		
Poxviruses	Smallpox, cowpox,* monkeypox, and economically important diseases of domestic fowl	**dsDNA;** large, complex viruses; replicate in the cytoplasm of the host cell
Herpesviruses	Cold sores (herpes simplex virus type 1); genital herpes, a sexually transmitted disease (herpes simplex virus type 2); chickenpox and shingles (herpes varicella–zoster virus); infectious mononucleosis and Burkitt's lymphoma (Epstein–Barr virus)	**dsDNA;** medium to large, enveloped viruses; replicate in the host nucleus†
DNA Viruses with No Envelope		
Adenoviruses	Respiratory tract disorders (e.g., sore throat, tonsillitis), conjunctivitis, and gastrointestinal disorders are caused by more than 40 types of adenoviruses in humans; other varieties infect other animals	**dsDNA;** replicate in the host nucleus
Papovaviruses‡	Human warts and some degenerative brain diseases; some cancers, including cervical cancer	**dsDNA**
Parvoviruses	Infections in dogs, swine, arthropods, rodents; gastroenteritis in humans (transmitted by consumption of infected shellfish)	**ssDNA;** some require a helper virus in order to multiply
RNA Viruses with Envelope		
Togaviruses	Rubella (German measles)	**ssRNA** that can serve as mRNA; large diverse group of medium-sized, enveloped viruses; many transmitted by arthropods
Orthomyxoviruses	Influenza (flu) in humans and other animals	**ssRNA** that serves as template for mRNA synthesis; medium-sized viruses that often exhibit projecting spikes
Paramyxoviruses	Rubeola (measles) and mumps in humans; distemper in dogs	**ssRNA;** resemble orthomyxoviruses but somewhat larger
Rhabdoviruses	Rabies	**ssRNA**
Coronaviruses	Upper respiratory infections; SARS	**ssRNA**
Flaviviruses	Yellow fever; West Nile virus; hepatitis C (the most common reason for liver transplants in the United States)	**ssRNA**
Filoviruses	Hemorrhagic fever, including that caused by the Ebola virus	**ssRNA**
Bunyaviruses	St. Louis encephalitis; hantavirus pulmonary syndrome (caused by Sin Nombre virus, a hantavirus)	**ssRNA**
Retroviruses	AIDS; some types of cancer	**ssRNA** viruses that contain reverse transcriptase for transcribing the RNA genome into DNA; two identical molecules of ssRNA
RNA Viruses with No Envelope		
Picornaviruses	Polio (poliovirus); hepatitis A (hepatitis A virus); intestinal disorders (enteroviruses); common cold (rhinoviruses); aseptic meningitis (coxsackievirus, echovirus)	**ssRNA** that can serve as mRNA; diverse group of small viruses
Reoviruses	Vomiting and diarrhea; encephalitis	**dsRNA**

* The vaccinia (cowpox) virus is used to produce genetically engineered vaccines.

† These viruses frequently cause latent infections; some cause tumors.

‡ The virus SV40 has been used as a vector to transport genes into cells.

Clostridium botulinum, which causes botulism, a serious form of food poisoning, is harmless unless it contains certain provirus DNA that induces synthesis of the toxin.

Many viruses infect vertebrates

Hundreds of different viruses infect humans and other vertebrates. Animal viruses cause hog cholera, foot-and-mouth disease, canine distemper, influenza, and certain types of cancer (such as feline leukemia and cervical cancer). Viruses cause chickenpox, herpes simplex (one type causes genital herpes), mumps, rubella (German measles), rubeola (measles), rabies, warts, infectious mononucleosis, influenza, viral hepatitis, and AIDS (▮ Table 24-1 and *Focus On: Influenza and Other Emerging and Re-emerging Diseases*). Most humans suffer from two to six viral infections each year, including common colds.

INFLUENZA AND OTHER EMERGING AND RE-EMERGING DISEASES

The development of antibiotics, vaccines, and improved health care has made it possible for public health officials to effectively control some diseases. However, many familiar diseases, such as influenza, malaria, tuberculosis, and bacterial pneumonias, continue to infect large numbers of people and sometimes reappear in forms that are resistant to drug treatments. **Re-emerging diseases** are those that have been almost eradicated and then strike unpredictably, causing an epidemic, sometimes in a new geographic area. **Emerging diseases,** those new to the human population—such as AIDS, severe acute respiratory syndrome (SARS), Ebola, eastern equine encephalitis, and West Nile virus—often appear suddenly. According to the U.S. Centers for Disease Control and Prevention, more than 200 new, continual, or re-emerging pathogens have the potential to strike globally.

Historically, new viral strains have claimed many human lives. For example, in 1918 an influenza (flu) pandemic killed more than 20 million people throughout the world. Flu pandemics also occurred in 1957 and 1968. The outbreak of influenza A (H5N1) in 2005 was a major warning to the World Health Organization (WHO) and other public health agencies to mobilize resources and prepare for a new pandemic. Some epidemiologists warn that an influenza epidemic today could kill huge numbers of people, perhaps as many as one third of the human population. Pathogens can strike quickly and spread rapidly.

Typically, new strains of the avian influenza virus (orthomyxovirus) at first infect mainly birds and are not able to spread among mammals. However, a virus of the avian strain can mutate and become virulent. The avian virus can also exchange genes with a virus that has the genes necessary to spread among pigs and other mammals. Pigs can be susceptible to both avian and human strains of the virus. Inside the pig's body, the viruses can exchange genes and thereby produce a virus that can infect humans. Gene exchange can also occur inside a human host and produce a viral strain that can spread from person to person. If the new combination of viral genes is unfamiliar to the human immune system and can spread easily, a pandemic can occur (see figure).

Each year new strains of influenza virus evolve and become infectious, so the challenge to scientists and public health officials is ongoing. In addition, the virus has a very brief incubation period (about 2 days) and so spreads rapidly. Minimizing the effects of a pandemic will require careful surveillance and willingness for countries to rapidly share information. Effective vaccines and treatments must be developed, and containment measures (such as quarantines) must be planned.

As new technology is developed, researchers can more quickly characterize emerging disease organisms and explore treatments and vaccines. Hepatitis E, a viral disease that may be re-emerging, was documented as an epidemic in India in 1955 but was not isolated as a separate virus until the development of modern immunologic research tools in the early 1980s. In contrast, SARS, first recognized as a global threat in 2003, was successfully contained in less than 4 months. Researchers isolated and identified the SARS virus as a coronavirus in a matter of a few weeks. This information coupled with public health response helped speed efforts to diagnose and treat the disease and to reduce transmission, thus preventing a global epidemic of this deadly disease. However, WHO cautions that the SARS virus could hide in some animal or environmental reservoir and resurface when conditions again become favorable for spread to its new human host. Epidemiologists are modeling the SARS epidemic in an effort to answer basic questions, such as whether we can move from control of local outbreaks to global eradication of this disease. The SARS virus does not become infectious for about 10 days, which allows more time to track its spread and contain it than for a flu virus.

Even at the level of our current knowledge about viruses and epidemiology, just how prepared are we to contain a particularly virulent virus? How well are we containing HIV (the virus that causes AIDS), which infects 5 million and kills 3 million people worldwide every year?

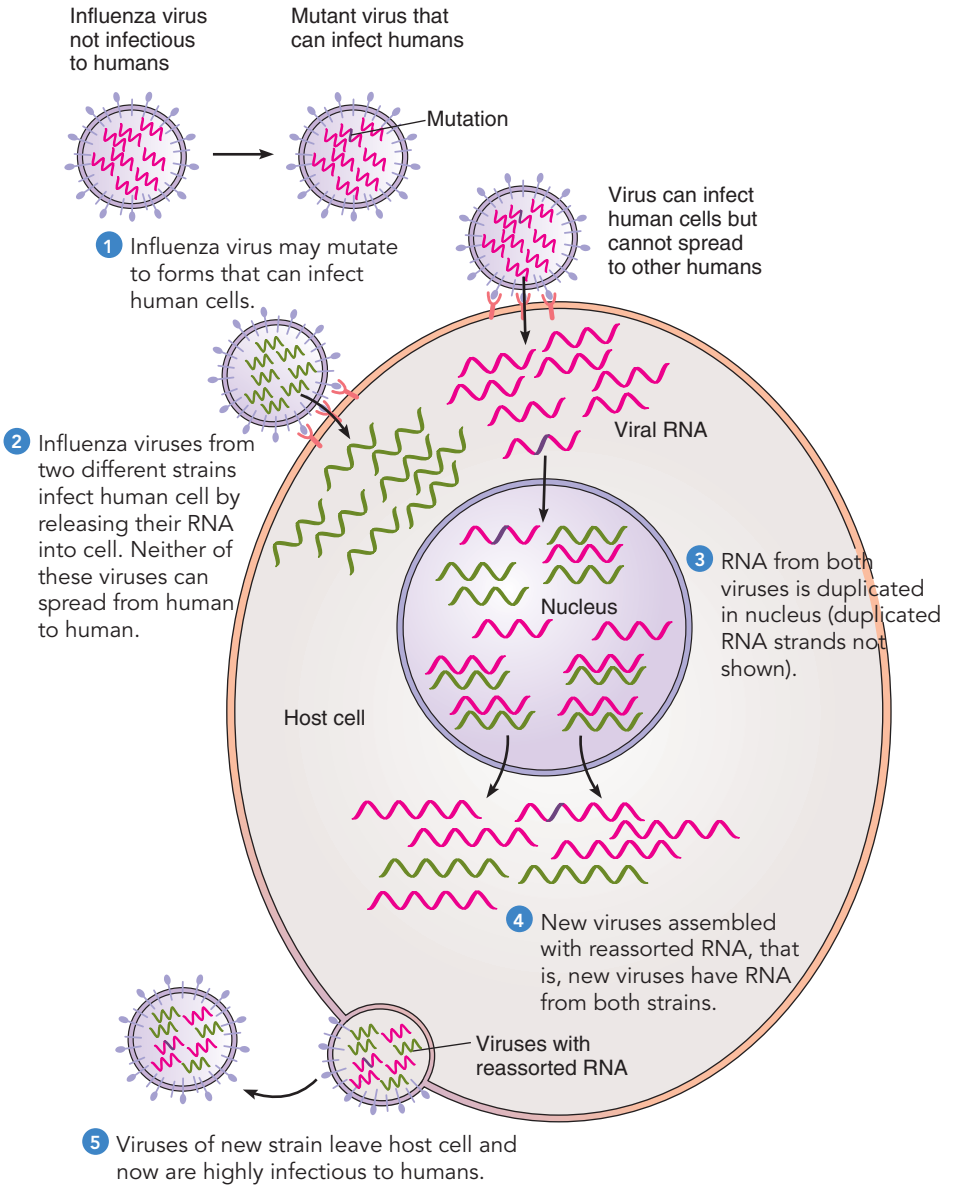
Since the September 11, 2001, terrorist attacks in the United States, bioterrorism has become a critical concern worldwide. Bioterrorism is the intentional use of microorganisms or toxins derived from living organisms to cause death or disease in humans, animals, or plants on which humans depend. For example, in 2001 *Bacillus anthracis,* the causative agent of anthrax, was intentionally released and disseminated through the U.S. postal system. Terrorists could conceivably initiate epidemics of anthrax, smallpox, plague, and other potentially fatal diseases. The quest for effective treatments and vaccines for these diseases has taken on new urgency.

Whether disease outbreaks occur naturally or intentionally, countries must be prepared to protect their citizens. How well are public health agencies prepared to quickly detect and investigate new outbreaks? How well are they prepared to help the health-care community contain the spread of disease? Are we training physicians, nurses, and other health-care providers to recognize, report, and treat infectious diseases? Do we have sufficient supplies of medications and vaccines that would be necessary to contain an epidemic? Are systems of communication effective in reporting and sharing information among health-care agencies, providers, and the public?

Human activity, including social factors such as urbanization, global travel, and war, contributes to epidemics of infectious disease. For example, as human populations concentrate in cities, large numbers

Many vertebrate viruses have lytic reproductive cycles

Most viruses cannot survive very long outside a living host cell, so their survival depends on their being transmitted from animal to animal. However, their host range may be quite limited because attachment to a host cell is very specific. The type of attachment proteins on the surface of a virus determines what type of cell it can infect. Receptors typically vary with each species and sometimes with each type of tissue. Thus, many human viruses can infect only humans because the viral attachment proteins combine only with receptor sites found on human cell surfaces. The measles virus and poxviruses infect many types of human tissue



of people come into close contact, permitting the rapid spread of viruses. Living conditions, including sanitation, nutrition, physical stress, level of health care, and sexual practices, are important factors in the spread of disease. In the United States and other highly developed countries, infectious disease accounts for about 4% to 8% of deaths compared with death rates of 30% to 50% in developing regions. Lessons learned from dealing with emerging viruses and the resurgence of old ones will help us contain future epidemics, but much more research is needed.

because their attachment proteins combine with receptor sites on a variety of cells. In contrast, polioviruses attach to specific types of human cells, such as those that line the digestive tract and motor neurons of the brain and spinal cord.

Some viruses, such as the adenoviruses, have fibers that project from the capsid and adhere to complementary receptors on the host cell. Other viruses, such as those that cause herpes and rabies, are surrounded by a lipoprotein envelope with projecting glycoprotein spikes that attach to a host cell. The influenza virus also has rodlike spikes that project from its envelope. The glycoprotein spikes bind with specific receptors present only on cells lining the respiratory tract of certain vertebrates, including wild

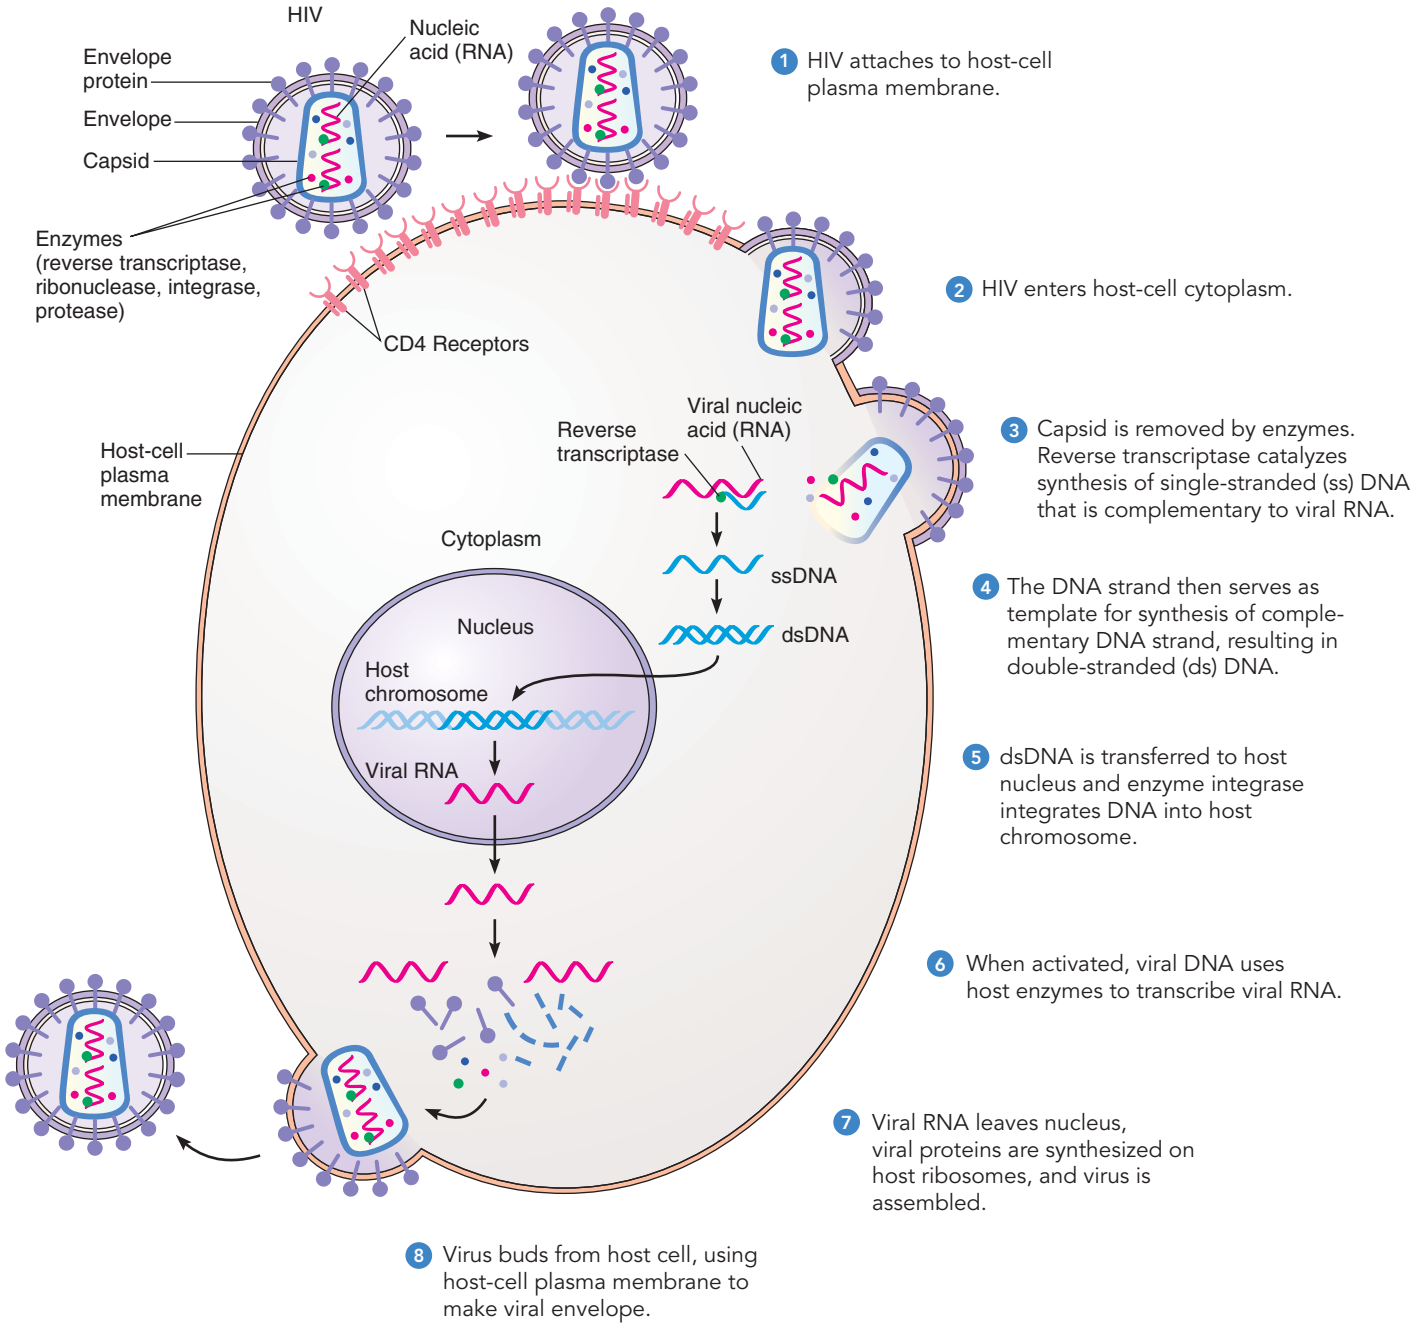

Figure 24-5 ***Animated*** Life cycle of HIV, the retrovirus that causes AIDS

HIV infects T helper cells, specialized cells of the host's immune system. The virus attaches to protein receptors, known as CD4, on the plasma membrane of the T helper cell. HIV has two identical single-stranded RNA molecules.

and domestic birds, horses, pigs, and humans. Influenza vaccine prevents attachment by stimulating the host's antibodies to cover the spikes projecting from the virus.

Viruses have several ways to penetrate animal cells (Fig. 24-4). After attachment to a host-cell receptor, some enveloped viruses fuse with the animal cell's plasma membrane. The viral capsid and nucleic acid are both released into the animal cell. Other viruses enter the host cell by *endocytosis.* In this process, the plasma membrane of the animal cell invaginates to form a membrane-bound vesicle that contains the virus. Endocytosis is advantageous to the virus because the endocytotic vesicle delivers the virus deep into the cytosol.

In DNA animal viruses, replication of viral DNA and protein synthesis are similar to the processes by which the host cell would normally carry out its own DNA replication and protein synthesis. In most RNA viruses, RNA synthesis takes place with the help of an RNA-dependent RNA polymerase.

Retroviruses are RNA viruses that have a DNA polymerase called **reverse transcriptase,** which is used to transcribe the RNA genome into a DNA intermediate (Fig. 24-5). This DNA be-

comes integrated into the host DNA by an enzyme also carried by the virus. Copies of the viral RNA are synthesized as the incorporated DNA is transcribed by host RNA polymerases. The **human immunodeficiency virus (HIV)** that causes acquired immunodeficiency syndrome (AIDS) is a retrovirus. Certain cancer-causing viruses are also retroviruses.

After viral genes are transcribed, the viral structural proteins are synthesized. The capsid is produced, and then assembly of new virus particles takes place. Finally, release occurs. Viruses that do not have an outer envelope exit by cell lysis. The plasma membrane ruptures, releasing many new viral particles. Enveloped viruses obtain their lipoprotein envelopes by picking up a fragment of the host plasma membrane as they leave the infected cell (see Figs. 24-4b and 24-5).

Viral proteins damage the host cell in several ways. These proteins may alter the permeability of the plasma membrane or may inhibit synthesis of host nucleic acids or proteins. Viruses sometimes damage or kill their host cells by their sheer numbers. A poliovirus can produce 100,000 new viruses within a single host cell!

Figure 24-6 Plant viruses

Antiviral drugs are being developed

Antibiotics are specific for fighting bacteria, so they do not kill viruses. However, researchers have developed several antiviral drugs. Most of these drugs inhibit the replication of many RNA and DNA viruses. Amantadine has been used mainly to treat patients with influenza. The drug inhibits penetration or uncoating of viral nucleic acids. However, recent strains of influenza virus have become resistant to Amantadine, perhaps as a result of using the drug in poultry feed in certain areas of Asia. A newer group of antiviral drugs, including Tamiflu, inhibit neuraminidase, a viral enzyme necessary for the virus to leave the host cell. Other antiviral drugs are in clinical trials. Some inhibit viral attachment to host cells, and others interfere with replication of viral nucleic acid.

Some viruses infect plant cells

Viruses cause many important plant diseases and are responsible for huge agricultural losses and lower crop quality. Infected crops almost always produce lower yields. The genome of most plant viruses consists of single-stranded RNA. Most plant viruses do not have envelopes. Symptoms of viral infection include reduced plant size and spots, streaks, or mottled patterns on leaves, flowers, or fruits (Fig. 24-6).

As they feed on plant tissues, insects such as aphids and leafhoppers spread viral diseases among plants. Because of plants' thick cell walls, viruses cannot penetrate plant cells unless the cells are damaged. Plant viruses are inherited through infected seeds or by asexual propagation. Once a plant is infected, the virus spreads through the plant body by passing through plasmodesmata (cytoplasmic connections) that penetrate the walls between adjacent cells (see Fig. 5-27).

There are no known cures for most viral diseases of plants, so infected plants are commonly burned. Some agricultural scientists are focusing their efforts on preventing viral disease by developing virus-resistant strains of important crop plants.

VIROIDS AND PRIONS

Learning Objective

6 Compare and contrast viroids and prions.

The ICTV recognizes four types of subviral agents. They are smaller and simpler than viruses. Here we will discuss two of them: viroids and prions.

Viroids are the smallest known pathogens

In 1961, scientists discovered an infective agent in potatoes that had a short RNA strand but no protein coat. The agent, named a **viroid,** is much smaller than a virus. Each viroid consists of a

very short strand of naked RNA (only 250 to 400 nucleotides) that serves as a template copied by host RNA polymerases. The virus has no protective protein coat and no associated proteins to assist in duplication. Viroids are extremely hardy and resist heat and ultraviolet radiation because of the condensed folding of their RNA.

Viroids cause diseases in many plants. These infective agents, transmitted by pollen or seeds, are generally found within the host cell nucleus and may interfere with gene regulation. They cause stunted or distorted growth and sometimes kill the plant.

Prions are protein particles

Stanley Prusiner, professor of neurology and biochemistry at the University of California School of Medicine, San Francisco, began his studies of prions in the early 1970s, motivated by the death of a patient from Creutzfeldt–Jakob disease (CJD), a degenerative brain disease. Prusiner discovered that the infective agent was not affected by radiation (which typically mutates nucleic acids), and he could not find DNA or RNA in the particles. In 1982, he named the infective agent **prion,** for "proteinaceous infectious particle."

Prusiner's hypothesis that a pathogen could exist and transfer information without nucleic acids went against all accepted biological dogma. However, Prusiner and other researchers continued to study prions, and their findings supported Prusiner's hypothesis. In 1997, Prusiner was awarded the Nobel Prize in Physiology or Medicine for his discovery of prions—a new biological principle of infection.

Prusiner and others have shown that animals have a gene that encodes a normally harmless protein known as PrP. This protein, which consists of 208 amino acids, may help process copper. Normal forms of the protein are found on the surfaces of brain cells and many other types of cells. Sometimes, the PrP protein folds into a different shape, an insoluble form that can cause disease. This misfolded protein is the prion. Mutations in the gene that encodes the PrP protein increase the risk that the protein will misfold and become a prion. The prion then somehow induces other PrP molecules to misfold into the pathogenic form (Fig. 24-7). Prions apparently can aggregate and accumulate in the brain and in certain other tissues and cause serious damage.

Prions are found in the brains of patients with **transmissible spongiform encephalopathies (TSEs).** This group of fatal degenerative brain diseases, which have been identified in birds and mammals, are called TSEs because when infected, the brain appears to develop holes and becomes somewhat spongelike. The TSEs are in some ways like viral illnesses. However, there is a long latency period (about 5 years in cows and up to 10 years in humans) between contracting the infection and developing symptoms of the illness. Also, the TSEs have proven very difficult to treat. Genetically engineered mice that lack the prion protein gene are immune to TSE infection.

The oldest known prion disease is *scrapie* in sheep and goats. When infected, animals lose coordination, become irritable, and itch so severely that they scrape off their wool or hair. Bovine spongiform encephalopathy (BSE) is a related prion disease popularly referred to as "mad cow disease" because some diseased cattle become aggressive. BSE became epidemic in cattle in the United Kingdom in the 1990s.

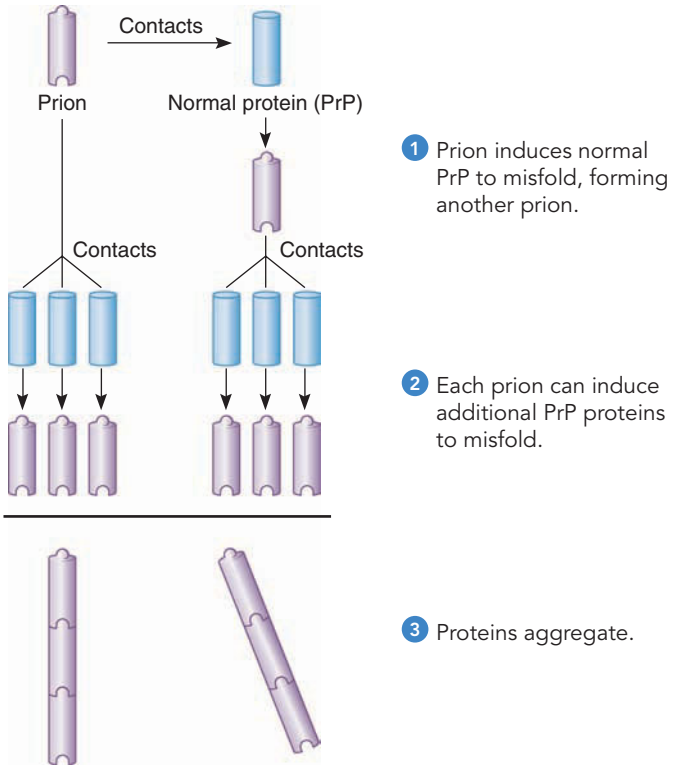

Figure 24-7 A model for how the prion population expands

Prions contact normal PrP proteins and induce them to misfold and become prions. Each new prion can then contact additional PrP molecules and induce them to misfold, thus expanding the prion population. Prions can form clumps by aggregating.

More than 150 people have died from a human variety of BSE, providing evidence that the disease is transmissible from cow to human. The human disease is called vCJD because it is a variant of CJD, which is caused by the transformation of PrP proteins into prions. The infectious agent of vCJD has been recovered from infected human neural tissue and appears similar to the prion that causes scrapie in sheep. New regulations have been instituted in several countries to safeguard the food supply. Human-to-human transmission of vCJD has been associated with tissue and organ transplants and transfusion with contaminated blood.

Chronic wasting disease, an illness related to mad cow disease, has spread among deer and elk populations in North America. Studies are under way to determine whether this disease can infect livestock or humans.

Like viruses, prions exhibit variability. Investigators now understand that there are different strains of prions. Strains may differ from one another in the conformation of their proteins, in their properties, and in the diseases they cause. Prions are different from viruses in that they can arise spontaneously, most likely as a result of mutation. Researchers are studying ways to block prions from forming. They are also looking for ways to stimulate cells to destroy prions. Early diagnosis is critical, and the search is on for a blood test that would detect prion disease.

Review

- How do viroids differ from prions?
- How do viroids and prions differ from viruses?

PROKARYOTES

Learning Objectives

7 Describe the structure and common shapes of prokaryotic cells.
8 Describe asexual reproduction in prokaryotes, and summarize three mechanisms (transformation, transduction, and conjugation) that may lead to genetic recombination.
9 Describe the modes of nutrition and metabolic adaptations of prokaryotes.

In contrast to viruses, viroids, and prions, which consist only of nucleic acid and/or protein, **prokaryotes** are cellular organisms. Recall from Chapters 4 and 23 that the cell structure of prokaryotes is fundamentally different from that of the eukaryotic cells of other living organisms. Microbiologists assign prokaryotes to two domains: **Archaea** and **Bacteria.**

Most prokaryotic cells are very small. Typically, their diameter ranges from 0.5 to 1.0 μm, and their length, from 1.0 to 5.0 μm. Their cell volume is only about one thousandth that of small eukaryotic cells, and their length is only about one tenth. Most prokaryotes are unicellular, but some form colonies or filaments containing specialized cells.

Prokaryotes have several common shapes

Prokaryotes have two basic shapes: spherical and rod shaped. Spherical prokaryotes, known as **cocci** (sing., *coccus*), occur singly in some species and in groups of independent cells in others (Fig. 24-8a). Cells may be grouped in twos (*diplococci*), in long chains (*streptococci*), or in irregular clumps that look like bunches of grapes (*staphylococci*). Rod-shaped prokaryotes, called **bacilli** (sing., *bacillus*), may occur as single rods or as long chains of rods (Fig. 24-8b). Some prokaryotes form spirals. If the spiral-shaped cell is flexible, it is a **spirochete;** if rigid, it is a **spirillum** (pl., *spirilla*) (Fig. 24-8c). A spirillum shaped like a comma is called a **vibrio.**

Prokaryotic cells lack membrane-enclosed organelles

Prokaryotic cells do not have membrane-enclosed organelles typical of eukaryotic cells. Thus, these cells do not have nuclei, mitochondria, chloroplasts, endoplasmic reticula, Golgi complexes, or lysosomes (Fig. 24-9). Although the prokaryotic cell does not have a membrane-enclosed nucleus, it does have a **nuclear area,** also referred to as the **nucleoid,** which contains DNA.

The dense cytoplasm of the prokaryotic cell contains ribosomes (smaller than those found in eukaryotic cells) and storage granules that hold glycogen, lipid, or phosphate compounds. Enzymes needed for metabolic activities may be located in the cytoplasm. Although the membranous organelles of eukaryotic cells are absent, in some prokaryotic cells the plasma membrane is extensively folded inward. Enzymes needed for cellular respiration and photosynthesis may be associated with the plasma membrane or its folds.

A cell wall typically covers the cell surface

Most prokaryotic cells have a **cell wall** surrounding the plasma membrane. The cell wall provides a rigid framework that sup-

Figure 24-8 Common shapes of prokaryotes

Key Point

In contrast to the organelles of eukaryotic cells, the organelles of prokaryotic cells are not enclosed by membranes.

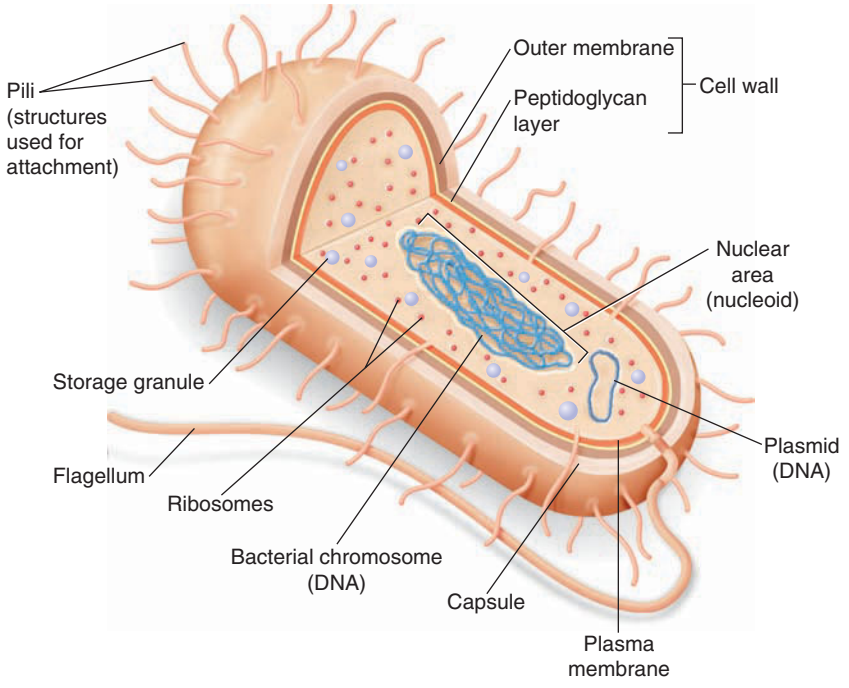

Figure 24-9 ***Animated*** Structure of a prokaryotic cell

This bacillus is a gram-negative bacterium (discussed in text). Note the absence of a nuclear envelope surrounding the bacterial DNA.

ports the cell, maintains its shape, and keeps it from bursting under hypotonic conditions (see Chapter 5). Most bacteria are adapted to hypotonic surroundings. When wall-less forms of bacteria are produced experimentally, they must be maintained in isotonic solutions to keep them from bursting. However, cell walls are of little help when a bacterium is in a hypertonic environment, as in food preserved by a high sugar or salt content. For this reason, most bacteria grow poorly in jellies, jams, salted fish, and other foods preserved in these ways.

The bacterial cell wall includes **peptidoglycan,** a complex polymer that consists of two unusual types of sugars (amino sugars) linked with short polypeptides. The sugars and polypeptides are linked to form a single macromolecule that surrounds the entire plasma membrane.

Differences in bacterial cell wall composition are of great interest to microbiologists and are important clinically. In 1888, the Danish physician Christian Gram developed the Gram staining procedure. Bacteria that absorb and retain crystal violet stain in the laboratory are referred to as **gram-positive,** whereas those that do not retain the stain when rinsed with alcohol are **gram-negative.** The cell walls of gram-positive bacteria are very thick and consist primarily of peptidoglycan. The cell walls of gram-negative bacteria have two layers: a thin peptidoglycan layer and a thick outer membrane. The outer membrane resembles the plasma membrane but contains polysaccharides bonded to lipids (▮ Fig. 24-10).

Distinguishing between gram-positive and gram-negative bacteria is important in treating certain diseases. For example, the antibiotic penicillin interferes with peptidoglycan synthesis, ultimately resulting in a fragile cell wall that cannot protect the cell (see Chapter 7 discussion of drugs that are enzyme inhibitors). Predictably, penicillin works most effectively against gram-positive bacteria.

Some species of bacteria produce a **capsule** or slime layer that surrounds the cell wall. In free-living species, the capsule may provide the cell with added protection against phagocytosis (engulfment; see Chapter 5) by other microorganisms. In disease-causing bacteria, the capsule may protect against phagocytosis by the host's white blood cells. For example, the ability of *Streptococcus pneumoniae* to cause bacterial pneumonia depends on its capsule. A strain of *S. pneumoniae* that lacks a capsule does not cause the disease. Bacteria also use their capsules to attach to surfaces such as rocks, plant roots, or human teeth (where they cause dental plaque).

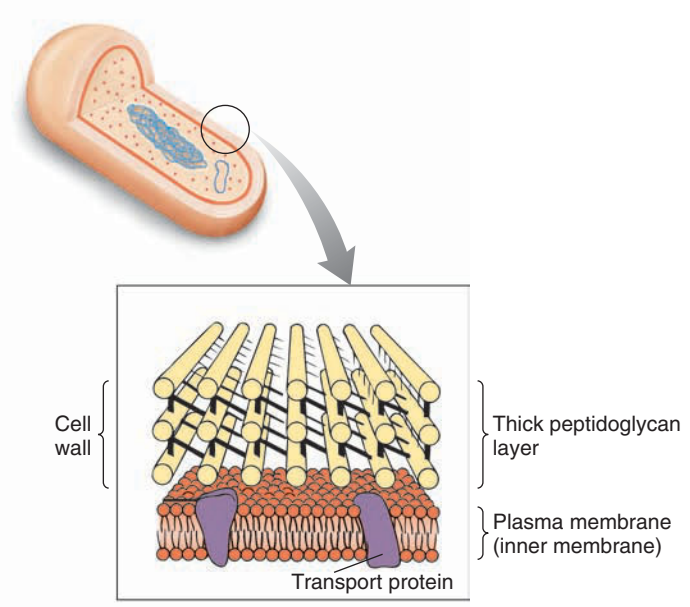
Some bacteria have hundreds of hairlike appendages known as **pili** (sing., *pilus*). These protein structures help bacteria adhere to one another or attach to certain surfaces, such as the cells they infect. Some elongated pili, called *sex pili,* are important in transmitting DNA between bacteria.

Many types of prokaryotes are motile

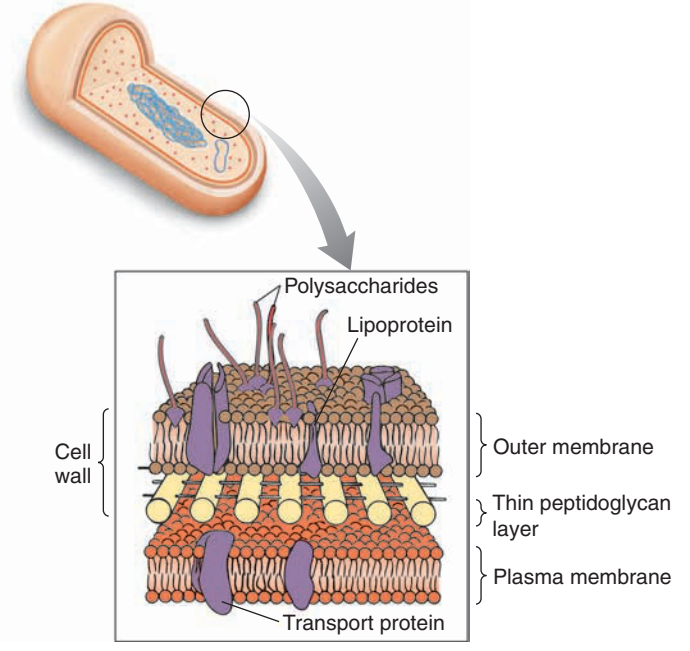
Can you imagine trying to swim through molasses? Water has the same relative viscosity to prokaryotes that molasses has to humans. Most motile prokaryotes manage to move by means of rotating **flagella.** The number and location of flagella are important in classifying some bacterial species.

Unlike eukaryotic flagella, prokaryotic flagella do not consist of microtubules (see Chapter 4). A bacterial flagellum consists of three parts: a basal body, a hook, and a single filament (▮ Fig. 24-11). The basal body is a complex structure that anchors the flagellum into the cell wall by disc-shaped plates. The curved hook connects the basal body to the long, hollow filament that extends into the outside environment. The basal body is a motor. The bacterium uses energy from ATP to pump protons out of the cell. Diffusion of these protons back into the cell powers the motor that spins the flagellum. The rotary motion produced pushes the cell much like a propeller pushes a ship through the water. The flagellum rotates counterclockwise, pushing the cell forward.

Many prokaryotes exhibit **chemotaxis,** movement in response to chemicals in the environment. For example, bacteria move toward food. Certain bacteria also move toward one another; however, bacteria move away from certain harmful chemicals.



(a) Gram-positive cell wall. A thick layer of peptidoglycan molecules is held together by amino acids.



(b) Gram-negative cell wall. A thin layer of peptidoglycan is covered by an outer membrane.

Figure 24-10 ***Animated*** Bacterial cell walls

Prokaryotes have a circular DNA molecule

The genetic material of a prokaryote lies in the nuclear area but is not surrounded by a nuclear envelope. In most species, the genetic material is contained in a single, circular DNA molecule. If stretched out to its full length, this molecule would be about 1000 times as long as the cell itself. Unlike eukaryotic chromosomes, prokaryote DNA has little protein associated with it.

In addition to their genomic DNA, most bacteria have a small amount of genetic information present as one or more **plasmids,** smaller circular fragments of DNA. Plasmids replicate independently of the genomic DNA (see Chapter 15) or become integrated into it. Bacterial plasmids often have genes that code for catabolic enzymes, for genetic exchange, or for resistance to antibiotics.

Most prokaryotes reproduce by binary fission

Prokaryotes are extremely successful organisms in terms of their numbers and distribution. Their success is in large part due to their remarkable ability to reproduce rapidly. Prokaryotes reproduce asexually, generally by **binary fission,** a process in which one cell divides into two similar cells, as in the chapter opening photograph (also see Fig. 10-11). First, the circular DNA replicates; and then an ingrowth of both the plasma membrane and the cell wall forms a transverse wall.

Binary fission occurs with remarkable speed. Under ideal conditions, some bacterial species divide in less than 20 minutes. At this rate, if nothing interfered, one bacterium could give rise to more than 1 billion bacteria within 10 hours! However, bacteria cannot reproduce at this rate for very long before lack of food or the accumulation of waste products slows their population expansion.

A less common form of asexual reproduction among bacteria is **budding.** In budding, a cell develops a bulge, or bud, that enlarges, matures, and eventually separates from the mother cell. A few species of bacteria (actinomycetes) divide by **fragmentation.** Walls develop within the cell, which then separates into several new cells.

Bacteria transfer genetic information

Although sexual reproduction involving the fusion of gametes does not occur in prokaryotes, genetic material can be exchanged among bacteria and among archaea. Such exchange of genes, or **gene transfer,** results in genetic recombination. **Horizontal gene transfer** occurs when an organism transfers genetic material to another organism that is not its offspring. (Transfer of genetic material from parent to offspring is called *vertical gene transfer.*) Gene transfer among bacteria takes place by three different mechanisms: transformation, transduction, and conjugation.

1. When bacteria die, they release DNA that can be taken in by certain other bacteria. In **transformation,** a bacterial cell takes up fragments of foreign DNA (or RNA) released by another bacterium. The DNA must bind to DNA-binding proteins on the surface of the bacterium. Once it enters the bacterial cell, some of the DNA is incorporated into the host's own genome by reciprocal recombination (the DNA is exchanged) between the new DNA and the host chromosome (Fig. 24-12). Recall from Chapter 12 that Oswald T. Avery and his colleagues identified DNA as the agent that transformed bacterial cells experimentally and showed that DNA is the chemical basis of heredity. Foreign DNA can also be taken up as plasmids. When this occurs, DNA does not

(b) Structure of a bacterial flagellum. The motor is the basal body, which consists of a series of disc-shaped plates that anchor the flagellum to the cell wall and plasma membrane and spin the hook and filament of the flagellum.

Figure 24-11 Bacterial flagella

undergo recombination; it remains as a plasmid separate from the bacterial chromosome.

2. In a different process of gene transfer, **transduction,** a phage carries bacterial genes from one bacterial cell into another (Fig. 24-13). Normally, a phage contains only its own DNA. However, sometimes a phage incorporates some of the bacterial DNA of its host. Then, when the phage infects another bacterium, it transfers that DNA to its new host.
3. In **conjugation,** two cells of different mating types come together, and genetic material is transferred from one to the other (Fig. 24-14). In contrast to transformation and transduction, conjugation involves contact between two cells.

Conjugation has been most extensively studied in the bacterium *E. coli.* In the *E. coli* population there are **donor cells,** or **F^+ cells,** that have DNA that can be transmitted to **recipient cells,** or **F^- cells.** F^+ cells have a DNA sequence known as the **F factor** (F stands for fertility) that is necessary for a bacterium to serve as a donor during conjugation. The F factor, which consists of about 20 genes, can be in the form of a plasmid or it can be part of the DNA in the bacterial chromosome.

F genes encode enzymes essential for transferring DNA. Certain F genes encode **sex pili,** long, hairlike extensions that project from the cell surface. The sex pilus recognizes and binds to the surface of an F^- cell, forming a cytoplasmic conjugation bridge between the two cells. The F plasmid replicates itself, and DNA is transferred from donor to recipient bacterium through the conjugation bridge. F plasmids may also have other types of genes, including those that determine resistance to antibiotics.

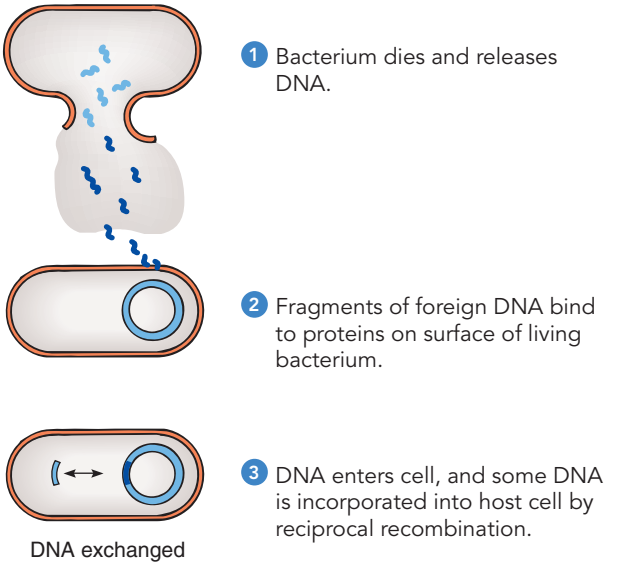

Figure 24-12 Transformation

In this process, foreign DNA from a bacterium that has died enters a host bacterium. DNA is exchanged by recombination.

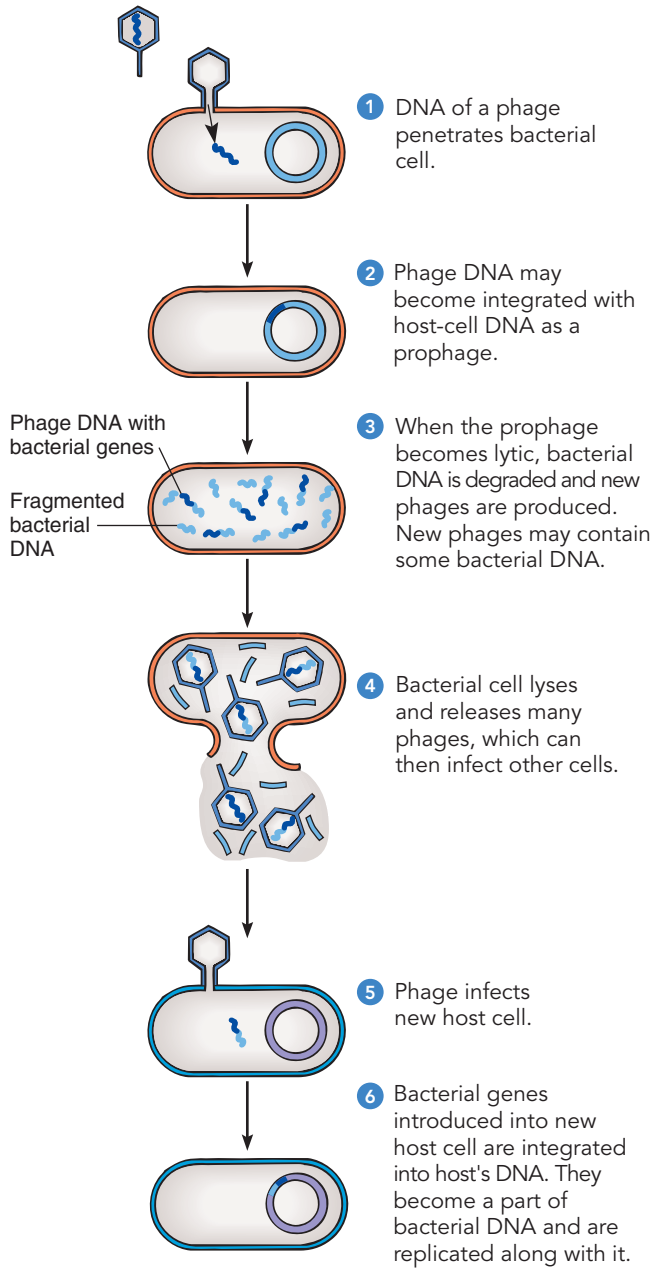

Figure 24-13 Transduction

In transduction, a phage transfers bacterial DNA from one bacterium to another. Transduction is an important means of gene transfer.

Evolution proceeds rapidly in bacterial populations

Bacteria reproduce rapidly by binary fission, so mutations are quickly passed on to new generations, and the effects of natural selection are quickly evident. Bacteria that have some advantage rapidly pass the genes that facilitate their survival to future generations.

Horizontal gene transfer greatly contributes to the rapid evolution that takes place in prokaryotes. Acquisition of new DNA and genetic recombination are important sources for diversification and adaptation. New DNA introduced into a bacterium's genome represents new raw material for evolution. New genes are subject to mutation and are acted on by the forces of natural selection. The changes in the genetic material are passed on to succeeding generations by binary fission. Changes that result in adaptation can quickly spread through future bacterial populations. Recent studies provide evidence that genetic recombination is also an important mechanism in the evolution of archaea.

Some bacteria form endospores

When the environment becomes unfavorable, for example, when nutrients are limited or the environment becomes very dry, some types of bacteria become dormant. The cell loses water, shrinks slightly, and remains inactive until water is again available. Certain bacteria form dormant, extremely durable cells called **endospores.** After the endospore forms, the cell wall of the original cell lyses, releasing the endospore. Formation of endospores is not a type of reproduction in bacteria; endospores are not comparable to the reproductive spores of fungi and plants. Only one endospore is formed per original cell, so the total number of individuals does not increase. Archaea do not form endospores; these prokaryotes produce unique enzymes on the cell surface that protect them from cold, heat, and desiccation.

Endospores survive in very dry, hot, or frozen environments or at times when food is scarce (Fig. 24-15). Some endospores are so resistant that they can survive an hour or more of boiling or centuries of freezing. When environmental conditions are again suitable for growth, the endospore germinates, forming an active, growing bacterial cell.

Several types of bacteria that form endospores cause disease. The endospore of *Bacillus anthracis,* the bacterium that causes anthrax, is so hardy that this pathogen has become a concern as an agent of biological warfare. The bacteria (*Clostridium tetani*) that cause tetanus and the bacteria (*C. perfringens*) that cause gas gangrene typically enter the body with soil when a person suffers a deep cut or puncture wound. Patients may also be exposed to these serious diseases when surgical instruments are not effectively sterilized, which results in survival of endospores.

Many bacteria form biofilms

Many types of bacteria that inhabit watery environments form dense films called **biofilms** that attach to solid surfaces. The bacteria in a biofilm form layers up to 200 μm thick. The bacteria secrete a slimy, gluelike substance rich in polysaccharides and become embedded in this matrix. Most biofilms consist of many species of bacteria and may include other types of organisms, such as fungi and protozoa. Scientists have found evidence of ancient biofilms in sediments from coastal marine environments 3.5 billion years old.

The dental plaque that forms on teeth is a familiar example of a biofilm. These films also commonly form on the surfaces of contact lenses and catheters. They sometimes develop on surgical implants such as pacemakers and joint replacements.

Metabolic diversity has evolved among prokaryotes

Based on the two main ways of obtaining nutrition, prokaryotes are classified as heterotrophs or autotrophs (*-troph* comes from a Greek word that means "nutrition"). Most prokaryotes are **heterotrophs** that obtain carbon atoms from the organic compounds of other organisms. Some bacteria are **autotrophs** that are able to use carbon dioxide as a source of carbon for manufacturing their organic molecules.

Based on two principal ways of capturing energy, prokaryotes are classified as chemotrophs and phototrophs. **Chemotrophs** obtain their energy from chemical compounds. **Phototrophs** capture energy from light. When we consider the source of carbon *and* the source of energy, we can classify prokaryotes into four main groups:

1. The majority of prokaryotes are **chemoheterotrophs.** They depend on organic molecules for both their carbon and energy. Many bacterial chemoheterotrophs are free-living decomposers that obtain their carbon and energy from dead organic matter. These bacteria are sometimes called *saprotrophs.* Some chemoheterotrophs are pathogens, which obtain their nourishment from the organisms they infect. They harm their hosts by causing diseases. Other heterotrophic bacteria benefit their hosts, for example, by producing needed vitamins.
2. **Photoheterotrophs,** like the purple nonsulfur bacteria, obtain their carbon from other organisms but use chlorophyll and other photosynthetic pigments to trap energy from sunlight.
3. **Photoautotrophs,** like the cyanobacteria, use the energy from sunlight to synthesize organic compounds from carbon dioxide and other inorganic compounds.
4. **Chemoautotrophs** also use carbon dioxide as a carbon source, but they do not use sunlight as their energy source. Instead, they obtain energy by oxidizing inorganic chemical substances such as ammonia (NH_3) and hydrogen sulfide (H_2S).

Most prokaryotes require oxygen

Whether they are heterotrophs or autotrophs, most bacterial cells are **aerobic** and require oxygen for cellular respiration. Many are **facultative anaerobes** that use oxygen for cellular respiration if it is available but can carry on metabolism anaerobically when necessary. Other bacteria are **obligate anaerobes** that carry out anaerobic respiration; they respire with terminal electron acceptors other than oxygen, for example, sulfate (SO_4^{2-}), nitrate (NO_3^-), or iron (F^{2+}). Some

obligate anaerobes, including certain archaea, are actually killed by even low concentrations of oxygen.

Review

- In what ways do prokaryotic cells differ from eukaryotic cells?
- How do prokaryotes reproduce? What mechanisms result in gene transfer?
- How do facultative anaerobes differ from obligate anaerobes? How do they differ from aerobes?

THE TWO PROKARYOTE DOMAINS

Learning Objectives

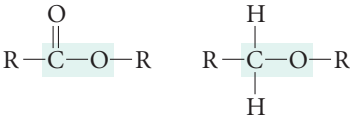
10 Compare the three domains: Archaea, Bacteria, and Eukarya.

11 Distinguish among the main groups of archaea based on their ecology, identify the archaean phyla (see Table 24-3), and describe the main groups of bacteria (see Table 24-4).

Under a microscope, most prokaryotes appear rather similar in size and form. However, using sequence analysis of small subunit 16S ribosomal RNA (SSU rRNA), Carl Woese and his coworkers demonstrated that there are two fundamentally different groups of prokaryotes (see Chapter 23). Each group has **signature sequences,** regions of SSU rRNA that have unique nucleotide sequences. The reason is that after they diverged, prokaryote populations diversified and mutations occurred that affect RNA sequences. Based on such analyses, Woese hypothesized that ancient prokaryotes split into two lineages early in the history of life.

Based on Woese's work, microbiologists now classify the modern descendants of these two ancient lines in two domains: Archaea and Bacteria (Fig. 24-16). Domain **Archaea,** which corresponds to kingdom Archaea, includes a group of prokaryotes that produce methane gas from simple carbon sources and two groups that live in extreme environments. Domain **Bacteria,** which corresponds to kingdom Bacteria, includes all other prokaryotes. In this system, all eukaryotes are classified in domain **Eukarya.**

Several key characteristics distinguish archaea from bacteria. In contrast to bacteria, archaea do not have peptidoglycan in their cell walls. Although their plasma membranes are structurally similar, they are chemically unique. In the plasma membranes of bacteria and eukaryotes, straight-chain fatty acids are linked to glycerol molecules by *ester linkages.* In contrast, fatty acid components are not found in archaea. Instead, branched-chain hydrocarbons (synthesized from isoprene units) are bonded to glycerol by *ether linkages* (Table 24-2).



Ester linkage **Ether linkage**

The absence of a second electronegative oxygen atom makes ether linkages stronger than ester linkages. This unique membrane structure may contribute to the ability of the archaea to survive and thrive in harsh environments.

In some ways, archaea are more like eukaryotes than like bacteria. For example, archaea do not have the simple RNA polymerase found in bacteria. Like eukaryotes, their translation process begins with methionine, whereas in bacteria, translation begins with formylmethionine (see Chapter 13). In addition, several antibiotics that affect bacteria do not affect archaea or eukaryotes.

Prokaryote taxonomy is now based largely on RNA sequencing. Groups that branched off earlier had more time to accumulate mutations in their SSU rRNA. Their nucleotide sequences are less similar than those of groups that diverged more recently. However, some microbiologists are developing phylogenetic trees based on entire genomes. They argue that there may be 1000 genes that code proteins for every 1 gene that codes an rRNA. These researchers prefer to consider the proportions of genes (or proteins) that genomes of various groups have in common.

Although prokaryotic taxonomy is controversial and continuously changing, more than 1220 genera and 6000 species of prokaryotes have been classified. The editors of *Bergey's Manual of Systematic Bacteriology,* considered the definitive reference text by microbiologists, have divided prokaryotes into more than 25 phyla based on 16S rRNA analysis.[1]

[1] *Bergey's Manual of Systematic Bacteriology,* 2nd ed., Springer, New York, 2001, 2005; the first two of five volumes of the second edition have now been published.

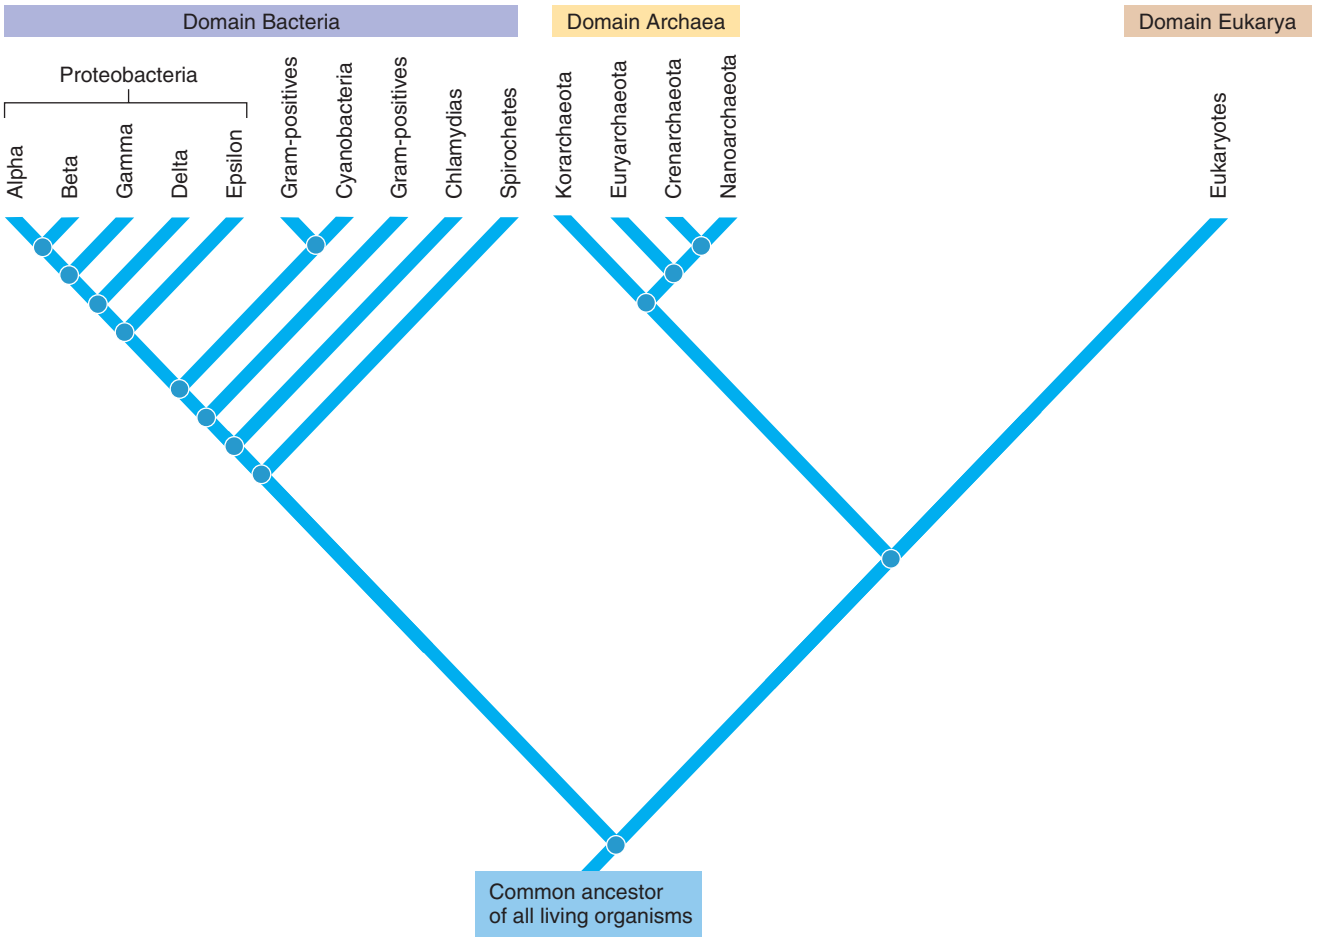


Figure 24-16 Three domains

This highly simplified diagram depicts some representative taxa of domain Bacteria and domain Archaea. The relationships are based on analyses of nucleotide sequences of small subunit rRNA. As taxonomists consider additional data, these relationships will be modified.

Note that because biologists cannot extract rRNA from fossils, no extinct species are shown in this phylogenetic tree. Thus, this tree does not show evolutionary lineages.

Some archaea survive in harsh environments

Many members of domain Archaea inhabit environments thought to be similar to conditions on early Earth. We can identify three main types of archaea based on their metabolism and ecology: methanogens, extreme halophiles, and extreme thermophiles.

The **methanogens** (methane producers) are a large, diverse group that inhabit oxygen-free environments in sewage and swamps and are common in the digestive tracts of humans and other animals. They are obligate anaerobes that produce methane gas from simple carbon compounds. The methanogens are important in recycling components of organic products of organisms that inhabit swamps. Methanogens that inhabit the digestive tracts of cows and other grazing animals produce methane, which is belched out by the animals. Methanogens produce more than 80% of the methane (more than 2 billion tons each year) in Earth's atmosphere.

Extreme halophiles are heterotrophs that live in saturated brine solutions such as salt ponds, the Dead Sea, and Great Salt Lake (Fig. 24-17). The extreme halophiles use aerobic respiration to make ATP. However, they also carry out a form of photosynthesis in which they capture the energy of sunlight using a purple pigment (*bacteriorhodopsin*). (This pigment is very similar to the pigment rhodopsin involved in animal vision.)

Extreme thermophiles require a very high temperature for growth and normally inhabit hot (45°C to 110°C), sometimes acidic, environments. One species is found in the hot sulfur springs of Yellowstone Park at temperatures near 60°C and pH values of 1 to 2 (the pH of concentrated sulfuric acid). Others inhabit volcanic areas under the sea. One species, found in hot deep-sea vents on the seafloor, lives at temperatures ranging from 80°C to 110°C.

Archaea also inhabit less extreme conditions. For example, nonextreme archaea are abundant in the soil and in the cold ocean surface waters near Antarctica. Microbiologists have sug-

TABLE 24-2

Comparison of the Three Domains

Characteristic	Bacteria	Archaea	Eukarya
Nuclear envelope	Absent	Absent	Present
Membrane-enclosed organelles	Absent	Absent	Present
Circular chromosome	Present (linear in some species)	Present	Absent
Number of chromosomes	Typically one (may also have plasmid)	Typically one (may also have plasmid)	Typically many
Histones associated with DNA	Absent	Present	Present
Peptidoglycan in cell wall	Present	Absent	Absent
Structure of lipids in plasma membrane	Straight-chain fatty acids bonded to glycerol by ester linkages	Branched-chain hydrocarbons linked to glycerol by ether linkages	Straight-chain fatty acids bonded to glycerol by ester linkages
Size of ribosomes	70S*	70S	80S except in mitochondria and chloroplasts
RNA polymerase	One relatively simple RNA polymerase	Several relatively complex RNA polymerases	Several relatively complex RNA polymerases
Translation	Begins with formylmethionine	Begins with methionine	Begins with methionine

*The numbers 70S and 80S refer to the sedimentation coefficient (a measure of relative size) when centrifuged.

gested that the archaea may be important in biogeochemical cycles and in marine food chains. No pathogenic archaea have been identified.

Bergey's Manual divides Archaea into four phyla: Crenarchaeota, Euryarchaeota, Korarchaeota, and Nanoarchaeota. The archaean phyla are summarized in Table 24-3.

Bacteria are the most familiar prokaryotes

The bacteria are widely distributed in the environment and are better known to microbiologists than are the archaea. *Bergey's Manual* divides the bacteria into more than 20 phyla. Major groups of bacteria include the gram-negative proteobacteria, cyanobacteria, gram-positive bacteria, chlamydias, and spirochetes. These groups are summarized in Table 24-4.

Review

- What are three main types of archaea, based on their ecology?
- How do these bacteria differ (listed in Table 24-4): (1) proteobacteria, (2) cyanobacteria, and (3) chlamydias?

IMPACT OF PROKARYOTES

Learning Objective

12 Discuss the ecological roles of prokaryotes, their importance as pathogens, and their commercial importance.

Prokaryotes are vital members of the biosphere. They interact with other organisms in many ways. An intimate relationship between members of two or more species is called **symbiosis.** The partners in a symbiotic relationship are called **symbionts.** Symbiotic relationships arise by coevolution. Three forms of symbiosis are mutualism, commensalism, and parasitism.

Mutualism is a symbiotic relationship in which both partners benefit. Cows and other ruminants (cud-chewing animals) have mutualistic relationships with bacteria that inhabit their digestive tracts. Ruminants lack enzymes for digesting cellulose, so they provide the bacteria with a nutrient-rich home and the bacteria digest the cellulose for them.

TABLE 24-3

Three Groups of Archaea*

Crenarchaeota

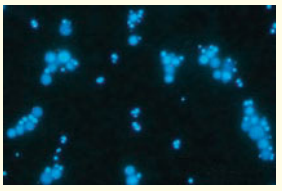
TEM of a methanogen (*Methanospirillum hungatii*) undergoing cell division
Two other archaea are visible in cross section. When not dividing, these archaea are spiral shaped.

Includes methanogens, halophiles (not all extreme), and acidophiles. Some extreme thermophiles included in this phylum.

Nanoarchaeota



Courtesy K. O. Stetter, University of Regensburg, Germany

Fluorescence LM of *Nanoarchaeum equitans*
Nanoarchaeum equitans (tiny cells) attached to its archaean host *Ignicoccus spec* (big cells).

Nanoarchaeum equitans, the first-described member of this group, is a very small (400 nm), anaerobic, extreme thermophile. Symbiotic with another archaean. As of 2005, *Nanoarchaeum* was the smallest known organism.

*Members of a fourth group, Korarchaeota, have been discovered in hot springs in the ocean floor and on land. The Korarchaeota may be the oldest group of archaeans.

Some investigators estimate that up to 100 trillion bacteria inhabit the nutrient-rich human intestine. Many of these are mutualistic bacteria. For example, in exchange for nutrients and a place to live, *Bacteroides thetaiotaomicron* break down indigestible complex carbohydrates into sugars that their human host can absorb. They produce certain vitamins that the host absorbs and uses. These bacteria also promote proliferation of blood vessels that improve intestinal function. Investigators have reported that *B. thetaiotaomicron* can turn on specific genes in cells of the host's intestine; apparently, these bacteria can induce synthesis of a compound that may kill competing bacteria.

In **commensalism,** one partner benefits and the other is neither harmed nor helped. Many bacteria that inhabit the human intestine are commensals that live on unused food. In **parasitism,** one partner lives on or in the other. The **parasite** benefits and the **host** is harmed. Pathogenic bacteria are parasites.

Bacteria, especially actinomycetes and myxobacteria, are the most numerous inhabitants of soil. As described in the chapter introduction, prokaryotes are essential decomposers, chemoheterotrophs that break down dead organic matter and wastes. They use the products of decomposition as an energy source. When prokaryotes break down organic compounds, many of their components, including nitrogen, oxygen, carbon, phosphorus, sulfur, and certain trace elements, are recycled. (The roles of bacteria in biogeochemical cycles, particularly the nitrogen cycle, are discussed in Chapter 54.)

Nitrogen is constantly removed from the soil by plants and other natural processes, as well as by human activities, such as agriculture. Plant growth depends on the availability of usable nitrogen, so it must be continually added to the soil. Several types of bacteria, including cyanobacteria, transform atmospheric nitrogen to forms that can be used by plants (Fig. 24-18).

TABLE 24-4

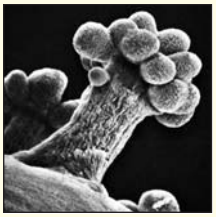
Major Groups of Bacteria

Proteobacteria (Gram-negative)

David Scharf/Peter Arnold, Inc.

10 μm

SEM of *Escherichia coli* colony



(From P. L. Grilicone and J. Pangborn, *Journal of Bacteriology* 124:1558, 1975.)

10 μm

SEM of fruiting body of the myxobacterium *Stigmatella aurantiaca*
Protective resting cells within the fruiting bodies are very resistant to heat and drying.

A large, very diverse group of gram-negative bacteria. Based on rRNA sequences, the group is divided into five subgroups designated as alpha, beta, gamma, delta, and epsilon.

Alpha Proteobacteria
Includes many symbionts of plants and animals, and some pathogens. ***Rhizobium*** species live symbiotically in root nodules of legumes (e.g., beans) and convert atmospheric nitrogen to a form usable by plants (nitrogen fixation). **Rickettsias** are very small, rod-shaped bacteria. A few species are pathogenic to humans and other animals; transmitted by arthropods through bites or through contact with their excretions. Among these are typhus (transmitted by fleas and lice) and Rocky Mountain spotted fever (transmitted by ticks).

Beta Proteobacteria
Several diverse groups, including *Nitrosomonas,* which oxidizes ammonia. Pathogenic bacteria in this group include *Neisseria gonorrhoeae,* which causes gonorrhea.

Gamma Proteobacteria
Includes the **enterobacteria,** decomposers that live on decaying plant matter, pathogens, and a variety of bacteria that inhabit humans. Although *Escherichia coli* is a normal inhabitant of the animal intestinal tract, certain strains can cause moderate to severe diarrhea. One species of *Salmonella* infects food and produces a toxin that causes a form of food poisoning; another species causes typhoid fever.

Vibrios are mainly marine; some are bioluminescent. *Vibrio cholerae* causes cholera.

Pseudomonads are heterotrophs that produce nonphotosynthetic pigments; cause disease in plants and animals, including humans.

Purple sulfur bacteria are photoautotrophs that do not produce oxygen.

Delta Proteobacteria
Includes the **myxobacteria** (slime bacteria), which secrete slime and glide or creep along. When nutrients are exhausted, these bacteria aggregate into stalked, multicellular reproductive structures called fruiting bodies. Bacterial cells within the fruiting body enter a resting stage. When conditions are favorable, resting cells become active.

Epsilon Proteobacteria
A small group of bacteria that inhabit the animal digestive tract. *Helicobacter* can cause peptic ulcers.

Cyanobacteria (Gram-negative)

Gram-negative; photosynthetic. Inhabit ponds, lakes, swimming pools, moist soil, dead logs, tree bark. Contain chlorophyll *a* and use a photosynthetic process similar to that of plants and algae. Many species also fix nitrogen.

Gram-positive Bacteria

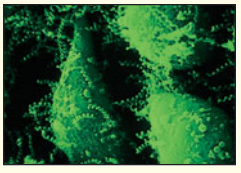
5 μm

SEM of *Actinomycetes naeslundi,* a soil-dwelling bacterium that forms filamentous colonies



© David M. Phillips/ Visuals Unlimited

5 μm

SEM of *Mycoplasma* on fibroblast cells

An extremely diverse group. A few examples follow.

Actinomycetes superficially resemble fungi. However, they have peptidoglycan in their cell walls, lack nuclear envelopes, and have other prokaryotic characteristics. Most actinomycetes are saprotrophs that decompose organic materials in soil. Some are anaerobic. Several species of the genus *Streptomyces* produce antibiotics such as streptomycin, erythromycin, chloramphenicol, and the tetracyclines. Some actinomycetes cause serious lung disease or generalized infections in humans and other animals.

Lactic acid bacteria ferment sugar, producing lactic acid as the main end product. Inhabit decomposing plant material, milk, and other dairy products; responsible for the characteristic taste of yogurt, pickles, sauerkraut, and green olives. Among the normal inhabitants of the human mouth and vagina.

Mycobacteria are slender, irregular rods; contain a waxy substance in their cell walls. One species causes tuberculosis; another causes leprosy.

Streptococci inhabit the mouth and digestive tract of humans and some other animals. Among the harmful species are those that cause "strep throat," dental caries, a form of pneumonia, scarlet fever, and rheumatic fever.

Staphylococci normally live in nose and on skin. Opportunistic pathogens that cause disease when the immunity of the host is lowered. *Staphylococcus aureus* causes boils and skin infections (some extremely serious); may infect wounds. Certain strains of *S. aureus* cause a form of food poisoning; other strains cause toxic shock syndrome.

Clostridia are anaerobic. One species causes tetanus; another causes gas gangrene. *Clostridium botulinum* can cause botulism, an often fatal type of food poisoning.

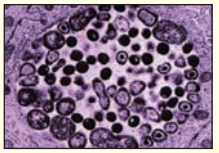
The **mycoplasmas** are a group of bacteria that lack cell walls. They may have evolved from bacteria with gram-positive cell walls. They inhabit soil and sewage; some are parasitic on plants or animals. Some inhabit human mucous membranes but do not generally cause disease; one species causes a mild type of bacterial pneumonia in humans.

continues

TABLE 24-4

Continued

Chlamydias (Gram-negative)



TEM of *Chlamydia trachomatis* in human oviduct cell

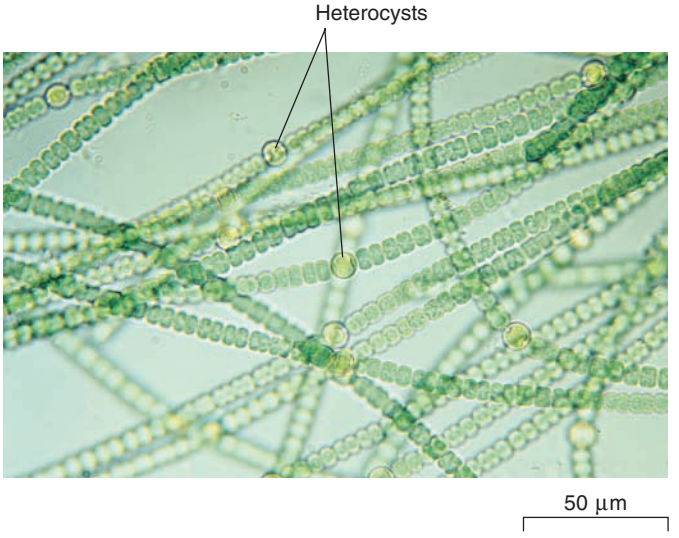
Chlamydias lack peptidoglycan in their cell walls. They are energy parasites, completely dependent on their hosts for ATP. Infect almost every species of bird and mammal. A strain of *Chlamydia* causes trachoma, the leading cause of blindness in the world. Sexually transmitted chlamydias are the major cause of pelvic inflammatory disease in women.

Spirochetes (Gram-negative)

LM of *Treponema pallidum*, the spirochete that causes syphilis

Spirochetes are spiral-shaped bacteria with flexible cell walls; move by means of unique internal flagella called *axial filaments*. Some species are free-living, whereas others form symbiotic associations; a few are parasitic. The spirochete of greatest medical importance is *Treponema pallidum*, which causes syphilis. Lyme disease, a tick-borne disease of humans and some other animals, is caused by a spirochete belonging to genus *Borrelia*.

Rhizobial bacteria, a type of motile bacteria that inhabit the soil, form mutualistic relationships with the roots of legumes, a large family of plants that includes important crops such as beans, peas, and peanuts. The infected plant cells form tumorlike nodules in which the bacteria reside and fix nitrogen (see Fig. 54-9). The bacteria supply the plant with all the nitrogen it requires, and the plant provides the bacteria with organic compounds, including sugar needed for cellular respiration. Because many soils are deficient in nitrogen, legumes that have formed mutualistic associations with rhizobial bacteria have a decided advantage over other plants. When the legumes die and are decomposed, the fixed nitrogen is released into and enriches the soil.



Dennis Drenner

Figure 24-18 LM of *Anabaena*, a filamentous cyanobacterium that fixes nitrogen

Nitrogen fixation takes place in the rounded cells, called *heterocysts*.

Many prokaryotes, such as the cyanobacteria, carry out photosynthesis, using water as the electron source and generating oxygen. During this process, they fix huge amounts of carbon dioxide into organic molecules.

Microbiologists are only beginning to unravel the mysteries of prokaryote ecology. For example, proteobacteria in the SAR11 clade are among the most successful organisms on Earth. Although they are one of the most abundant organisms in the Atlantic Ocean, they were not successfully cultured until 2002, and very little is known about their ecological role. There is some evidence that they are important in cycling carbon, nitrogen, and sulfur in the ocean.

Some types of bacteria appear to influence the course of evolution of other species. The proteobacteria *Wolbachia* infect many invertebrates, including insects, spiders, crustaceans, and nematodes (roundworms). *Wolbachia* are transmitted from generation to generation in the eggs of their hosts, so male hosts are not useful to them. Consequently, these parasites limit or eradicate males from the population. In some insect species, infected males can reproduce only when they mate with infected females carrying the same *Wolbachia* strain. In other species, these parasites convert male insects into females. Some infected females reproduce parthenogenetically (that is, their eggs develop without fertilization). Because they affect reproduction in their hosts, *Wolbachia* and other reproductive parasites may influence evolutionary divergence and even extinction in some species.

Some prokaryotes cause disease

Some prokaryote species have coevolved with eukaryotes and are interdependent with them. All plants and animals harbor a popu-

TABLE 24-5

Important Bacterial Diseases and Their Causative Agents

Disease	Pathogen	Epidemiology/Comments
Anthrax	*Bacillus anthracis*	Most commonly occurs in domestic animals such as cattle. Can be transmitted to humans from infected animals or animal products. Endospores can live in soil for many years. Anthrax is not spread from person to person. Infection can occur in three forms: cutaneous, by inhalation, and gastrointestinal.
Botulism	*Clostridium botulinum*	Contracted by eating foods that contain the endotoxin or from infected wound. Infant botulism is caused by ingesting endospores. Causes muscle paralysis and can cause death from respiratory failure.
Chlamydia	*Chlamydia trachomatis*	One of the most frequently reported sexually transmitted disease in the U.S. About 75% of infected women and 50% of infected men have no symptoms. If untreated, the infection spreads and damages reproductive organs; can lead to infertility. This pathogen can also infect eyes and causes millions of cases of blindness worldwide each year.
Cholera	*Vibrio cholerae*	Contracted by eating food or drinking water contaminated with the bacterium. Common in areas with inadequate sewage treatment and impure water. Infects intestine and can cause severe diarrhea. Rapid fluid loss can lead to dehydration and death.
Diphtheria	*Corynebacterium diphtheriae*	Transmitted from person to person by intimate respiratory and physical contact. Endemic in developing countries. Not common in U.S. since vaccine became available in 1920s. Infects the heart muscle and respiratory passageways.
Epidemic typhus	*Rickettsia prowazekii*	Transmitted by infected body lice. After an 8- to 12-day incubation period, symptoms include fever, severe headache, muscle aches, and chills. Several days later a rash appears. About 40% of untreated patients die.
Gonorrhea	*Neisseria gonorrhoeae*	Common sexually transmitted disease.
Hansen disease (leprosy)	*Mycobacterium leprae*	Thought to be spread from person to person in nasal secretions. Worldwide, this disease has disabled up to 2 million people. Typically affects the skin, nerves, and mucous membranes.
Lyme disease	*Borrelia burgdoferi*	Transmitted to humans by bite of infected blacklegged ticks. Symptoms include skin rash, headache, fever, and fatigue. If untreated, infection can spread to joints, heart, and nervous system.
Peptic ulcer disease	*Helicobacter pylori*	Causes peptic ulcer, a lesion in the lining of the stomach or duodenum (upper part of small intestine).
Pertussis (whooping cough)	*Bordetella pertussis*	Highly communicable from person to person. Causes spasms of severe coughing. Vaccination available.
Plague	*Yersinia pestis*	Transmitted from wild rodents, squirrels, and cats to people by infected fleas. If untreated, can cause death. Killed millions of people in Europe during the Middle Ages.
Pneumonia	*Streptococcus pneumoniae*	Transmitted from person to person. Strains of *S. pneumoniae* are resistant to one or more antibiotics commonly used to treat this infection. Incidence has decreased since introduction of a vaccine.
Salmonella (salmonellosis)	*Salmonella* sp.	Transmitted to people in contaminated chicken, eggs, or other food. Also transmitted from feces of infected animals, e.g., lizards, turtles, chicks, birds, even dogs and cats. Symptoms include fever, diarrhea, and stomach pain.
Tetanus	*Clostridium tetani*	Bacteria enter the body through a wound in the skin. Affects the nervous system; causes lockjaw, stiffness in neck, difficulty swallowing, fever, and muscle spasms. Vaccination available.
Travelers' diarrhea	Enterotoxigenic *Escherichia coli* is most common cause	Ingested in contaminated food and water. From 30% to 50% of travelers to high-risk areas (Central and South America, Africa, Middle East, and most of Asia) develop travelers' diarrhea.
Syphilis	*Treponema pallidum*	Sexually transmitted disease passed through direct contact with a syphilis sore. If untreated, eventually damages brain, liver, bone, and spleen and can cause death.
Tuberculosis	*Mycobacterium tuberculosis*	Transmitted from person to person through inhalation of air containing the pathogen. Symptoms include fatigue, cough, fever, weight loss. Not common in U.S. However, multidrug-resistant form is a growing threat.
Typhoid fever	*Salmonella typhi*	Transmitted from person to person in food or water contaminated with feces. Risk greatest for travelers in developing countries, but vaccine available. Symptoms include high fever, headache, and loss of appetite. Can cause death if not treated.

lation of microorganisms that are considered normal **microbiota** (also called microflora)—harmless symbiotic prokaryotes. In fact, the number of bacteria that normally inhabit the human body (approximately 700 trillion cells) exceeds the number of the body's human cells (about 70 trillion cells). The presence of certain bacterial populations prevents harmful microorganisms (including other bacteria) from flourishing.

A small percentage of bacterial species are important pathogens of plants and animals. Some of the normal bacterial (and viral) inhabitants are opportunistic pathogens that cause disease only under certain conditions. For example, when the immune system is compromised, opportunistic bacteria increase in number and cause disease. Some important bacterial diseases and the pathogens that cause them are listed in Table 24-5.

Many scientists have contributed to our understanding of infectious disease

The idea that some unknown agent causes disease was debated long before Leeuwenhoek discovered microorganisms with his microscope in the late 1600s. However, not until much later did scientists develop the tools or the methods needed to accurately understand the relationships between bacteria and disease. During the late 19th century several physicians, microbiologists, and chemists working independently laid the foundations for the science of microbiology. French chemist Louis Pasteur disproved the prevailing views of spontaneous generation by demonstrating that sterilization of a sugar and protein culture prevented bacterial growth. Pasteur also developed a rabies vaccine, showing that people can be stimulated to develop immunity to disease.

The German physician Robert Koch was the first to clearly demonstrate that bacteria cause infectious disease. In 1876, he showed that *Bacillus anthracis* causes anthrax. Using a microscope, Koch observed the bacteria in the blood and spleens of dead sheep. When he inoculated mice with the infected sheep blood, he was able to identify *B. anthracis* in the blood of the mice. He also cultured *B. anthracis* and showed that when he injected the bacteria into healthy mice, they developed anthrax.

Koch proposed a set of guidelines, now known as **Koch's postulates,** that are still used to demonstrate that a specific pathogen causes specific disease symptoms: (1) the pathogen must be present in every individual with the disease, (2) a sample of the microorganism taken from the diseased host can be grown in pure culture, (3) a sample of the pure culture causes the same disease when injected into a healthy host, and (4) the microorganism can be recovered from the experimentally infected host.

Many adaptations contribute to pathogen success

Pathogenic microorganisms can enter the body in food, dust, or droplets or through wounds. Many diseases are transmitted by insect or animal bites. To cause disease, a pathogen must adhere to a specific cell type, multiply, and produce toxic substances. Adherence and multiplication occur only when the pathogen competes successfully with the normal microbiota and counteracts the host's defenses against invasion.

Helicobacter pylori, the most common cause of peptic ulcers (ulcers of the stomach and duodenum), is an extremely successful pathogen (Fig. 24-19). It is also associated with chronic gastritis (stomach inflammation) and with stomach cancer (the second most common type of cancer in the world). *Helicobacter pylori* inhabits the intestinal tracts of an estimated 40% of adults in developed countries and 80% of adults in developing countries. Among its many adaptations is its ability to produce an alkaline shield around itself that protects it from stomach acid. Also contributing to its success are several powerful flagella used to propel the pathogen through the thick mucus lining the stomach.

Pathogens produce a variety of substances that increase their success. Some bacteria produce **exotoxins,** strong poisons that are either secreted from the cell or leak out when the bacterial cell is destroyed. The toxin, not the presence of the bacteria themselves, is responsible for the disease. As mentioned previously, diphtheria is caused by a gram-positive bacillus (*Corynebacterium diphtheriae*) that produces a toxin only when lysogenized by a phage. The diphtheria toxin kills cells and causes inflammation.

Chris Bjornberg/Photo Researchers, Inc.

(b) An ulcer caused by *Helicobacter pylori.*

Figure 24-19 *Helicobacter pylori,* the bacteria that cause peptic ulcers

Botulism, a type of food poisoning that can lead to paralysis and sometimes death, results from eating improperly canned food. Botulism is caused by an exotoxin released by the gram-positive, endospore-forming *Clostridium botulinum.* During the canning process, food must be heated sufficiently to kill any highly heat-resistant endospores that may be present. If not, the endospores can germinate. The resulting bacterial population grows and releases an exotoxin so powerful that 1 g could kill a million humans! Like many exotoxins, the one that causes botulism is inactivated by heating. (Food must be heated to 80°C for 10 minutes, or boiled for 3 to 4 minutes.) The botulism exotoxin, marketed under the trade name Botox, is used in extremely tiny amounts to treat several medical conditions involving spasms (involuntary muscle contractions). Because Botox is a neurotoxin that works by paralyzing muscles, it can also relax facial wrinkles

caused by contraction of the underlying muscles. However, its effects last for only 3 to 8 months.

Endotoxins are not secreted by pathogens but are components of the cell walls of most gram-negative bacteria. These compounds affect the host only when they are released from dead bacteria. Endotoxins bind to the host's macrophages and stimulate them to release substances that cause fever and other symptoms of infection. Unlike exotoxins, which cause specific symptoms, endotoxins appear to affect the entire body. Endotoxins are not destroyed by heating.

Many bacteria have become resistant to antibiotics

Bacteria mutate frequently and reproduce rapidly. Many antibiotics target protein synthesis. For example, streptomycin and related antibiotics block the initiation of protein synthesis. The tetracyclines block aminoacyl tRNA from binding to the A site on the ribosome.

Drug resistance may result from an accumulation of mutations in plasmid or chromosomal DNA. Plasmids that have genes for antibiotic resistance are called **R factors.** They have genes for resistance to a specific drug and for transferring the resistance to other bacteria. Some R factors have several genes for drug resistance, each encoding resistance to a different drug.

Overuse of antibiotics is the principal contributing factor to drug resistance. In any bacterial population, there are likely at least a few bacteria that are genetically resistant to a particular antibiotic. The bacteria that are *not* resistant are killed by the antibiotic, leaving the resistant bacteria to multiply and produce a resistant population. Note that this is a common, present-day example of natural selection.

Another type of drug resistance has recently been described, explaining why some infections, for example, urinary tract infections, are difficult to cure. When *E. coli* infect the bladder, the immune system launches a powerful defense. The bacteria subvert the attack by forming *biofilms* (discussed previously). Each biofilm is surrounded by a matrix rich in polysaccharides and by a protective shell. The bacteria in the biofilm are resistant to antibiotics, as well as to host defenses. By one estimate, bacteria growing in a biofilm are up to 1000 times as resistant to antibiotics as are the same type of bacteria that have not formed a biofilm. Within biofilms, differential gene expression and mutation lead to diverse bacterial colonies. The biofilm strategy also explains some other types of chronic or recurrent infections. A high percentage of infections acquired in hospitals involve biofilms.

Prokaryotes are used in many commercial processes

Some microorganisms produce *antibiotics.* These compounds limit competition for nutrients by inhibiting or destroying other microorganisms. By the 1950s, antibiotics had become important clinical tools that transformed the treatment of infectious disease. Today about 100 clinically useful antibiotics are available, and literally tons of antibiotics are produced annually. Pharmaceutical companies obtain most antibiotics from three groups of microorganisms: a large group of gram-positive soil bacteria, the *actinomycetes;* gram-positive bacteria of the genus *Bacillus;* and molds (eukaryotes belonging to kingdom Fungi).

Figure 24-20 LM of lactic acid bacteria (*Lactobacillus acidophilus*)

Because of their prolific reproduction rates, bacteria are ideal "factories" for the production of biomolecules. Researchers have genetically engineered bacteria (see Chapter 15) to produce certain vaccines, human growth hormone, insulin, and many other clinically important compounds. Most of the insulin used to treat diabetics is now derived from genetically engineered bacteria. Researchers are developing genetically engineered bacteria for production of many other medically and agriculturally useful products.

Microbial fermentation helps produce many foods and beverages. Lactic acid bacteria are used in producing acidophilus milk, yogurt, pickles, olives, and sauerkraut (Fig. 24-20). Several types of bacteria are used in the production of cheese. Bacteria are involved in making fermented meats such as salami and in producing vinegar, soy sauce, chocolate, certain B vitamins (B_{12} and riboflavin), and citric acid, a compound added to candy and to most soft drinks.

Bacteria are used in sewage treatment and to break down solid wastes in landfills. They are also used in **bioremediation,** a process in which a contaminated site is exposed to microorganisms that break down the toxins, leaving behind harmless metabolic by-products such as carbon dioxide and chlorides. More than 1000 different species of bacteria and fungi have been used to clean up various forms of pollution, and microbiologists are searching for others.

Archaea are also economically important. For example, archaeal enzymes have been added to laundry and industrial detergents to increase their performance at higher temperatures and pH levels. Another archaeal enzyme has been useful in the food industry to convert corn starch to dextrins.

Review

- What important roles do prokaryotes play in ecosystems?
- Why is each of Koch's postulates essential?
- What is bioremediation?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Describe the structure of a virus, and contrast a virus with a living cell (page 501).

- A **virus,** or **virion,** is a subcellular particle consisting of a DNA or RNA genome surrounded by a protein coat, called a **capsid.**
- In contrast to a living cell, viruses cannot metabolize on their own. Viruses contain the nucleic acids necessary to make copies of themselves, but in order to reproduce, they must invade living cells and commandeer their metabolic machinery.

ThomsonNOW™ Learn more about virus structure by clicking on the figure in ThomsonNOW.

2 Trace the evolutionary origin of viruses according to current hypotheses (page 501).

- Viruses may be bits of nucleic acid that originally "escaped" from animal, plant, or bacterial cells.
- Some biologists hypothesize that viruses must have evolved before the three domains diverged; they think it unlikely that the similarities between viruses that infect archaea and those that infect bacteria evolved twice.

3 Characterize bacteriophages, and contrast a lytic cycle with a lysogenic cycle (page 501).

- **Bacteriophages,** or **phages,** are viruses that infect bacteria.
- A viral reproductive cycle can be lytic or lysogenic. In a **lytic cycle,** the virus destroys the host cell. There are five steps in a lytic cycle: **attachment** to the host cell; **penetration** of viral nucleic acid into the host cell; **replication** of the viral nucleic acid; **assembly** of newly synthesized components into new viruses; and **release** from the host cell.
- **Temperate viruses** do not always destroy their hosts. In a **lysogenic cycle,** the viral genome is replicated along with the host DNA. The nucleic acid of some phages becomes integrated into the bacterial DNA and is then called a **prophage.** Bacterial cells that carry prophages are lysogenic cells. In **lysogenic conversion,** bacterial cells containing certain temperate viruses exhibit new properties.

ThomsonNOW™ Watch the lytic and lysogenic cycles by clicking on the figure in ThomsonNOW.

4 Compare viral infection of animals and plants, and identify specific diseases caused by animal viruses (page 501).

- Viruses enter animal cells by membrane fusion or by endocytosis. Viral nucleic acid is replicated within the host cell, proteins are synthesized, and new viruses are assembled and released from the cell. Among the diseases caused by DNA viruses are smallpox, herpes, respiratory infections, and gastrointestinal disorders. RNA viruses cause influenza, upper respiratory infections, AIDS, and some types of cancer.
- Most plant viruses are RNA viruses. Plant viruses can be spread among plants by insect vectors. Viruses spread through the plant via plasmodesmata.

5 Describe the reproductive cycle of a retrovirus, such as human immunodeficiency virus (HIV) (page 501).

- **Retroviruses,** such as HIV, use **reverse transcriptase** to transcribe their RNA genome into a DNA intermediate that becomes integrated into the host DNA. Copies of the viral RNA are then synthesized.

ThomsonNOW™ Watch the HIV life cycle by clicking on the figure in ThomsonNOW.

6 Compare and contrast viroids and prions (page 510).

- **Viroids** and **prions** are smaller than viruses. A viroid consists of a short strand of RNA with no protein coat. A prion consists only of protein. Prions cause **transmissible spongiform encephalopathies (TSEs).**

7 Describe the structure and common shapes of prokaryotic cells (page 512).

- Prokaryotic cells do not have membrane-enclosed organelles such as nuclei and mitochondria.
- Bacterial cells have several common shapes: spherical (**cocci**), rod shaped (**bacilli**), and spiral. Spiral bacteria include the **spirillum,** which is a rigid helix, and **spirochete,** which is a flexible helix. **Vibrios** are comma shaped.
- Most bacteria have **cell walls** composed of **peptidoglycan.** The walls of **gram-positive** bacteria are very thick and consist mainly of peptidoglycan. The cell walls of **gram-negative** bacteria consist of a thin peptidoglycan layer and an outer membrane resembling the plasma membrane. Some species of bacteria produce a **capsule** that surrounds the cell wall.
- Some bacteria have **pili,** protein structures that extend from the cell and help bacteria adhere to one another or to certain other surfaces.
- Bacterial **flagella** are structurally different from eukaryotic flagella; each flagellum consists of a basal body, hook, and filament. They produce a rotary motion.

ThomsonNOW™ Learn more about the structure of prokaryotes and their cell walls by clicking on the figures in ThomsonNOW.

8 Describe asexual reproduction in prokaryotes, and summarize three mechanisms (transformation, transduction, and conjugation) that may lead to genetic recombination (page 512).

- The genetic material of a prokaryote typically consists of a circular DNA molecule and one or more **plasmids,** smaller circular fragments of DNA.
- Prokaryotes reproduce asexually by **binary fission** (the cell divides, forming two cells), **budding** (a bud forms and separates from the mother cell), or **fragmentation** (walls form inside the cell, which then separates into several cells.)
- In bacteria, genetic material may be exchanged by transformation, transduction, or conjugation. In **transformation,** a bacterial cell takes in DNA fragments released by another cell. In **transduction,** a phage carries bacterial DNA from one bacterial cell into another. In **conjugation,** two cells of different mating types exchange genetic material.

ThomsonNOW™ Watch conjugation by clicking on the figure in ThomsonNOW.

9 Describe the modes of nutrition and metabolic adaptations of prokaryotes (page 512).

- Most prokaryotes are **heterotrophs** that obtain energy and carbon from other organisms; some are **autotrophs** that make their own organic molecules from simple raw materials.
- The majority of bacteria are **chemoheterotrophs.** Most are free-living **decomposers** that obtain both carbon and

energy from dead organic matter. **Photoheterotrophs** obtain carbon from other organisms but use chlorophyll and other photosynthetic pigments to trap energy from sunlight.

- Autotrophs may be **photoautotrophs,** which obtain energy from sunlight, or **chemoautotrophs,** which obtain energy by oxidizing inorganic chemicals such as ammonia.
- Most bacteria are **aerobic,** that is, they require oxygen for cellular respiration. Some prokaryotes are **facultative anaerobes** that metabolize anaerobically when necessary; others are **obligate anaerobes** that can carry on metabolism *only* anaerobically.

10 Compare the three domains: Archaea, Bacteria, and Eukarya (page 518).

- Prokaryotes are assigned to domain **Archaea** and domain **Bacteria.**
- Unlike those of bacteria, the cell walls of archaea do not have peptidoglycan. The translational mechanisms of archaea more closely resemble eukaryotic mechanisms than those of other prokaryotes. Domain **Eukarya** includes the four kingdoms of eukaryotes.

11 Distinguish among the main groups of archaea based on their ecology, identify the archaean phyla (see Table 24-3), and describe the main groups of bacteria (see Table 24-4) (page 518).

- Three main groups of archaea are methanogens, extreme halophiles, and extreme thermophiles. **Methanogens** produce methane gas from simple carbon compounds. They inhabit anaerobic environments such as marshes, marine sediments, and the digestive tracts of animals. **Extreme halophiles** inhabit saturated salt solutions. **Extreme thermophiles** can inhabit environments at temperatures higher than 100°C. Archaeans are currently assigned to four phyla (see Table 24-3).
- Major groups of bacteria include the gram-negative proteobacteria, cyanobacteria, gram-positive bacteria, chlamydias, and spirochetes (see Table 24-4).

12 Discuss the ecological roles of prokaryotes, their importance as pathogens, and their commercial importance (page 520).

- Prokaryotes play essential ecological roles as decomposers and are important in recycling nutrients. Some prokaryotes carry out photosynthesis.
- Many bacteria are symbiotic with other organisms. **Mutualism** is a symbiotic relationship in which both partners benefit. In **commensalism,** one partner benefits and the other is neither harmed nor helped. In **parasitism,** the **parasite** benefits and the **host** is harmed. Some parasitic bacteria are important **pathogens** of plants and animals.
- Anton van Leeuwenhoek, Louis Pasteur, and Robert Koch were important pioneers in microbiology. **Koch's postulates** are a set of guidelines used to demonstrate that a specific pathogen causes specific disease symptoms.
- Some pathogenic bacteria release strong poisons called **exotoxins;** others produce **endotoxins,** poisonous components of their cell walls that are released when bacteria die. See Table 24-5 for a description of some pathogenic bacteria.
- Many bacteria have become resistant to antibiotics. Plasmids that have genes for antibiotic resistance are called **R factors.**
- Bacteria are important in many commercial processes. For example, some bacteria produce antibiotics. Several types of bacteria are used to produce cheese. Lactic acid bacteria are used in the production of yogurt, pickles, olives, and sauerkraut.

TEST YOUR UNDERSTANDING

1. The genome of a virus consists of (a) DNA (b) RNA (c) prions (d) DNA and RNA (e) DNA or RNA
2. The capsid of a virus consists of (a) protein (b) nucleic acid (c) helical proteins (d) a simple carbohydrate (e) RNA and lipid
3. The types of organisms a particular virus can infect are referred to as its (a) assembly (b) commensal cohort (c) host range (d) prophage range (e) restriction cycle
4. Viruses that kill host cells are (a) lysogenic (b) lytic (c) viroids (d) prophages (e) temperate
5. Arrange the following list into the correct sequence for viral reproduction.

   1. penetration 2. assembly 3. replication 4. attachment 5. release

   (a) 1, 2, 3, 4, 5 (b) 5, 2, 3, 4, 1 (c) 4, 1, 3, 2, 5 (d) 4, 1, 2, 3, 5 (e) 3, 1, 2, 4, 5
6. In lysogenic conversion (a) bacterial cells may exhibit new properties (b) the host cell dies (c) prions sometimes convert to viroids (d) reverse transcriptase transcribes DNA into RNA (e) prion proteins convert to infective agents
7. Peptidoglycan is a chemical compound found in the cell walls of (a) most viroids (b) most Archaea (c) all prokaryotes (d) most Bacteria (e) most Eukarya
8. Retroviruses (a) are DNA viruses (b) are RNA viruses (c) use reverse transcriptase to transcribe DNA into RNA (d) use prion protein to transcribe RNA (e) are DNA viruses that cause AIDS
9. Bacterial flagella (a) are homologous with eukaryotic flagella (b) exhibit a rotary motion (c) consist of a basal body and nine pairs of microtubules (d) are important in transduction (e) are characteristic of gram-positive bacteria
10. In conjugation (a) two bacterial cells of different mating types come together, and genetic material is transferred from one to another (b) a bacterial cell develops a bulge that enlarges and eventually separates from the mother cell (c) fragments of DNA released by a broken cell are taken in by another bacterial cell (d) a phage carries bacterial genes from one bacterial cell into another (e) walls develop in the cell, which then divides into six new cells
11. Endospores (a) are formed by some viruses (b) are extremely durable cells (c) are comparable to the reproductive

spores of fungi and plants (d) cause fever and other symptoms in the host (e) are extremely vulnerable to infection by phages

12. The majority of heterotrophic bacteria are (a) free-living chemoheterotrophs (b) photoautotrophs (c) chemoautotrophs (d) facultative anaerobes (e) obligate anaerobes
13. Which of the following do *not* belong to domain Archaea? (a) bacteria that produce methane from carbon dioxide and hydrogen (b) thermophiles (c) halophiles (d) bacteriophages (e) prokaryotes with cell walls that lack peptidoglycan
14. Which of the following scientists proposed a set of guidelines to demonstrate that a specific pathogen causes specific disease symptoms? (a) Leeuwenhoek (b) Pasteur (c) Koch (d) Prusiner (e) Woese
15. Bacteria that thrive in puncture wounds are likely to be (a) chemoheterotrophs (b) photoautotrophs (c) chemoautotrophs (d) endospores (e) obligate anaerobes
16. Prions (a) consist of a short strand of RNA with no protein coat (b) are deadly viruses that have caused several hundred deaths in Uganda and other parts of Africa (c) appear to consist only of protein; no nucleic acid component has been found (d) are responsible for causing hepatitis C (e) are not transmissible from human to human
17. Bacteria that are autotrophs (a) do not require atmospheric oxygen for cellular respiration (b) manufacture their own organic molecules from simple raw materials (c) must obtain organic compounds from other organisms (d) get their nourishment from dead organisms (e) produce endospores when oxygen levels are too low for active growth
18. Pathogens (a) are agents that cause disease (b) include most bacteria (c) include most myxobacteria (d) include many commensals (e) are cyanobacteria that cause disease
19. Lactic acid bacteria (a) have gram-negative cell walls (b) fix nitrogen under anaerobic conditions (c) were formerly known as blue-green algae (d) contribute to the unique taste of yogurt, pickles, and sauerkraut (e) secrete slime on which they glide
20. Which group of bacteria contains the gram-positive, anaerobic bacterium that causes botulism? (a) clostridia (b) actinomycetes (c) enterobacteria (d) spirochetes (e) streptococci

CRITICAL THINKING

1. Imagine that you discover a new microorganism. After careful study you determine that it should be classified in domain Archaea. What characteristics might lead you to this classification?
2. How would life on Earth be affected if all prokaryotes were suddenly annihilated?
3. **Evolution Link.** Historically, biologists thought that viruses, because of their simple structure, evolved before cellular organisms. Later, the hypothesis that viruses escaped from cells gained favor. Recently, microbiologists have again suggested that viruses evolved early in the history of life. Based on what you have learned about viruses, present an argument for one of these hypotheses.

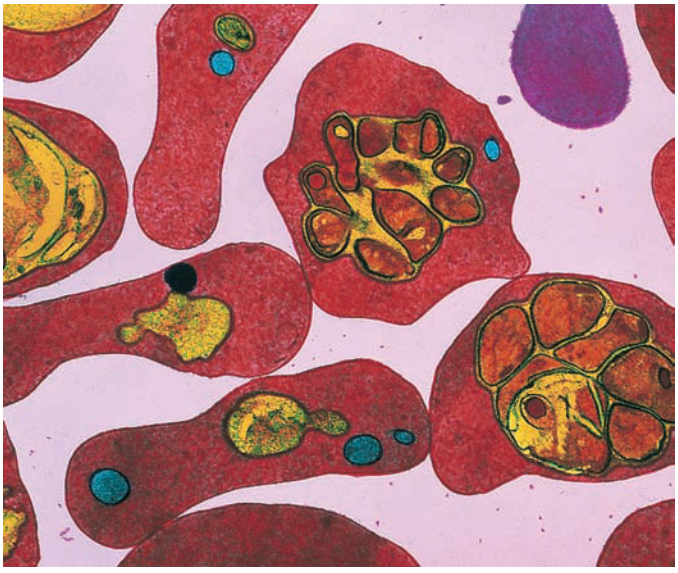
Protists



Gopal Murti /Science Photo Library/Photo Researchers, Inc.

Human red blood cells filled with malarial parasites. In this colorized TEM, the parasites multiply inside human red blood cells (*red*), safe from the body's immune system. Malaria is a tropical disease caused by the protist *Plasmodium* and transmitted to humans by the mosquito *Anopheles gambiae* as it feeds on human blood.

KEY CONCEPTS

Protists are a diverse group of eukaryotic organisms, most of which are microscopic.

Protists vary in body plan (unicellular, colonial, coenocytic, multicellular), method of motility (pseudopodia, cilia, flagella), nutrition type (autotrophic, heterotrophic), and mode of reproduction (asexual, sexual).

Protists are descendants of early eukaryotes.

Animals, fungi, and plants evolved from protist ancestors.

Biologists are making progress in understanding the evolutionary relationships among various protist taxa.

In Chapter 23, you learned that the kingdom Protista was first proposed in 1866, to include bacteria and other microorganisms that differ from plants and animals. When Robert Whittaker recommended the five-kingdom system of classification in 1969, only unicellular eukaryotic organisms were placed in kingdom Protista. Since then the boundaries of this kingdom have expanded to include any eukaryote that is not a fungus, animal, or land plant. More recently, some biologists have proposed eliminating the kingdom Protista by splitting it into several kingdoms based largely on molecular data that have clarified certain evolutionary relationships. Many relationships among protists remain uncertain, however.

Kingdom Protista currently consists of a vast assortment of primarily aquatic eukaryotic organisms whose diverse body forms, types of reproduction, modes of nutrition, and lifestyles make them difficult to characterize. **Protists** are unicellular, colonial, or simple multicellular organisms that have a eukaryotic cell organization. The word *protist*, from the Greek for "the very first," reflects the idea that protists were the first eukaryotes to evolve.

Because of their huge numbers, members of kingdom Protista are crucial to the natural balance of the living world. Protists are an important source of food for other organisms, and photosynthetic protists supply oxygen to aquatic and terrestrial ecosystems. Certain protists are economically important, and others cause devastating diseases (see photograph).

Biologists currently recognize as many as 60 major taxa of protists. Consideration of all protist groups is beyond the scope of this text, but we discuss a number of representative taxa. ■

INTRODUCTION TO THE PROTISTS

Learning Objectives

1 Characterize the features common to the members of kingdom Protista.

2 Discuss in general terms the diversity inherent in the protist kingdom, including means of locomotion, modes of nutrition, interactions with other organisms, habitats, and modes of reproduction.

Protists are members of Eukarya, the third domain on the tree of life. Eukaryotic cells are characteristic of protists as well as of complex multicellular organisms belonging to the kingdoms Fungi, Animalia, and Plantae. However, having a eukaryotic cell structure clearly differentiates protists from members of the prokaryotic domains Bacteria and Archaea. Recall from Chapter 4 that unlike prokaryotic cells, eukaryotic cells have nuclei and other membrane-enclosed organelles such as mitochondria and plastids, 9 + 2 flagella, and multiple chromosomes in which DNA and proteins form a complex called *chromatin*. Sexual reproduction, meiosis, and mitosis are also characteristic of eukaryotes.

Size varies considerably within the protist kingdom, from microscopic protists to giant kelps, which are multicellular brown algae that reach 75 m (about 250 ft) in length. Most protists are **unicellular,** with each cell forming a complete organism capable of performing all the functions characteristic of life. Some protists form **colonies,** loosely connected groups of cells; some are **coenocytic,** consisting of a multinucleate mass of cytoplasm; and some are **multicellular,** composed of many cells. Unlike animals, plants, and many fungi, most multicellular protists have relatively simple body forms without specialized tissues.

Size and structural complexity are not the only variable features of protists. During the course of evolutionary history, organisms in kingdom Protista have evolved diversity in their (1) means of locomotion, (2) ways of obtaining nutrients, (3) interactions with other organisms, (4) habitats, and (5) modes of reproduction.

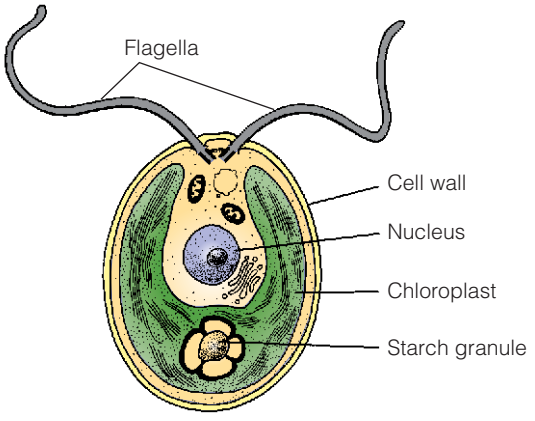


Figure 25-1 *Chlamydomonas,* a unicellular protist

Chlamydomonas is a motile organism with two flagella and a cup-shaped chloroplast.

Protists, most of which are motile at some point in their life cycle, have various means of locomotion. They may move by pushing out cytoplasmic extensions (*pseudopodia*) along the leading edge and retracting the cytoplasm that trails behind, as an amoeba does; by flexing individual cells; by gliding over surfaces; by waving *cilia,* short, hairlike organelles; or by lashing *flagella,* long, whiplike organelles (Fig. 25-1; also see Fig. 4-25). Some protists have two or more means of locomotion—for example, both flagella and pseudopodia.

Methods of obtaining nutrients differ widely in kingdom Protista. Most algae are autotrophic and photosynthesize as plants do. Some heterotrophic protists obtain their nutrients by absorption, as fungi do, whereas others resemble animals in that they ingest food. Some protists switch their modes of nutrition and are autotrophic at certain times and heterotrophic at others.

Although many protists are free-living, others form stable symbiotic associations with unrelated organisms. These intimate associations range from **mutualism,** a more or less equal partnership where both partners benefit; to **commensalism,** where one partner benefits and the other is unaffected; to **parasitism,** where one partner (the parasite) lives on or in another (the host) and metabolically depends on it (see Chapter 53). Some parasitic protists are important *pathogens* (disease-causing agents) of plants or animals. Throughout this chapter, we describe specific examples of symbiotic associations involving protists.

Most protists are aquatic and live in the ocean or in freshwater ponds, lakes, and streams. They make up most of the **plankton,** the floating, often microscopic organisms that inhabit surface waters and are the base of the food web in aquatic ecosystems. Other aquatic protists attach to rocks or other surfaces in the water. Even parasitic protists are aquatic, because they live in the watery environments of other organisms' body fluids. Terrestrial protists are restricted to damp places such as soil, cracks in bark, and leaf litter.

Reproduction is varied in kingdom Protista. Almost all protists reproduce asexually, and many also reproduce sexually. However, most protists do not develop multicellular reproductive organs, nor do they form embryos the way more complex organisms do.

- What are the features of a "typical" protist?
- How do protists vary in their means of obtaining nutrients?
- What are some of the ways protists interact with other organisms?

EVOLUTION OF THE EUKARYOTES

Learning Objectives

3 Discuss the hypothesis of serial endosymbiosis, and briefly explain some of the evidence that supports it.

4 Describe the kinds of data biologists use to classify eukaryotes.

Biologists hypothesize that protists were the first eukaryotic cells to evolve from ancestral prokaryotes. They may have appeared in the fossil record as early as 2.2 billion years ago. The first eukaryotes were probably *zooflagellates,* heterotrophic unicellular protists that have flagella. However, other than a few protists with hard shells, such as diatoms and foraminiferans, most ancient protists did not leave many fossils because their bodies were too soft to leave permanent traces. Evolutionary studies of protists focus primarily on molecular and structural comparisons of present-day organisms, which contain many clues about their evolutionary history.

Mitochondria and chloroplasts probably originated from endosymbionts

According to the hypothesis of **serial endosymbiosis,** certain eukaryotic organelles, particularly mitochondria and chloroplasts, arose from symbiotic relationships between larger cells and smaller prokaryotes that were incorporated and lived within them (see Fig. 21-7). Cell biologists hypothesize that mitochondria originated from aerobic bacteria. Studies of mitochondrial DNA suggest it is a remnant from the mitochondrion's past, when it was an independent organism. Ribosomal RNA (rRNA) sequences from mitochondria closely match rRNAs found in purple bacteria, suggesting that ancient purple bacteria were the ancestors of mitochondria.

Chloroplast evolution is more complex, as there were probably several endosymbiotic events. Molecular evidence supports the view that incorporation of an ancient cyanobacterium within a host cell, known as the *primary endosymbiosis,* resulted in the chloroplasts in today's red algae, green algae, and plants. Biologists hypothesize that these chloroplasts, which are enclosed by two external membranes, later provided other nonphotosynthetic eukaryotes with their chloroplasts during *secondary endosymbiosis* (Fig. 25-2).

Secondary endosymbiosis occurred frequently in eukaryote evolution, as evidenced by the presence of additional chloroplast membranes. For example, *three* membranes envelop the chloroplasts of euglenoids and dinoflagellates, and *four* membranes surround the chloroplasts of diatoms, golden algae, and brown algae. Understanding how these membranes originated is an essential aspect of serial endosymbiosis, and many researchers are studying the origin of chloroplasts in different organisms.

Even nonphotosynthetic protists may contain chloroplast relics from secondary endosymbiotic events. Apicomplexans—protists such as *Plasmodium,* which causes malaria—have a nonfunctional chloroplast surrounded by four membranes. Some researchers hypothesize that drugs that inhibit chloroplasts may also kill *Plasmodium.* This nonfunctional chloroplast, which is probably derived from either a red alga or a green alga, therefore has great medical potential in treating malaria.

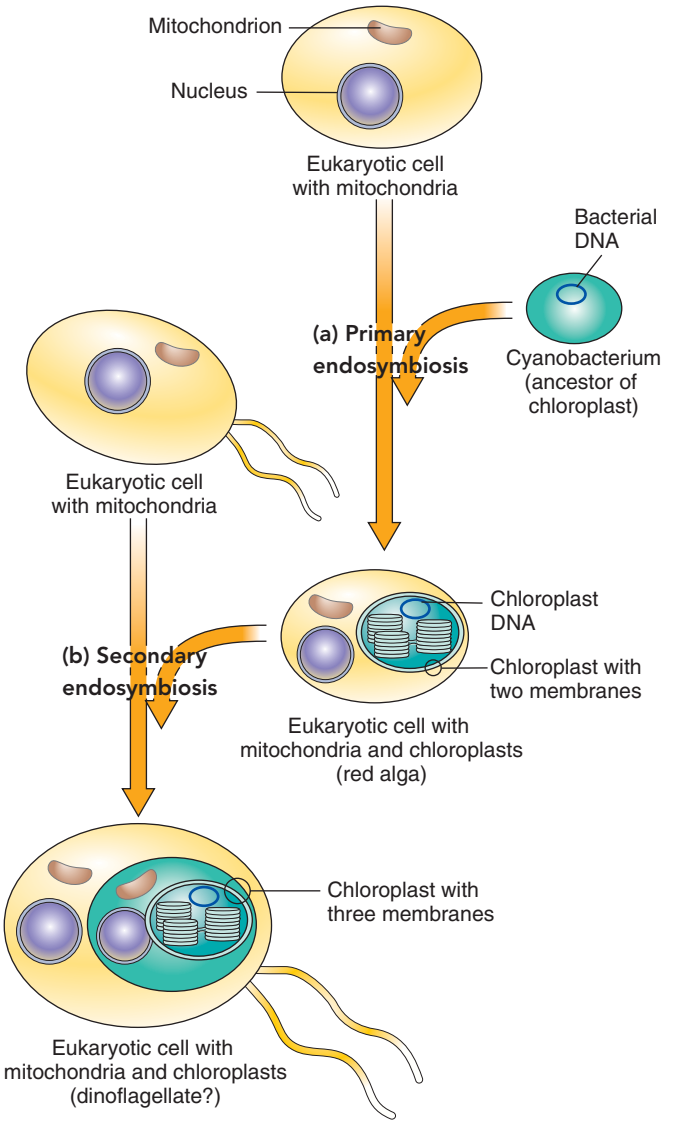

Figure 25-2 Chloroplast evolution by primary and secondary endosymbiosis

(a) In primary endosymbiosis, an ancient eukaryotic cell engulfed a cyanobacterium, which survived and evolved into a chloroplast. The ancient cell is depicted as a eukaryotic cell because mitochondria almost certainly evolved before chloroplasts. **(b)** In a secondary endosymbiotic event, a heterotrophic eukaryotic cell (with mitochondria) engulfed a eukaryotic cell with chloroplasts (a red alga is depicted). The red alga survived and evolved into a chloroplast surrounded by three membranes (a dinoflagellate chloroplast is depicted). Other secondary endosymbiotic events resulted in more complex chloroplast membrane structures.

A consensus is emerging in eukaryote classification

Scientists re-evaluate evolutionary relationships among the eukaryotes as additional evidence becomes available. Two types of modern research, molecular and ultrastructure, have contributed substantially to scientific understanding of the phylogenetic relationships among protists. Molecular data were initially obtained for the gene that codes for small subunit ribosomal RNA in different eukaryotes (SSU rRNA; see Chapter 23). More recently, biologists compared other nuclear genes, many of which code for proteins, in different protist taxa.

Key Point

Unraveling phylogenetic relationships among the protists has been difficult, but progress is occurring. At present, some relationships remain unclear.

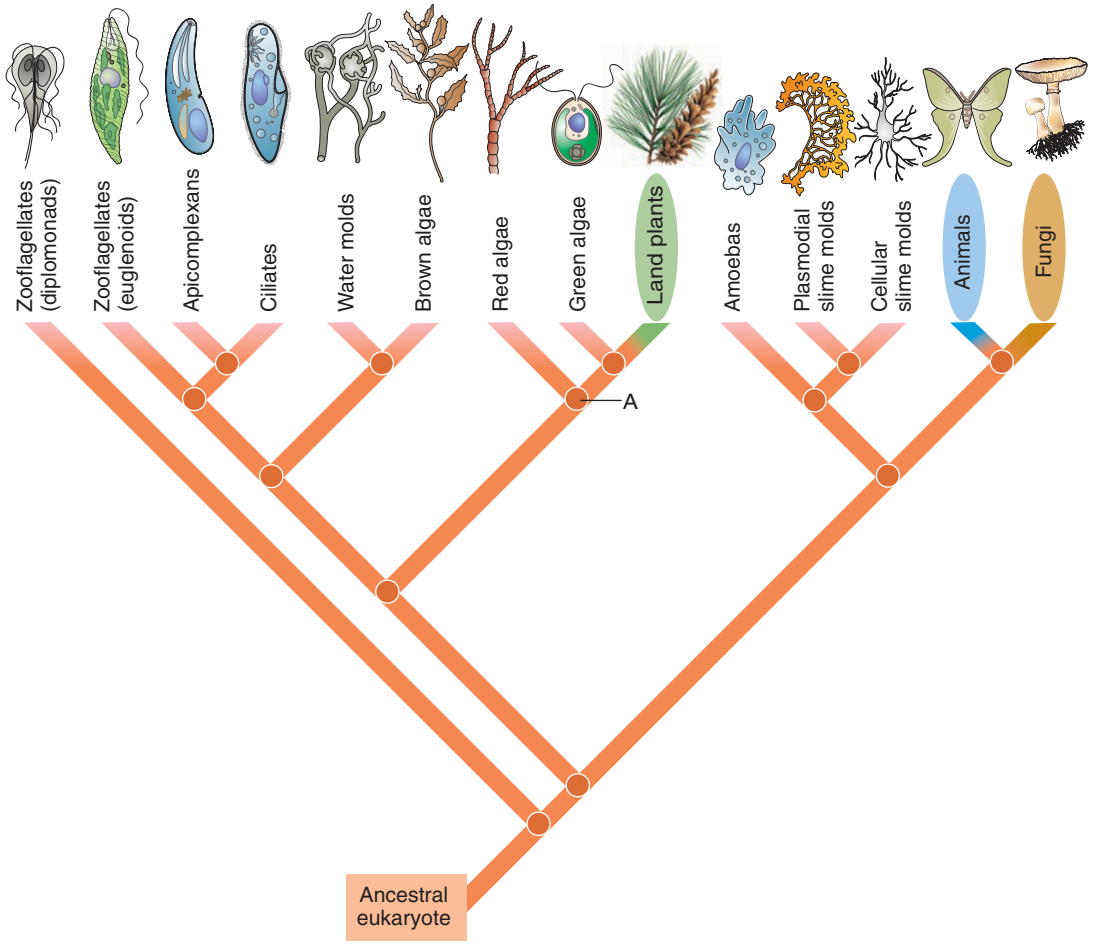

Figure 25-3 Evolutionary relationships among eukaryotes

Relationships among eukaryotes are diverse and debated; this cladogram presents just one interpretation. It is based on comparisons of four protein sequences among many eukaryotic phyla. Foraminiferans, actinopods, dinoflagellates, diatoms, and golden algae are not included. Groups within ovals represent separate eukaryotic kingdoms in the six-kingdom system used in this text. All other eukaryotes (without the ovals) are in kingdom Protista, a paraphyletic group. Node A indicates the common ancestor of red algae, green algae, and plants. (Based on S. L. Baldauf, A. J. Roger, I. Wenk-Siefert, and W. F. Doolittle, "A Kingdom-Level Phylogeny of Eukaryotes Based on Combined Protein Data," *Science*, Vol. 290, Nov. 3, 2000.)

Ultrastructure is the fine details of cell structure revealed by electron microscopy. In many cases, ultrastructure data complement molecular data. Electron microscopy reveals similar structural patterns among those protist taxa that comparative molecular evidence suggests are **monophyletic**—that is, evolved from a common ancestor (see Chapter 23). For example, molecular and ultrastructure data suggest that water molds, diatoms, golden algae, and brown algae—protist taxa that at first glance seem to share few characteristics—are a monophyletic group.

Given the diversity in protist structures and molecules, most biologists regard the protist kingdom as a **paraphyletic** group—that is, the protist kingdom contains some, but not all, of the descendants of a common eukaryote ancestor. Molecular and ultrastructural analyses continue to help biologists clarify relationships among the various protist phyla and among protists and the other eukaryotic kingdoms (Fig. 25-3).

Biologists also use these data to develop various proposals that split organisms in kingdom Protista into several kingdoms. One proposal, for example, removes red algae and green algae from the protists and classifies them within the plant kingdom. Figure 25-3 supports such a classification change, because it suggests they share a common ancestor (see node A).

Review

- How does serial endosymbiosis explain the origin of mitochondria and chloroplasts?
- What kinds of evidence support the hypothesis that the protist kingdom is a paraphyletic group?

REPRESENTATIVE PROTISTS

Learning Objectives

5 Explain why zooflagellates are no longer classified in a single phylum, and distinguish among diplomonads, euglenoids, and choanoflagellates.
6 Briefly describe and compare the following alveolates: ciliates, dinoflagellates, and apicomplexans.
7 Briefly describe and compare the following heterokonts: water molds, diatoms, golden algae, and brown algae.
8 Describe the foraminiferans and actinopods, and explain why many biologists classify them in the monophyletic group cercozoa.
9 Support the hypothesis that red algae and green algae should be included in a monophyletic group with land plants.
10 Briefly describe and compare the following amoebozoa: amoebas, plasmodial slime molds, and cellular slime molds.

The protists include those organisms traditionally known as protozoa, algae, and "lower fungi." Biologists continue to resolve evolutionary relationships among the protists and between the protists and other eukaryotes (plants, animals, and fungi). As a result of ongoing research, many biologists are developing different ways to classify eukaryotes, including new names for major taxa. In the classification scheme we are currently using in this text, almost all known eukaryotes are assigned to one of eight major clades: excavates, discicristates, alveolates, heterokonts, plants, cercozoa, amoebozoa, and opisthokonts (Table 25-1). Figure 25-4 shows these eight major clades superimposed over Figure 25-3.

As additional data accumulate, these groups may be elevated to the status of kingdoms, resulting in a 10-kingdom system that replaces the 6-kingdom system currently in use. (Of the 10 kingdoms, 8 are eukaryotes; the remaining 2 are prokaryotes—the bacteria and the archaea.) However, it is also possible that new data will prompt biologists to abandon or reorganize at least some of the eight clades.

Excavates are anaerobic zooflagellates

Zooflagellates are mostly heterotrophic, unicellular (a few are colonial) organisms with spherical or elongated bodies. They move rapidly by lashing one to many long, whiplike **flagella** that are usually located at the anterior (front) end. Some zooflagellates ingest food by means of a definite "mouth," or *oral groove*. Biologists traditionally classified zooflagellates in a single phylum. However, evidence indicates that zooflagellates are polyphyletic, and most biologists have separated them into several groups, such as the excavates and discicristates, based on close evolutionary relationships.

Most **excavates** are endosymbionts and live in anoxic (without oxygen) environments. Unlike virtually all other protists, excavates lack mitochondria, or if they are present, the mitochondria are atypical. Excavates do not carry out aerobic respiration; they obtain energy by the anaerobic pathway of glycolysis (pre-

TABLE 25-1

Major Monophyletic Eukaryote Clades

Monophyletic Group	Representative Members	Key Characters
Excavates	Diplomonads and other zooflagellates	Mitochondria absent or atypical; cells specialized for glycolysis instead of aerobic respiration; deep (excavated) oral groove
Discicristates	Euglenoids and other zooflagellates	Disc-shaped cristae in mitochondria
Alveolates	Ciliates Dinoflagellates Apicomplexans	Alveoli, flattened vesicles just inside the plasma membrane; tubular cristae in mitochondria
Heterokonts	Water molds Diatoms Golden algae Brown algae	No flagella or two flagella, one plain and one with hairs
Plants	Red algae Green algae Land plants	Chloroplasts surrounded by two membranes (inner and outer membranes)
Cercozoa	Foraminiferans Actinopods	Tests (hard shells) through which cytoplasmic projections extend
Amoebozoa	Amoebas Plasmodial slime molds Cellular slime molds	Naked amoebas (no tests) with pseudopods
Opisthokonts	Fungi Choanoflagellates Animals	No flagella or single posterior flagellum on motile cells; flattened cristae in mitochondria

Source: S. L. Baldauf, "The Deep Roots of Eukaryotes," *Science*, Vol. 300, June 13, 2003.

Key Point

Many biologists currently classify eukaryotes into eight major groups. However, classification of protists is ongoing.

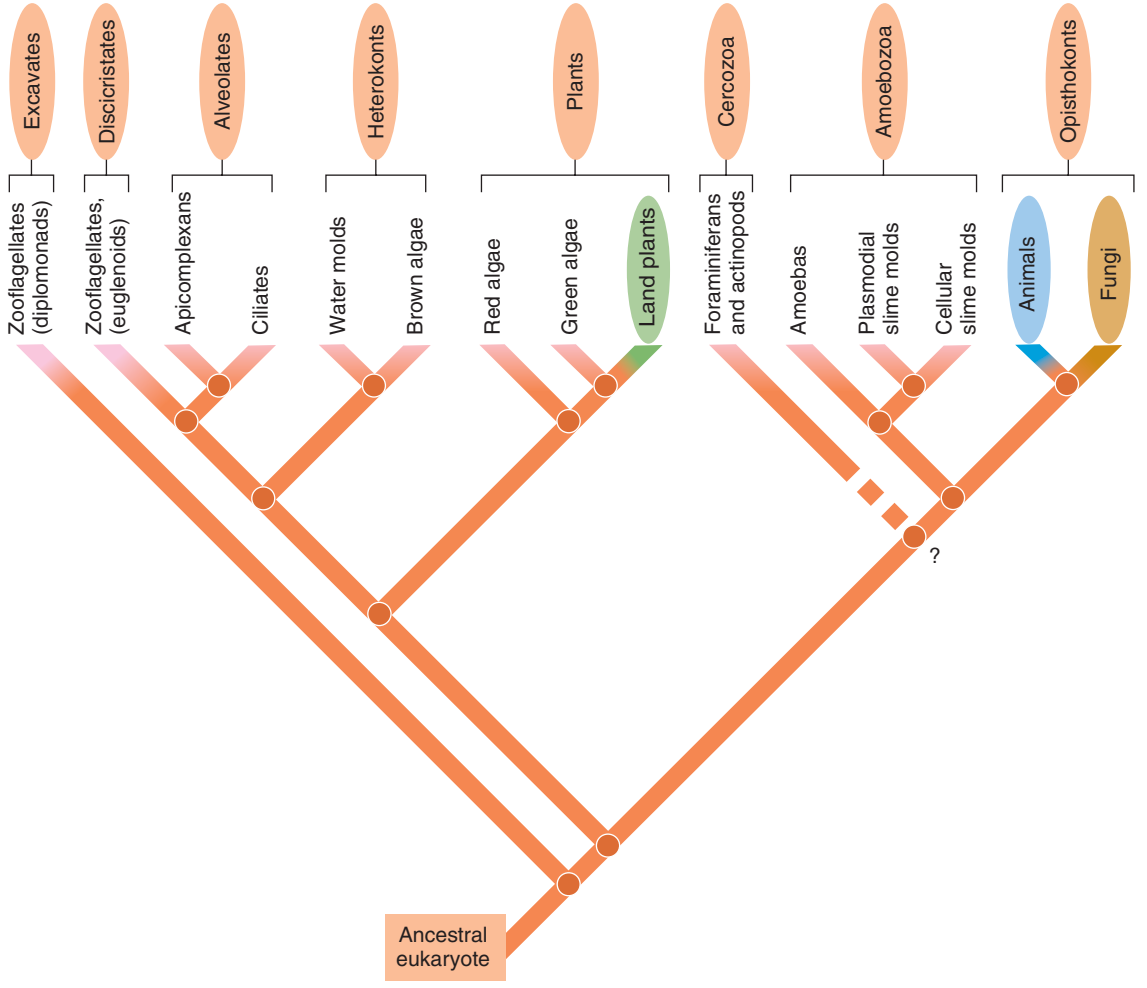

Figure 25-4 The eight monophyletic clades of eukaryotes

The major groups of eukaryotes are superimposed over Figure 25-3. Because classification of the protists is in a state of flux, biologists will modify this diagram as more data are collected and evaluated. (Based on S. L. Baldauf, "The Deep Roots of Eukaryotes," *Science*, Vol. 300, June 13, 2003.)

sumably by fermentation). These protists are so named because most have a deep, or *excavated,* oral groove.

From an evolutionary perspective, one of the most interesting groups of modern-day excavates is the **diplomonads,** which retain some characteristics thought to have been present in ancient protists. (Note in Figure 25-4 that excavates are depicted as branching off closest to the ancestral eukaryote; this denotes that excavates are the *outgroup* in the cladogram and therefore represent an approximation of the ancestral condition for eukaryotes.) Diplomonads have one or two nuclei, no functional mitochondria, no Golgi complex, and up to eight flagella.

Giardia is a parasitic diplomonad. Comparative ribosomal RNA sequencing suggests that diplomonads such as *Giardia* may be more closely related to prokaryotes than are any other protists (Fig. 25-5a). Interestingly, *Giardia*'s cell structure—it has two haploid nuclei—suggests a partial explanation of how diploid eukaryotes may have arisen from haploid prokaryotes. Some biologists hypothesize that the first eukaryotes had a single haploid nucleus. Most eukaryotes today have a single diploid nucleus formed at some stage in the life cycle when two haploid nuclei fuse. Perhaps the ancestors of *Giardia* represent an intermediate stage in eukaryotic evolution when cells each had two haploid nuclei but fusion had not yet occurred:

Haploid prokaryote ⟶ eukaryote with single haploid nucleus ⟶ eukaryote with two haploid nuclei ⟶ eukaryote with single diploid nucleus

(b) LM of *Trichonympha*, an excavate that lives in the gut of wood-eating termites and cockroaches. *Trichonympha* has hundreds of flagella.

Figure 25-5 The excavates

Giardia also lacks mitochondria, although it contains certain genes that code for proteins associated with mitochondria in other organisms. *Giardia* also possesses reduced structures that somewhat resemble mitochondria. This information suggests to some biologists that an early eukaryotic ancestor of *Giardia* may have possessed mitochondria, which were somehow lost or reduced at a later time during its evolutionary history.

Giardia intestinalis causes backpackers' diarrhea, a common infection among campers and hikers, particularly in the mountains of the western United States. *Giardia* is eliminated as a resistant cyst in the feces of many vertebrate animals. These cysts are a common contaminant in mountain streams. Campers and hikers become infected when they drink or rinse dishes in the "clean" mountain water. In a heavy infection, much of the wall of the small intestine is coated with these zooflagellates, which interfere with the absorption of digested nutrients and cause weight loss, abdominal cramps, and diarrhea.

Trichonymphs are specialized excavates with hundreds of flagella that live in the guts of termites and wood-eating cockroaches (Fig. 25-5b). These anaerobic zooflagellates lack mitochondria but have Golgi complexes. Trichonymphs ingest wood chips from the wood that termites or roaches eat. The trichonymphs rely on endosymbiotic bacteria to digest cellulose in the wood. The insects, trichonymphs, and bacteria all obtain their nutrients from this source. This is an excellent example of mutualism.

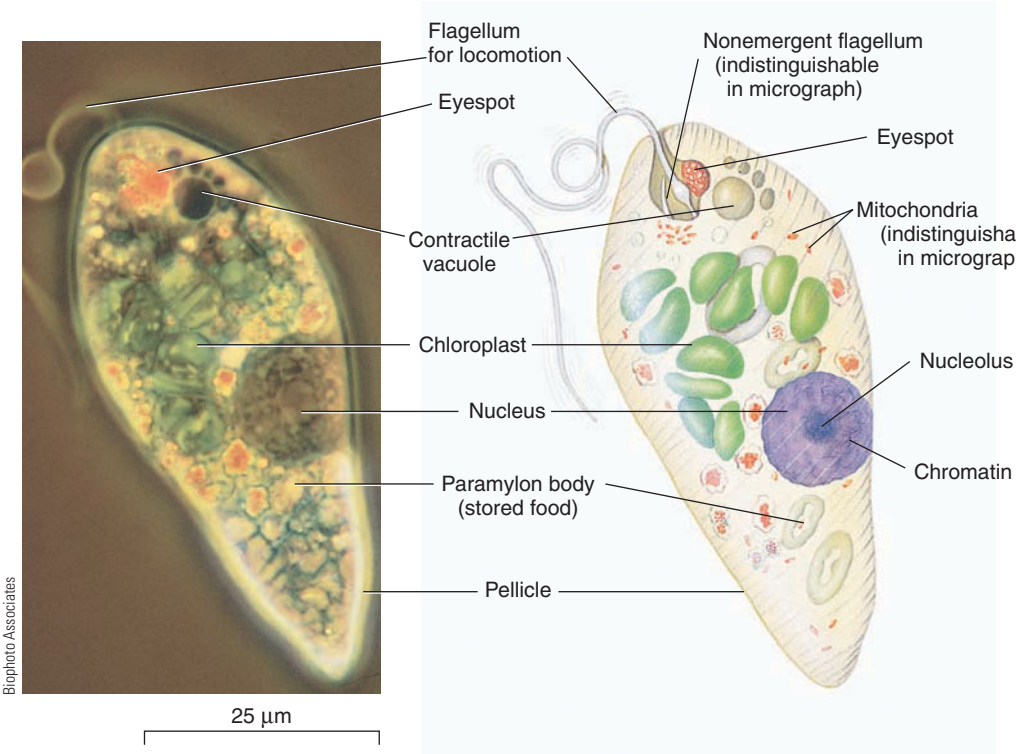
Discicristates include euglenoids and trypanosomes

Discicristates are zooflagellates named for their *disc*-shaped mitochondrial *cristae.* Discicristates include euglenoids, which are somewhat familiar to most students. Most **euglenoids** are unicellular flagellates, and about one third of them are photosynthetic (Fig. 25-6a and b). They generally have two flagella: one long and whiplike and one that is often so short that it does not extend outside the cell. Some euglenoids, such as *Euglena,* change shape continually as they move through the water, because their **pellicle,** or outer covering, is flexible. Euglenoids reproduce asexually by mitosis; none has been observed to reproduce sexually.

At various times scientists classified euglenoids in the plant kingdom (with the algae) and in the animal kingdom (when protozoa were considered animals). Autotrophic euglenoids have chlorophylls *a* and *b* and yellow and orange **carotenoids,** the same photosynthetic pigments that green algae and plants have. Although the euglenoids have the same pigments as the green algae and plants, they are not closely related to either group, as shown in Figure 25-3. They store energy reserves as *paramylon,* a polysaccharide. (Different protist groups produce a variety of storage compounds.) Some photosynthetic euglenoids lose their chlorophyll when grown in the dark, and they obtain their nutrients heterotrophically, by ingesting organic matter. Other species of euglenoids, such as *Peranema,* are always colorless and heterotrophic. Some heterotrophic species absorb organic compounds from the surrounding water, whereas others engulf bacteria and protists by **phagocytosis;** they digest the prey within food vacuoles.

Euglenoids inhabit freshwater ponds and puddles, particularly those with large concentrations of organic material. For this reason, researchers use them as indicator species of organic pollution. Some euglenoids also live in marine waters and mudflats.

Trypanosomes are colorless discicristates, many of which are parasitic and cause disease. In vertebrates, including humans, trypanosomes live in the blood. For example, *Trypanosoma brucei* is a human parasite that causes African sleeping sickness (Fig. 25-6c). It is transmitted by the bite of infected tsetse flies. Early symptoms include recurring attacks of fever. Later, when the trypanosomes have invaded the central nervous system, infected people are lethargic and have difficulty speaking or walking. An estimated 300,000 new cases occur each year, and if untreated, African sleeping sickness can cause death. Trypanosomes, like euglenoids, reproduce asexually by mitosis; none has been observed to reproduce sexually.



(a) Note the complex cell structure shown in this LM of *Euglena gracilis*, a unicellular, flagellate euglenoid.

(b) *Euglena*'s pellicle is flexible and changes shape easily. The eyespot may shield a light detector at the base of the long flagellum, thereby helping *Euglena* move to light of an appropriate intensity.

Alveolates have flattened vesicles under the plasma membrane

The unifying features of protists classified as **alveolates** are similar ribosomal DNA sequences and **alveoli** (sing., *alveolus*), flattened vesicles located just inside the plasma membrane. In some alveolates, the vesicles contain plates of cellulose. Alveolates include the ciliates, dinoflagellates, and apicomplexans.

Ciliates use cilia for locomotion

Ciliates are among the most complex of eukaryotic cells. These unicellular alveolates have a pellicle that gives them a definite but changeable shape. In *Paramecium,* the surface of the cell is covered with several thousand fine, short, hairlike **cilia** that extend through pores in the pellicle to facilitate movement (Fig. 25-7a and b; also see Fig. 1-1a). The cilia beat with such precise coordination that the organism can back up and turn around as well as move forward.

Not all ciliates are motile. Some sessile forms have stalks, and others, although capable of some swimming, are more likely to remain attached to a rock or other surface at one spot (Fig. 25-7c). Their cilia set up water currents that draw food toward them.

One group of ciliates, the **hypotrichs,** have greatly modified cilia and move with a creeping–darting motion. Hypotrichs lack cilia over much of the body except on the ventral (lowermost) surface, where they occur in stiff tufts called **cirri** (sing., *cirrus,* from the Latin for "a curl of hair") (Fig. 25-7d). Hypotrichs crawl about by means of these cirri, which beat in a coordinated manner.

Ciliates have a wide range of feeding habits and diets; most ingest bacteria or other tiny protists. Their cilia draw the food into a simple opening in some species and into a funnel-like oral groove in others. A vacuole forms around the food at the end of the opening, and the food is digested. Special organelles called **contractile vacuoles** control water regulation in freshwater ciliates. Being hypertonic to their environment, freshwater ciliates continually take in water by osmosis; the contractile vacuole continually expels excess water.

Figure 25-7 Ciliates

[(d) by H. Machemer in K. G. Grell, *Protozoology,* © 1973 Springer-Verlag.]

Ciliates differ from other protists in having two kinds of nuclei: one or more small, diploid **micronuclei** that function in reproduction; and a larger, polyploid **macronucleus** that controls cell metabolism and growth. Most ciliates are capable of a sexual process called **conjugation,** in which two individuals come together and exchange genetic material. Biologists divide each ciliate species into several different mating types. Individuals with different mating types are identical in appearance but genetically different in terms of sexual compatibility. Because there are no known physical differences between the mating types, it is not appropriate to refer to them as "male" and "female."

During conjugation in *Paramecium,* two individuals of compatible mating types press their oral surfaces together (Fig. 25-8). Within each individual the macronucleus disintegrates and the micronucleus undergoes meiosis, forming four haploid nuclei.[1] Three of these degenerate, leaving one, which divides mitotically to form two identical haploid nuclei. One of these remains within the cell, and the other nucleus crosses through the oral region into the other individual. The migrant haploid micronucleus fuses with the stationary haploid nucleus in that cell, and the two ciliates separate. The new diploid micronucleus in each cell divides a varying number of times, with one micronucleus developing into a new macronucleus.

A single act of conjugation yields two cross-fertilizations as each cell fertilizes the other. Conjugation results in two "new" cells that are genetically identical to each other but different from what they were before conjugation. Mitosis and cell division need not follow immediately after conjugation. Ciliates usually divide perpendicularly to their longitudinal axis.

[1]The details of conjugation vary somewhat among species.

Most dinoflagellates are a part of marine plankton

Most **dinoflagellates** are unicellular, although a few are colonial. Their alveoli contain interlocking cellulose plates impregnated with silicates (Fig. 25-9a). The typical dinoflagellate has two flagella. One flagellum wraps around a transverse groove in the center of the cell like a belt, and the other lies in a longitudinal groove (perpendicular to the transverse groove), projecting be-

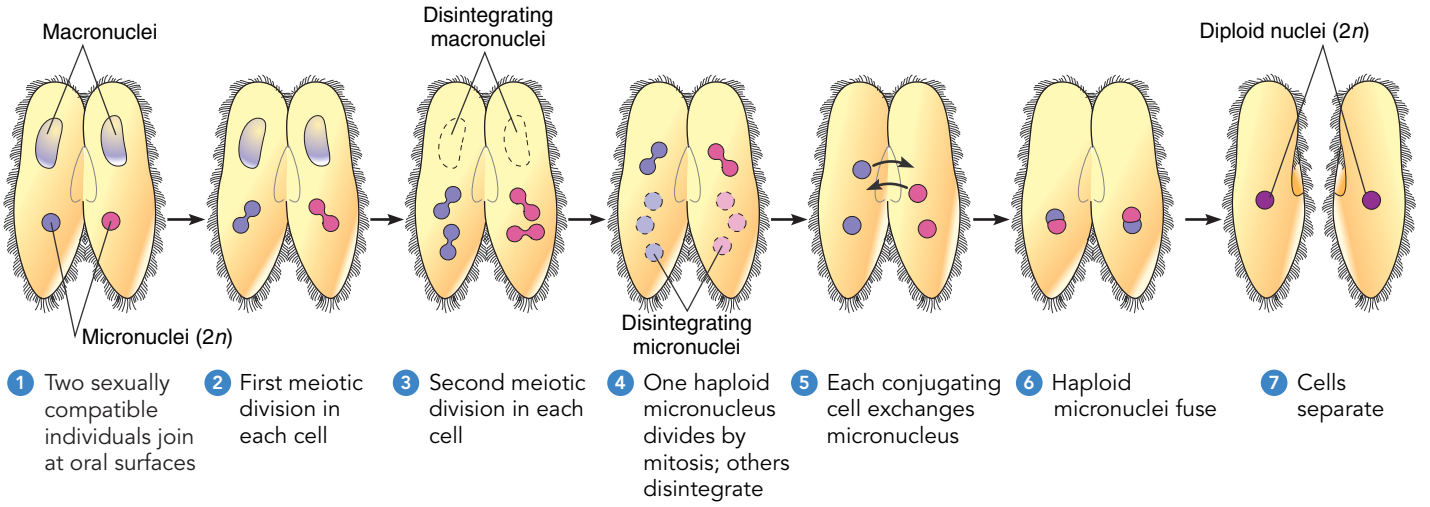

Figure 25-8 ***Animated*** Conjugation in *Paramecium caudatum*

hind the cell. The undulation of these flagella propels the dinoflagellate through the water like a spinning top. Indeed, the name is derived from the Greek *dinos,* meaning "whirling." Many marine dinoflagellates are bioluminescent.

Most dinoflagellates are photosynthetic and possess chlorophylls *a* and *c* and carotenoids, including **fucoxanthin,** a yellow-brown carotenoid (Fig. 25-9b). However, some are colorless and ingest other microorganisms for food. Dinoflagellates usually store energy reserves as oils or polysaccharides.

Many dinoflagellates are endosymbionts that live in the bodies of marine invertebrates such as mollusks, jellyfish, and corals (see Fig. 53-11). These symbiotic dinoflagellates, called **zooxanthellae,** lack cellulose plates and flagella. Zooxanthellae photosynthesize and provide carbohydrates for their invertebrate partners. Zooxanthellae contribute substantially to the productivity of coral reefs. Other dinoflagellates that are endosymbionts lack pigments and are parasites that live off their hosts.

Reproduction in the dinoflagellates is primarily asexual, by mitosis, although a few species reproduce sexually. The dinoflagellate nucleus is distinctive because the chromosomes lack histones, are permanently condensed, and always evident. Meiosis and mitosis are unusual because the nuclear envelope remains intact throughout cell division and the spindle lies *outside* the nucleus. The chromosomes attach to the nuclear envelope, and the spindle separates the new nuclei from each other.

Ecologically, dinoflagellates are important producers in marine ecosystems. A few dinoflagellates are known to have occasional population explosions, or blooms. These blooms, which frequently color coastal waters orange, red, or brown, are known as **red tides.** The environmental conditions that initiate dinoflagellate blooms are not known, but many experts think that human-produced coastal pollution is a factor. Some dinoflagel-

Figure 25-9 Dinoflagellates

late species that form red tides produce a toxin that attacks the nervous systems of fishes, leading to fish kills. Birds sometimes die after eating contaminated fish. Research has also linked red tides to manatee and dolphin deaths in Florida.

Humans sometimes get paralytic shellfish poisoning by eating filter-feeding mollusks, such as oysters, mussels, or clams, that have fed on certain dinoflagellates. The toxin may be produced by a bacterial endosymbiont living within the dinoflagellate. The poison is a neurotoxin that impairs breathing in humans who eat the contaminated shellfish; death from respiratory failure occasionally occurs. The dinoflagellates do not seem to harm the shellfish.

Apicomplexans are spore-forming parasites of animals

Apicomplexans are a large group of parasitic, spore-forming alveolates, some of which cause serious diseases in humans. They contain a vestigial plastid and may have evolved from parasitic dinoflagellates living in the intestines of marine invertebrates. Apicomplexans lack specific structures for locomotion (cilia, flagella, or pseudopodia); instead, they move by flexing. Apicomplexans have an *apical complex* of microtubules that attaches the parasite to its host cell; the apical complex is visible only by using electron microscopy. At some stage in their life cycle, apicomplexans produce **sporozoites,** small infective agents transmitted to the next host; for this reason, some biologists call these organisms **sporozoa.** Many apicomplexans spend part of their complex life cycle in one host species and part in a different host species.

Malaria is caused by an apicomplexan. According to the World Health Organization, approximately 500 million people currently have malaria, and more than 1 million people, mostly children in developing countries, die from the disease each year. Although for centuries Chinese, Greek, Arabic, and Roman writings described the disease, its causative agent and mode of transmission were not identified until the end of the 19th century. British scientist Ronald Ross received the Nobel Prize in 1902 for his role in elucidating the life cycle. Four species of *Plasmodium* cause malaria in humans. *Plasmodium* sporozoites enter human blood through the bite of an infected female *Anopheles* mosquito (Fig. 25-10). *Plasmodium* first enters liver cells, where it multiplies, and then red blood cells, where it continues to proliferate (see chapter opening micrograph). When each infected red blood cell bursts, many new parasites are released. The released parasites infect new red blood cells, and the process is repeated. The simultaneous bursting of millions of red cells causes the symptoms of malaria: a chill, followed by high fever as a result of toxic substances that are released and affect various organs of the body.

Today malaria is recurring in many countries where it was under control for decades. Formerly effective control methods—antimalarial drugs and pesticides—have lost much of their effectiveness. Chloroquine and several other antimalarial drugs are taken prophylactically to prevent malaria, but *Plasmodium* has evolved resistance to several of these, necessitating the use of a combination of drugs. Moreover, pesticides are used to control *Plasmodium*'s vector (carrier), the mosquito, but mosquitoes have evolved resistance to many pesticides. Researchers are currently testing new antimalarial drugs and several possible vaccines against malaria. In addition, the recent sequencing of the genomes of *P. falciparum* and the *Anopheles* mosquito has the potential to provide new diagnostics, drugs, and vaccines.

Motile cells of heterokonts are biflagellate

The **heterokonts** include water molds, diatoms, golden algae, and brown algae. At first glance, heterokonts appear too diverse to classify together. The name *heterokont,* derived from the Greek words for "different flagella," provides a clue. Most heterokonts have motile cells with two flagella, one of which has tiny hairlike projections off the shaft.

Water molds produce biflagellate reproductive cells

Water molds were once classified as fungi because of their superficial resemblance. Both water molds and fungi have a body, called a **mycelium,** that grows over organic material, digesting it and then absorbing the predigested nutrients (Fig. 25-11a). The threadlike **hyphae** that make up the mycelium in water molds are *coenocytic,* meaning that there are no cross walls, and the body of these heterokonts consists of a single multinucleate cell (see Fig. 26-1e). The cell walls of water molds are composed of cellulose (as in plants), chitin (as in fungi), or both.

When food is plentiful and environmental conditions are favorable, water molds reproduce asexually (Fig. 25-11b). A hyphal tip swells and a cross wall is formed, separating the hyphal tip from the rest of the mycelium. Within this structure, called a **zoosporangium,** tiny biflagellate zoospores form, each of which swims about, lands and encysts, and eventually develops into a new mycelium. When environmental conditions worsen, water molds initiate sexual reproduction. After fusion of male and female nuclei, thick-walled **oospores** develop from the oospheres (female gametes). Water molds often spend the winter as oospores.

Some water molds have played infamous roles in human history. For example, the Irish potato famine of the 19th century was precipitated by the water mold *Phytophthora infestans,* which causes late blight of potatoes. (The genus *Phytophthora* is named from Greek words meaning "plant destruction.") During several rainy, cool summers in Ireland in the 1840s, the water mold multiplied unchecked, causing potato tubers to rot in the fields. Because potatoes were the staple of the Irish peasants' diet, many people starved. Estimates of the number of deaths from the outbreak of the potato famine range from 250,000 to more than 1 million. The famine prompted a mass migration out of Ireland to the United States and other countries.

Late blight is still a problem today. New strains of *P. infestans* have appeared in the United States, Canada, northern Europe, Russia, South America, Japan, South Korea, the Middle East, and Africa. These strains resist the chemicals usually used to control the disease. Because today most people eat a varied diet, late

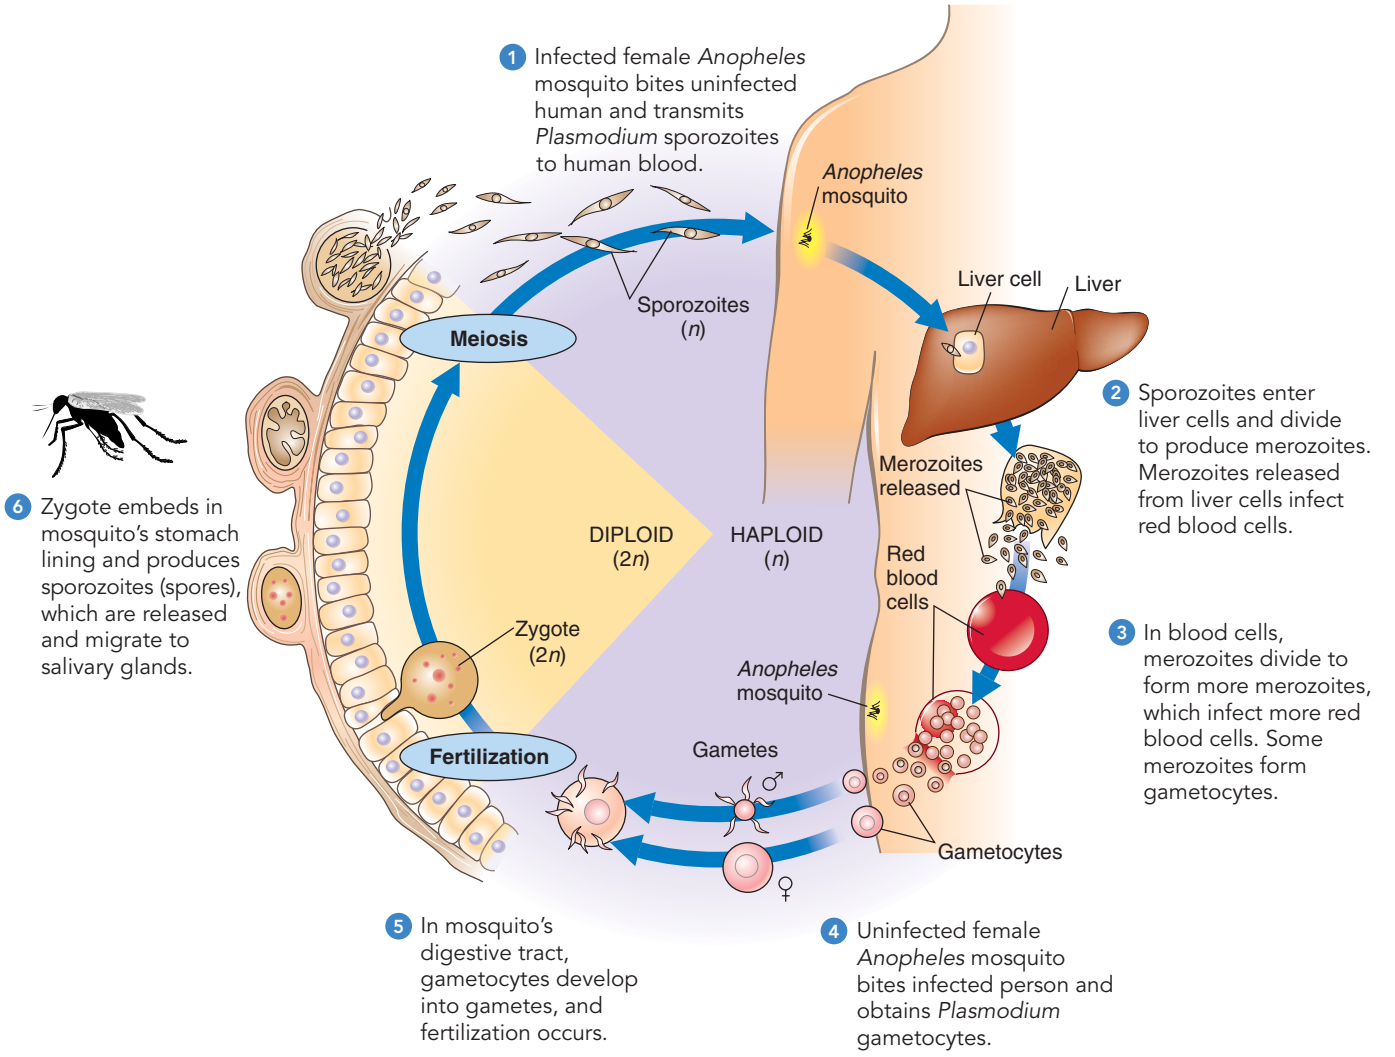

Figure 25-10 ***Animated*** The life cycle of *Plasmodium*, the causative agent of malaria

blight does not cause famine, but it costs potato growers millions of dollars annually in lost crops.

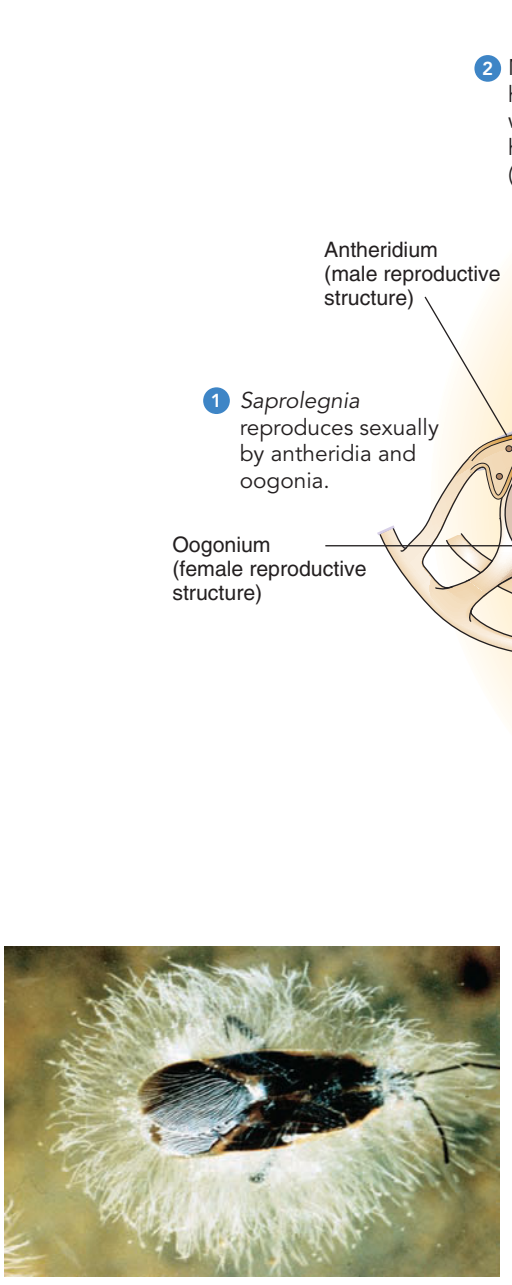
A close relative of the late blight water mold, *P. ramorum*, causes sudden oak death, which is killing oak forests in California and Oregon. Plant pathologists are concerned that the disease may spread to Midwestern and Eastern forests. This particular water mold also attacks redwoods, Douglas firs, bay trees, maples, and several other plant species, but most have only twig and leaf infections, not the rapid death observed in oaks.

Diatoms have shells composed of two parts

Most **diatoms** are unicellular algae, although a few exist as colonies. The cell wall of each diatom consists of two shells that overlap where they fit together, much like a petri dish. Silica is deposited in the shell, and this glasslike material is laid down in intricate patterns (Fig. 25-12a). There are two basic groups of diatoms: those with radial symmetry (wheel shaped) and those with bilateral symmetry (boat shaped or needle shaped). Although some diatoms are part of the floating plankton, others live on rocks and sediments, where they move by gliding. This gliding movement is facilitated by the secretion of a slimy material from a small groove along the shell.

Diatoms contain the photosynthetic pigments chlorophylls *a* and *c* and carotenoids, including fucoxanthin; their pigment composition gives them a yellow or brown color. Energy reserves are stored as oils or the water-soluble carbohydrate *chrysolaminarin*, which is similar to the laminarin stored in brown algae.

Diatoms most often reproduce asexually by mitosis. When a diatom divides, the two halves of its shell separate, and each becomes the larger half of a new diatom shell (Fig. 25-12b). Because the glass shell cannot grow, some diatom cells get progres-



(a) A mycelium of *Saprolegnia* radiates from this dead insect.

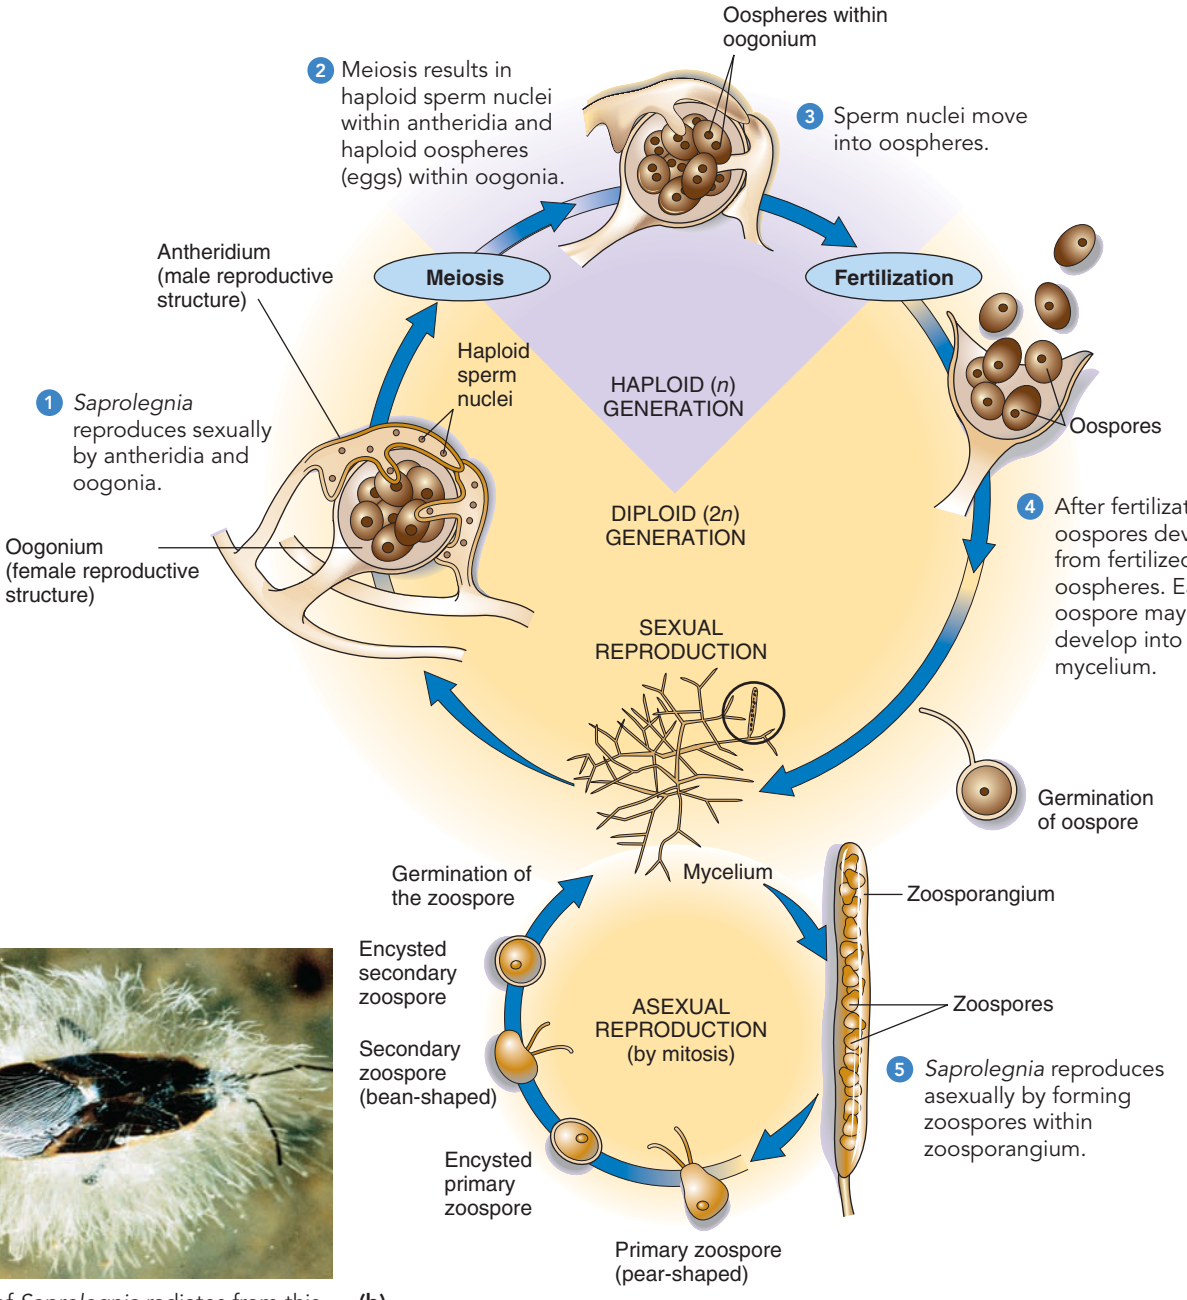


Figure 25-11 The life cycle of *Saprolegnia*, a water mold

sively smaller with each succeeding generation. When a diatom reaches a fraction of its original size, sexual reproduction occurs, with the production of shell-less gametes. Sexual reproduction restores the diatom to its original size because the resulting *zygote*, a 2*n* cell that results from the fusion of *n* gametes, grows substantially before producing a new shell.

Diatoms are common in fresh water, but they are especially abundant in relatively cool ocean water. They are major producers in aquatic ecosystems because of their extremely large numbers. At least one species is toxic and linked to shellfish poisonings, marine mammal strandings, and the deaths of sea lions along the central California coast.

When diatoms die, their shells trickle to the ocean floor and accumulate in layers that eventually become sedimentary rock. After millions of years, geologic upheaval has exposed some of these deposits on land. Called *diatomaceous earth*, these deposits are mined and used as filtering, insulating, and soundproofing materials. As a filtering agent, diatomaceous earth is used to refine raw sugar and to process vegetable oils. Because of its abrasive properties, diatomaceous earth is a common ingredient in

scouring powders and metal polishes; it is no longer added to most toothpastes because it is too abrasive for tooth enamel. The intricately detailed diatom shells are often used to test microscope resolution down to 1 μm.

Most golden algae are unicellular biflagellates

Golden algae are found in both freshwater and marine environments. Most species are biflagellate, unicellular organisms, although some are colonial (Fig. 25-13a). A few of these heterokonts lack flagella and are similar to amoebas in appearance except that golden algae contain chloroplasts. Tiny scales of either silica or calcium carbonate may cover the cells. Reproduction in golden algae is primarily asexual and involves the production of biflagellate, motile spores called **zoospores.**

Most golden algae are photosynthetic and produce the same pigments as diatoms: chlorophylls *a* and *c* and carotenoids, including fucoxanthin. The pigment composition of golden algae gives them a golden or golden brown color. As in diatoms, energy reserves are stored as oils or carbohydrates. A few species ingest bacteria and other particles of food. Ecologically, golden algae are important producers in marine environ-

Figure 25-13 Golden algae

ments. They compose a significant portion of the ocean's **nanoplankton,** extremely minute algae (2 to 10 μm) that are major producers because of their great abundance.

Classification of golden algae is controversial. Some biologists lump diatoms and golden algae in a single phylum, whereas others classify them as brown algae. At the other extreme, some biologists divide the golden algae into two phyla by placing many of the marine species, such as **coccolithophorids** (Fig. 25-13b), in a separate phylum.

Brown algae are multicellular heterokonts

Brown algae include the giants of the protist kingdom. They are the largest and most complex of all algae commonly called seaweeds. All brown algae are multicellular and range in size from a few centimeters (about an inch) to 75 m (about 250 ft). Their body forms are branched filaments; tufts; fleshy "ropes"; or thick, flattened branches. The largest brown algae, called *kelps,* are tough and leathery in appearance.

Many kelps have leaflike **blades** in which most photosynthesis occurs, stemlike **stipes,** and rootlike anchoring **holdfasts** (Fig. 25-14a). They often have gas-filled *bladders* that provide buoyancy. (The blades, stipes, and holdfasts of brown algae are not homologous to the leaves, stems, and roots of plants. Brown algae and plants arose from different unicellular ancestors, as shown in Figure 25-3.)

Brown algae are photosynthetic and have chlorophylls *a* and *c* and carotenoids, including fucoxanthin, in their chloroplasts. The main energy storage reserve in brown algae is a carbohydrate called *laminarin.*

Reproduction is varied and complex in the brown algae. Their reproductive cells, both asexual zoospores and sexual gametes, are usually biflagellate. Most have a life cycle that exhibits **alternation of generations,** in which they spend part of their life as multicellular haploid organisms and part as multicellular diploid organisms (see Fig. 10-17c).

Brown algae are commercially important for several reasons. Their cell walls contain a polysaccharide called *algin* that is harvested from kelps such as *Macrocystis* and used as a thickening and stabilizing agent in ice cream, toothpaste, shaving cream, hair spray, and hand lotion. Brown algae are an important human food, particularly in eastern Asia, and they are rich sources of certain vitamins and minerals such as iodine.

Brown algae are common in cooler marine waters, especially along rocky coastlines, where they live mainly in the intertidal zone or relatively shallow offshore waters. Kelps form extensive underwater "forests," or kelp beds (Fig. 25-14b). They are essential in that ecosystem as important food producers, and they

provide habitat for many marine invertebrates, fishes, and mammals. The diversity of life supported by kelp beds rivals that found in coral reefs. There is also an extensive population of floating brown algae in a central area of the North Atlantic Ocean called the Sargasso Sea, named for the brown alga *Sargassum.* The Sargasso Sea is not greatly affected by the surface ocean currents rotating around the margins of the North Atlantic, so the floating *Sargassum* remains there.

(b) *Bossiella* is a coralline red alga encrusted with calcium carbonate. It lives in the Pacific Ocean, where it grows to 12 cm (4.7 in).

Figure 25-15 ***Animated*** Red algae

Red algae, green algae, and land plants are collectively classified as plants

In the classification scheme adopted in this text, the monophyletic group of **plants** includes red algae and green algae, which are currently classified in kingdom Protista, and land plants, which are in a separate kingdom (see Chapters 27 and 28). Biologists classify these groups together based on molecular data and on the presence of chloroplasts bounded by outer and inner membranes (see Fig. 9-4).

Red algae do not produce motile cells

The vast majority of **red algae** are multicellular organisms, although there are a few unicellular species. The multicellular body form of red algae commonly consists of complex, interwoven filaments that are delicate and feathery (Fig. 25-15a); a few red algae are flattened sheets of cells. Most multicellular red algae attach to rocks or other substrates by a basal holdfast. Reproduction in the red algae is remarkably complex, with an alternation of sexual and asexual stages. Although sexual reproduction is common, no flagellate cells develop during the life cycle.

The chloroplasts of red algae contain **phycoerythrin,** a red pigment, and **phycocyanin,** a blue pigment, in addition to chlorophylls *a* and *d* and carotenoids. The red algae store energy reserves as *floridean starch,* a polysaccharide similar to glycogen. They have the same pigment composition as the cyanobacteria, a group of photosynthetic bacteria (see Chapter 24).

The cell walls of red algae often contain thick, sticky polysaccharides that have commercial value. For example, *agar* is a polysaccharide extracted from certain red algae and used as a food thickener and culture medium, a substrate on which to grow microorganisms and propagate some plants, such as orchids. Another polysaccharide extracted from red algae, *carrageenan,* is a food additive used to stabilize chocolate milk and to provide a thick, creamy texture to ice cream and other soft processed foods. Carrageenan is also used to stabilize paints and cosmetics. Red algae are a source of vitamins (particularly A and C) and minerals, especially in Japan and other eastern Asian countries where people eat red algae fresh, dried, or toasted in such traditional foods as sushi and nori.

Red algae primarily live in warm tropical ocean waters, although a few species occur in fresh water and in soil. Some red algae, known as *coralline algae,* incorporate calcium carbonate in their cell walls from the ocean water (Fig. 25-15b). The hard calcium carbonate may protect coralline algae from the rigors of wave action. These coralline red algae are extremely important in building "coral" reefs—perhaps more crucial than coral animals in this process.

Green algae share many similarities with land plants

Green algae have pigments, energy reserve products, and cell walls that are chemically identical to those of land plants. Green algae are photosynthetic, with chlorophylls *a* and *b* and carotenoids present in chloroplasts of a wide variety of shapes. They store their main energy reserves as starch. Most green algae have cell walls with cellulose, although some lack walls. Because of these and other similarities, biologists generally accept that land plants arose from ancestral green algae (see Fig. 25-3). Using recent molecular and ultrastructure data, some biologists want to reclassify this extremely diverse group as members of the plant kingdom.

Green algae exhibit a variety of body types, from single cells to colonial forms, to coenocytic algae (multinucleate), to multicellular filaments and sheets (Fig. 25-16). The multicellular forms do not have cells differentiated into tissues, a characteristic that separates them from land plants. Most green algae have, or produce, flagellate cells during their life cycle, although a few are totally nonmotile.

Reproduction in the green algae is as varied as their body forms, with both sexual and asexual reproduction. Many green

algae have life cycles with an alternation of multicellular haploid and diploid generations. Asexual reproduction is by mitosis and cell division in single cells or by fragmentation in multicellular forms. Many green algae produce spores asexually by mitosis; if these spores have flagella and are motile, they are called *zoospores* (Fig. 25-17).

Sexual reproduction in the green algae involves gamete formation in unicellular **gametangia** (sing., *gametangium*), reproductive structures in which gametes are produced. Green algae have three types of sexual reproduction—isogamous, anisogamous, and oogamous. If the two flagellate gametes that fuse are identical in size and appearance, sexual reproduction is **isogamous** (see Fig. 25-17). **Anisogamous** sexual reproduction involves the fusion of two flagellate gametes of different sizes (Fig. 25-18). Some green algae are **oogamous** and produce a nonmotile egg and a flagellate male gamete. In addition to sexual reproduction by the fusion of gametes, some green algae exchange genetic information by a form of conjugation in which the genetic material of one cell passes into a recipient cell (Fig. 25-19).

Green algae are found in both aquatic and terrestrial environments. Aquatic green algae primarily inhabit fresh water, although there are many marine species. Terrestrial green algae are restricted to damp soil, cracks in tree bark, and other moist places. Many green algae are symbionts with other organisms; some live as endosymbionts in body cells of invertebrates, and a few grow together with fungi as "dual organisms" called *lichens* (discussed in Chapter 26). Regardless of where they live, green algae are ecologically important as producers.

Figure 25-16 Green algae

Cercozoa are amoeboid cells enclosed in shells

The **cercozoa** are amoeboid cells that often have hard outer shells, called **tests,** through which cytoplasmic projections extend. The cytoplasmic projections suggest the name *cercozoa,* from the Greek *cerco,* meaning "rod." Foraminiferans and actinopods are cercozoa.

Foraminiferans extend cytoplasmic projections that form a threadlike, interconnected net

Almost all **foraminiferans** are marine cercozoa that produce elaborate tests (Fig. 25-20a). The ocean contains enormous numbers of foraminiferans, which secrete chalky, many-chambered tests with pores through which cytoplasmic projections are extended. (*Foraminifera* is derived from the Latin for "bearing openings.") The cytoplasmic projections form a sticky, interconnected net that entangles prey. Many foraminiferans contain unicellular algal endosymbionts (green algae, red algae, or diatoms) that provide food by photosynthesis. Many foraminiferan species live on the ocean floor, but others are part of the plankton.

Dead foraminiferans settle on the bottom of the ocean, where their tests form a gray mud that is gradually transformed into chalk. With geologic uplifting, these chalk formations become part of the land, for example, the White Cliffs of Dover in England (Fig. 25-20b). (The White Cliffs of Dover are the remains of a variety of carbonate organisms, not only foraminiferans.) Because foraminiferan tests often appear in rock layers covering

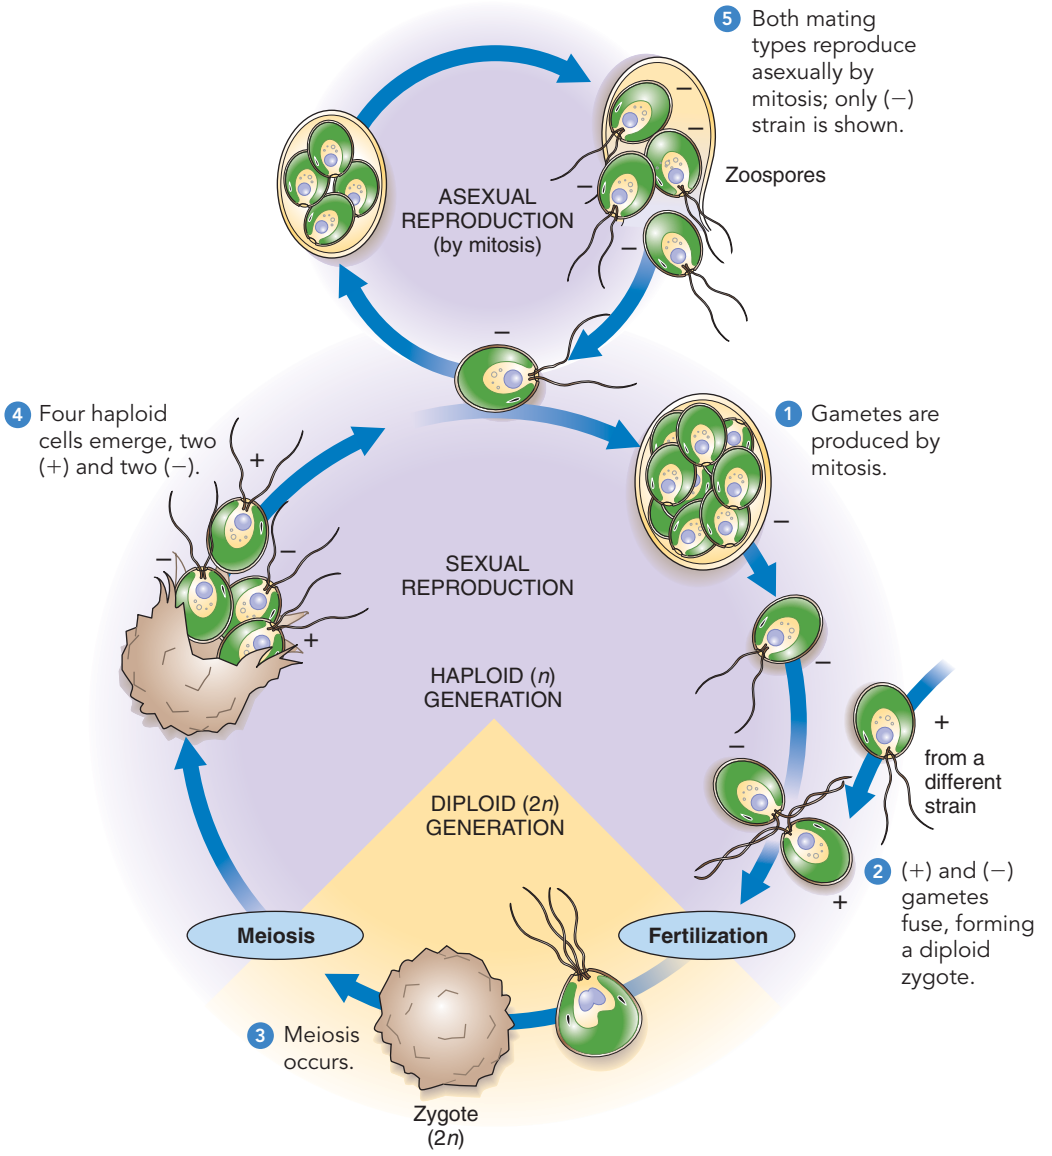

Figure 25-17 ***Animated*** The life cycle of *Chlamydomonas*

Chlamydomonas, a unicellular haploid green alga with two mating types, (+) and (−), is an example of isogamous sexual reproduction.

oil deposits, geologists exploring for oil look for foraminiferan tests in rock strata. Foraminiferans are well preserved in the fossil record, and biologists use some as **index fossils,** markers to help identify sedimentary rock layers (see Chapter 18).

Actinopods project slender axopods

Actinopods are mostly marine plankton cercozoa with long, filamentous cytoplasmic projections called **axopods** that protrude through pores in their shells (▮ Fig. 25-21). A cluster of microtubules strengthens each axopod. Unicellular algae and other prey become entangled in these axopods and are engulfed outside the main body of the actinopod; cytoplasmic streaming carries the prey inside the body. Many actinopods contain algal endosymbionts that provide them with the products of photosynthesis.

Some actinopods, called **radiolarians,** secrete elaborate, beautiful glassy shells made of silica. Radiolarians are an important constituent of marine plankton. When radiolarians and other actinopods die, their shells settle and become an ooze (sediment) that may be several meters thick on the ocean floor.

Amoebozoa have lobose pseudopodia

Most **amoebozoa** do not have tests and produce temporary cytoplasmic projections called **pseudopodia** (sing., *pseudopodium*, meaning "false foot") at some point in their life cycle. The

pseudopodia of amoebozoa are *lobose*—that is, rounded and wide—as opposed to the slender cytoplasmic projections characteristic of the cercozoa. Biologists currently classify amoebas, plasmodial slime molds, and cellular slime molds as amoebozoa.

Amoebas move by forming pseudopodia

Amoebas are unicellular amoebozoa found in soil, fresh water, the ocean, and other organisms (as parasites). Because of the extreme flexibility of their outer plasma membrane, many members of this group have an asymmetrical body form and continually change shape as they move. (The word *amoeba* derives from a Greek word meaning "change.") An amoeba moves by pushing out lobose pseudopodia from the surface of the cell. More cytoplasm flows into the pseudopodia, enlarging them until all the cytoplasm has entered and the organism as a whole has moved. Pseudopodia also capture and engulf food by surrounding and forming a vacuole around it (Fig. 25-22). Food particles are digested when the food vacuole fuses with a lysosome containing digestive enzymes. Digested materials are absorbed from the food vacuole, which gradually shrinks as it empties. Amoebas

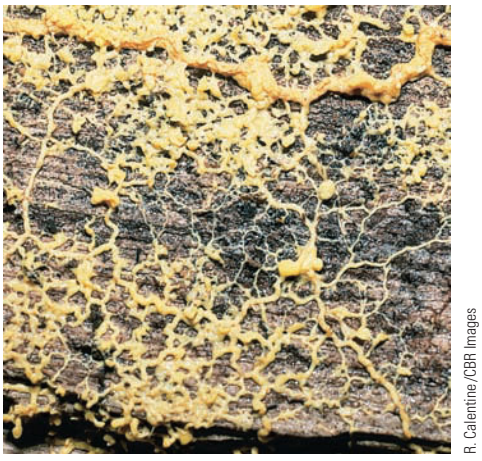
Figure 25-22 ***Animated*** Amoeba

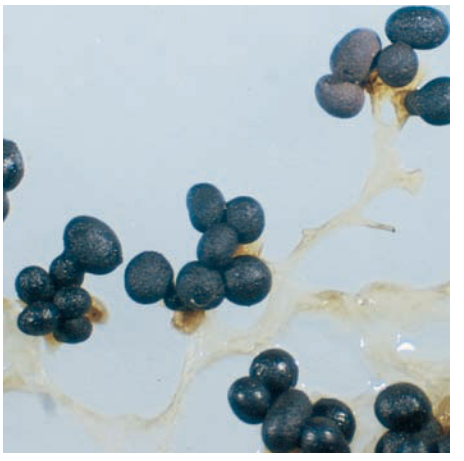
LM of a giant amoeba (*Chaos carolinense*). This unicellular protist, which moves and feeds by pseudopodia, is surrounding and ingesting a colonial green alga. *Chaos* amoebas are generally scavengers that feed on debris in freshwater habitats, but they ingest living organisms when the opportunity arises.

reproduce asexually, splitting into two equal parts after mitotic division of the nucleus; sexual reproduction has not been observed.

Parasitic amoebas include *Entamoeba histolytica,* which causes *amoebic dysentery,* a serious human intestinal disease characterized by severe diarrhea, bloody stools, and ulcers in the intestinal wall. In especially severe cases, the organism spreads from the large intestine and causes abscesses in the liver, lungs, or brain. *Entamoeba histolytica* is transmitted as cysts in contaminated drinking water. A **cyst** is a thick-walled, resistant, resting stage in the life cycle of some protists. Other amoebas, such as *Acanthamoeba,* are usually free-living but produce opportunistic infections such as eye infections in contact lens wearers.



(a) The brightly pigmented plasmodium, shown on a dead log, feeds on bacteria and other microorganisms.



(b) The reproductive structures are sporangia on stalks.

Figure 25-23 The plasmodial slime mold *Physarum polycephalum*

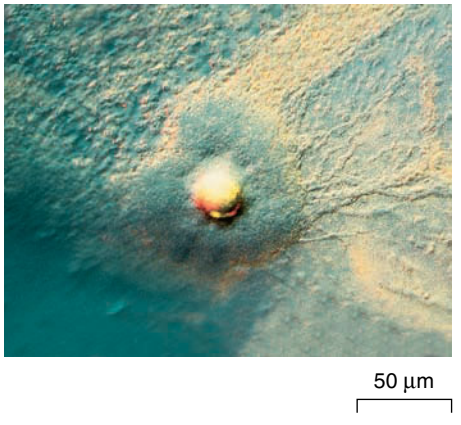
Plasmodial slime molds feed as multinucleate plasmodia

The feeding stage of a **plasmodial slime mold** is a **plasmodium,** a multinucleate mass of cytoplasm that can grow up to 30 cm (1 ft) in diameter (Fig. 25-23a). The slimy plasmodium streams over damp decaying logs and leaf litter, often forming a network of channels that covers a large surface area. As it creeps along, it ingests bacteria, yeasts, spores, and decaying organic matter.

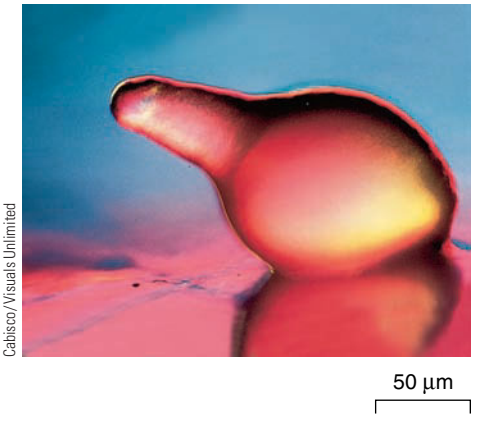
When the food supply dwindles or there is insufficient moisture, the plasmodium crawls to an exposed surface and starts reproducing. Stalked structures of intricate complexity and beauty usually form from the drying plasmodium (Fig. 25-23b). Within these structures, called **sporangia,** meiosis produces haploid spores that are extremely resistant to adverse environmental conditions.

When conditions become favorable, the spores germinate, and a haploid reproductive cell emerges from each. This haploid cell is either a biflagellate *swarm cell* or an amoeboid *myxamoeba,* depending on available moisture; flagellate cells form in wet conditions. Swarm cells and myxamoebas act as gametes, which fuse to form a zygote with a diploid nucleus. The resultant diploid nucleus divides many times by mitosis, but the cytoplasm does not divide, so the result is a multinucleate plasmodium.

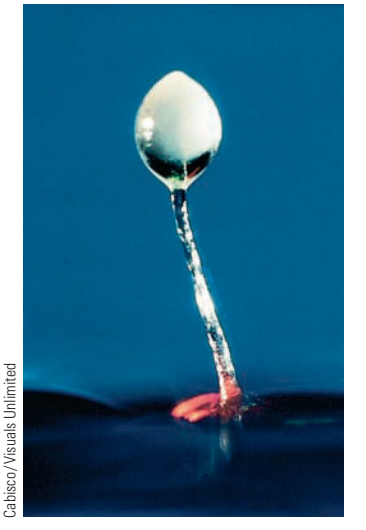
The plasmodial slime mold *Physarum polycephalum* is a model organism that researchers use to study many fundamental biological processes, such as growth, cytoplasmic streaming, and the function of the cytoskeleton.



(a)



(b)



(c)

Figure 25-24 ***Animated*** The cellular slime mold *Dictyostelium discoideum*

(a) Hundreds of amoeboid cells stream together and **(b)** form a migrating sluglike aggregate. When it stops migrating, the aggregate forms a fruiting body on a stalk. **(c)** The fruiting body releases spores, each of which opens in a favorable environment to liberate an amoeboid cell.

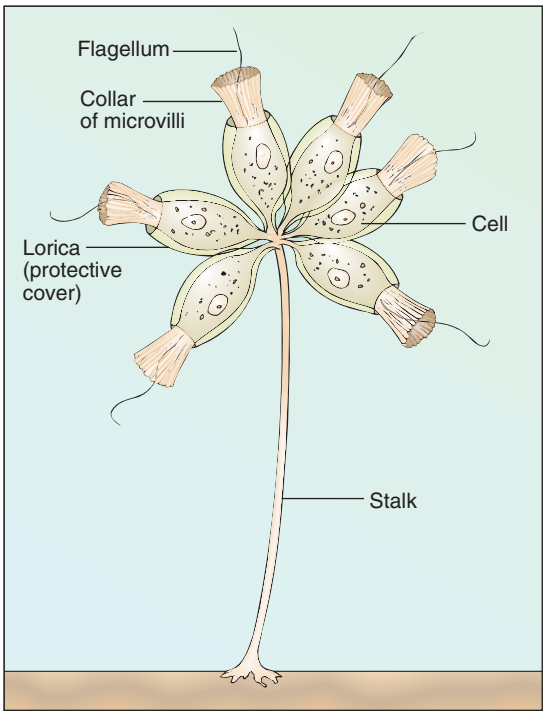


Figure 25-25 Choanoflagellate

Choanoflagellates are free-living zooflagellates that obtain food by waving their flagella, causing water currents to carry bacteria and other small particles of food into the collar of microvilli. A colonial form is shown. Each cell is 5 to 10 µm long, not including the flagellum.

Cellular slime molds feed as individual amoeboid cells

The **cellular slime molds** are amoebozoa with close affinities to amoebas and plasmodial slime molds. During its feeding stage, each cellular slime mold is an individual amoeboid cell that behaves as a separate, solitary organism. Each cell creeps over rotting logs and soil or swims in fresh water, ingesting bacteria and other particles of food as it goes. Each amoeboid cell has a haploid nucleus and reproduces by mitosis, as a true amoeba does.

When moisture or food becomes inadequate, certain cells send out a chemical signal, cyclic adenosine monophosphate (cAMP), that causes them to aggregate by the hundreds or thousands (Fig. 25-24a). During this stage the cells creep about for short distances as a single multicellular unit, called a **pseudoplasmodium,** or slug (Fig. 25-24b). Each cell of the slug retains its plasma membrane and individual identity. Eventually the slug settles and reorganizes, forming a stalked fruiting body containing spores (Fig. 25-24c). After being released, each spore opens and a single haploid amoeboid cell—the feeding stage—emerges. The spore-forming reproductive cycle is asexual, although sexual reproduction is observed occasionally. The life cycles of most cellular slime molds lack a flagellate stage.

The cellular slime mold *Dictyostelium discoideum* is a model organism for the study of cell differentiation, cell communication, and cell motility and adhesion. Its biology has been studied intensively, particularly as it relates to **cell signaling** molecules, such as cAMP, which are found in many organisms in addition to the cellular slime molds.

Opisthokonts include choanoflagellates, fungi, and animals

The **opisthokonts** are a monophyletic group that includes members of three kingdoms: choanoflagellates (kingdom Protista), fungi (kingdom Fungi), and animals (kingdom Animalia). Opisthokonts are characterized by a single posterior flagellum in flagellate cells such as sperm and motile spores. We consider fungi and animals in later chapters (see Chapters 26, 29, 30, and 31).

Choanoflagellates are collared zooflagellates. These small, inconspicuous marine and freshwater opisthokonts include both free-swimming and **sessile** species that are permanently attached by a thin stalk to bacteria-rich debris. Their single flagellum is surrounded at the base by a delicate collar of microvilli that trap food (Fig. 25-25). Choanoflagellates are of special interest because of their striking resemblance to collar cells in sponges (see Fig. 29-9). Other animal phyla, such as flatworms and rotifers, also contain choanoflagellate-like cells. Given structural similarities and comparative ribosomal RNA and DNA sequence data, many biologists hypothesize that choanoflagellates are related to the ancestor of animals—that is, living choanoflagellates and animals may share a common choanoflagellate-like ancestor.

Review

- What are some unique features of diplomonads?
- What characteristics do ciliates, dinoflagellates, and apicomplexans share?
- What are heterokonts?
- How do cercozoa and amoebozoa differ?
- Why do many biologists classify red algae and green algae with land plants?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Characterize the features common to the members of kingdom Protista (page 531).
- **Protists** are mostly unicellular eukaryotic organisms that live in aquatic environments.
- Protists range in size from microscopic **unicellular** organisms to **colonies** (loosely connected groups of cells) to **coenocytes** (multinucleate masses of cytoplasm) to **multicellular** organisms (composed of many cells).

2 Discuss in general terms the diversity inherent in the protist kingdom, including means of locomotion, modes of nutrition, interactions with other organisms, habitats, and modes of reproduction (page 531).
- Protists have various means of locomotion, including pseudopodia, flagella, and cilia. A few are nonmotile.
- Protists obtain their nutrients autotrophically or heterotrophically.

- Protists are free-living or symbiotic, with symbiotic relationships ranging from **mutualism** to **parasitism.**
- Most protists live in the ocean or in freshwater ponds, lakes, and streams. Parasitic protists live in the body fluids of their hosts.
- Many protists reproduce both sexually and asexually; others reproduce only asexually.

3 Discuss the hypothesis of serial endosymbiosis, and briefly explain some of the evidence that supports it (page 531).

- According to the hypothesis of **serial endosymbiosis,** mitochondria and chloroplasts arose from symbiotic relationships between larger cells and the smaller prokaryotes that were incorporated and lived within them.
- Mitochondria probably originated from aerobic bacteria. Ribosomal RNA data suggest that ancient purple bacteria were the ancestors of mitochondria.
- Chloroplasts of red algae, green algae, and plants probably arose in a single primary endosymbiotic event in which a cyanobacterium was incorporated into a cell. Multiple secondary endosymbioses led to chloroplasts in euglenoids, dinoflagellates, diatoms, golden algae, and brown algae and to the nonfunctional chloroplasts in apicomplexans.

4 Describe the kinds of data biologists use to classify eukaryotes (page 531).

- Relationships among protists are determined largely by **ultrastructure,** which is the fine details of cell structure revealed by electron microscopy, and comparative molecular data. Most biologists consider the protist kingdom as a **paraphyletic** group that contains some, but not all, descendants of a common eukaryotic ancestor.

5 Explain why zooflagellates are no longer classified in a single phylum, and distinguish among diplomonads, euglenoids, and choanoflagellates (page 534).

- **Zooflagellates** are mostly unicellular heterotrophs that move by means of whiplike **flagella.** Evidence indicates that zooflagellates are polyphyletic, and most biologists have separated them into several monophyletic groups.
- **Diplomonads** are **excavates,** organisms with a deep, or excavated, oral groove. Diplomonads that have one or two nuclei, no mitochondria, no Golgi complex, and up to eight flagella.
- **Euglenoids** are **discicristates,** organisms with disclike cristae in their mitochondria. Euglenoids are unicellular and flagellate. Some euglenoids are photosynthetic. The discicristate *Trypanosoma* causes African sleeping sickness.
- **Choanoflagellates** are **opisthokonts** (organisms with a single posterior flagellum in flagellate cells) and are related to fungi and animals. A collar of microvilli surrounds their single flagellum at the base.

6 Briefly describe and compare the following alveolates: ciliates, dinoflagellates, and apicomplexans (page 534).

- **Ciliates** are **alveolates** that move by hairlike **cilia,** have **micronuclei** (for sexual reproduction) and **macronuclei** (for controlling cell metabolism and growth), and undergo a complex sexual reproduction called **conjugation.**

ThomsonNOW™ Watch conjugation by clicking on the figure in ThomsonNOW.

- **Dinoflagellates** are mostly unicellular, biflagellate, photosynthetic alveolates of great ecological importance as major producers in marine ecosystems. Their **alveoli,** flattened vesicles under the plasma membrane, often contain cellulose plates impregnated with silicates. Some dinoflagellates produce toxic blooms known as **red tides.**
- **Apicomplexans** are parasites that produce **sporozoites** and are nonmotile. An apical complex of microtubules attaches the apicomplexan to its host cell. The apicomplexan *Plasmodium* causes malaria.

ThomsonNOW™ Watch the life cycle of the malaria parasite by clicking on the figure in ThomsonNOW.

7 Briefly describe and compare the following heterokonts: water molds, diatoms, golden algae, and brown algae (page 534).

- **Water molds** are **heterokonts,** organisms that have two different kinds of flagella. Water molds have a coenocytic **mycelium.** They reproduce asexually by forming biflagellate **zoospores** and sexually by forming **oospores.** The water mold *Phytophthora* causes serious plant diseases, such as late blight of potato and sudden oak death.
- **Diatoms,** which are major producers in aquatic ecosystems, are mostly unicellular heterokonts, with shells containing silica. Some diatoms are part of floating **plankton,** and others live on rocks and sediments where they move by gliding.
- **Golden algae** are mostly unicellular, biflagellate freshwater and marine heterokonts that are of ecological importance as a major component of the ocean's extremely minute **nanoplankton. Coccolithophorids** are golden algae covered by tiny, overlapping scales of calcium carbonate.
- **Brown algae** are multicellular heterokonts that are ecologically important in cooler ocean waters. The largest brown algae (kelps) possess leaflike **blades,** stemlike **stipes,** anchoring **holdfasts,** and gas-filled bladders for buoyancy.

8 Describe the foraminiferans and actinopods, and explain why many biologists classify them in the monophyletic group cercozoa (page 534).

- The **cercozoa** are amoeboid cells that often have hard outer shells, called **tests,** through which cytoplasmic projections extend.
- **Foraminiferans** secrete many-chambered tests with pores through which cytoplasmic projections extend to move and obtain food.
- **Actinopods** are mostly marine plankton that obtain food by means of **axopods,** slender cytoplasmic projections that extend through pores in their shells. **Radiolarians** are actinopods with glassy shells.

9 Support the hypothesis that red algae and green algae should be included in a monophyletic group with land plants (page 534).

- Red algae, green algae, and land plants, collectively called **plants,** are considered a monophyletic group based on molecular data and on the presence of chloroplasts bounded by outer and inner membranes.
- **Red algae,** which are mostly multicellular seaweeds, are ecologically important in warm tropical ocean waters. Red algae that incorporate calcium carbonate in their cell walls are important in reef building.
- **Green algae** exhibit a wide diversity in size, structural complexity, and reproduction. Botanists hypothesize that ancestral green algae gave rise to land plants.

10 Briefly describe and compare the following amoebozoa: amoebas, plasmodial slime molds, and cellular slime molds (page 534).

- **Amoebas** move and obtain food by **phagocytosis,** using cytoplasmic extensions called **pseudopodia.** The parasitic amoeba *Entamoeba histolytica* causes amoebic dysentery.
- The feeding stage of **plasmodial slime molds** is a multinucleate **plasmodium.** Reproduction is by haploid spores produced within **sporangia.**
- **Cellular slime molds** feed as individual amoeboid cells. They reproduce by aggregating into a **pseudoplasmodium** (slug), then forming asexual spores.

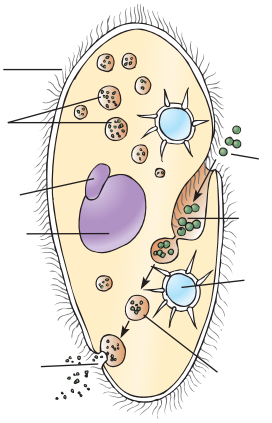
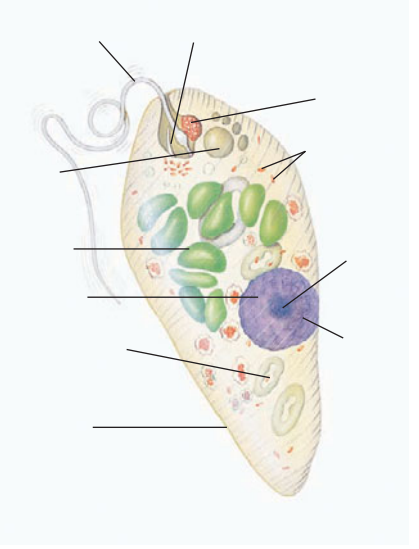
TEST YOUR UNDERSTANDING

1. Which of the following is *not* true of the protists? (a) they are unicellular, colonial, coenocytic, or simple multicellular organisms (b) their cilia and flagella have a 9 + 2 arrangement of microtubules (c) they are prokaryotic, as bacteria and archaea are (d) some are free-living, and some are endosymbionts (e) most are aquatic and live in the ocean or in freshwater ponds
2. Amoebas move and obtain food by means of (a) pseudopodia (b) flagella (c) cilia (d) gametangia (e) endosymbiosis
3. Foraminiferans (a) are endosymbionts in many marine invertebrates (b) were responsible for the Irish potato famine in the 19th century (c) secrete many-chambered tests with pores through which cytoplasmic extensions project (d) have numerous axopods that may aid in trapping and holding prey (e) contain phycocyanin and phycoerythrin, pigments found in no other protist group
4. Unicellular protists that are free-living or parasitic, move by means of flagella, and do not photosynthesize are informally called (a) euglenoids (b) dinoflagellates (c) myxamoebas (d) zooflagellates (e) apicomplexans
5. *Paramecium* and other ciliates often display a sexual phenomenon called (a) oogamy (b) conjugation (c) anisogamy (d) red tide (e) alternation of generations
6. Parasitic alveolates that form spores at some stage in their life belong to which group? (a) actinopods (b) ciliates (c) coccolithophorids (d) apicomplexans (e) dinoflagellates
7. Malaria (a) is transmitted by the bite of a female tsetse fly (b) is caused by a parasitic zooflagellate, *Giardia intestinalis* (c) is a serious form of amoebic dysentery caused by *Entamoeba histolytica* (d) is caused by an apicomplexan that spends part of its life cycle in the *Anopheles* mosquito and part in humans (e) is transmitted when people drink water tainted by a red tide
8. Alveolates characterized by two flagella, one wrapped around the center of the cell like a belt and the other projecting behind the cell, are (a) actinopods (b) ciliates (c) coccolithophorids (d) apicomplexans (e) dinoflagellates
9. Photosynthetic protists with shells composed of two halves that fit together like a petri dish are (a) golden algae (b) diatoms (c) euglenoids (d) brown algae (e) foraminiferans
10. Chlorophyll *a,* chlorophyll *b,* and carotenoids are found in (a) green algae, red algae, and land plants (b) green algae, euglenoids, and land plants (c) brown algae, green algae, and golden algae (d) brown algae, diatoms, and golden algae (e) green algae, euglenoids, and diatoms
11. Which protists have photosynthetic pigments similar to those of the cyanobacteria? (a) golden algae (b) diatoms (c) euglenoids (d) brown algae (e) red algae
12. The multicellular bodies of _____ are differentiated into blades, stipes, holdfasts, and gas-filled floats. (a) golden algae (b) diatoms (c) euglenoids (d) kelps (e) green algae
13. The feeding stage of plasmodial slime molds is a multinucleate (a) plasmodium (b) pseudoplasmodium (c) pseudopodium (d) gametangium (e) mycelium
14. Cellular slime molds (a) include *Physarum* and *Phytophthora* (b) are more closely related to prokaryotes than are any other protists (c) are responsible for late blight of potatoes, which led to starvation in Ireland in the 1840s (d) have isogamous sexual reproduction (e) form a pseudoplasmodium when cells aggregate in response to cyclic AMP
15. Water molds reproduce asexually by forming _____ and sexually by forming _____. (a) oospores; holdfasts (b) zoospores; zooxanthellae (c) zoospores; oospores (d) holdfasts; isogametes (e) oospores; isogametes
16. Label the diagrams. Use Figures 25-7b and 25-6b to check your answers.





CRITICAL THINKING

1. **Evolution Link.** Why is the protist kingdom considered paraphyletic? Use Figure 25-3 to help explain your answer.
2. **Analyzing Data.** Where on Figure 25-3 would you place the common ancestor of brown algae and water molds? The common ancestor of animals and fungi? The common ancestor of animals and plants?
3. **Analyzing Data.** Given what you have learned about dinoflagellates, where would you place them in the Figure 25-3 cladogram? Justify your decision.
4. **Analyzing Data.** In this chapter we discussed the hypothesis that choanoflagellates and animals share a common choanoflagellate-like ancestor. If this hypothesis is true, where would you place the choanoflagellate branch on Figure 25-3? Explain.

Kingdom Fungi

Jeff Lepore/Photo Researchers, Inc.

Fungal spores. The rounded earthstar (*Geastrum saccatum*) releases a puff of microscopic spores after the sac, which is about 1.3 cm (0.5 in) wide, is hit by a raindrop. This fungus is common in leaf litter under trees throughout North America.

KEY CONCEPTS

Fungi are eukaryotic heterotrophs that absorb nutrients from their surroundings.

A fungus may be a unicellular yeast or a filamentous, multicellular mold consisting of long, branched hyphae that form a mycelium.

Most fungi reproduce both asexually and sexually by means of spores.

According to current hypotheses, fungi evolved from a unicellular, flagellate protist and diverged into five main groups.

Fungi are of major ecological, economic, biological, and medical importance.

Mushrooms, morels, and truffles, delights of the gourmet, share a recent common ancestry with baker's yeast, the black mold that forms on stale bread, and the mildew that collects on damp shower curtains. All of these life-forms belong to kingdom Fungi, a diverse group of about 100,000 known species, most of which are terrestrial. Some biologists estimate that there may be as many as 1.5 million species of fungi.

Fungi grow best in moist habitats, but they are found universally wherever organic material is available. They require moisture to grow, and they obtain water from a humid atmosphere as well as from the medium on which they live. When the environment becomes dry, fungi survive by going into a resting stage or by producing spores (see photograph) that resist desiccation (drying out).

Some fungi grow to enormous size. In Washington State, a fungal clone (*Armillaria ostoyae*) has been identified that covers more than 1500 acres. This giant fungus, which is mainly underground, developed from a single spore that germinated more than a thousand years ago. The fungus has fragmented and is no longer one continuous body.

Like prokaryotes, most fungi are decomposers that obtain nutrients from dead organic matter. They are vital members of ecosystems because they break down the organic compounds found in dead organisms, leaves, garbage, sewage, and other waste. When they break down organic compounds, carbon and other elements are released into the environment, where they are recycled.

Many fungi form vital symbiotic relationships. For example, most terrestrial plants have fungal partners that live in close as-

sociation with their roots. The fungi help the plants obtain phosphate ions and other needed minerals from the soil. In exchange, the plants provide the fungi with organic nutrients. Some fungi live symbiotically with algae and cyanobacteria as lichens. Others are parasites and pathogens that cause disease in animals or plants. ■

CHARACTERISTICS OF FUNGI

Learning Objectives

1 Describe the distinguishing characteristics of kingdom Fungi.
2 Describe the body plan of a fungus.
3 Describe the life cycle of a typical fungus, including sexual and asexual reproduction.

Although they vary strikingly in size and shape, all **fungi** (sing., *fungus*) are eukaryotes; their cells contain membrane-enclosed nuclei, mitochondria, and other membranous organelles. Fungi share certain key characters, including their way of obtaining nutrition.

The optimum pH for most species is about 5.6, but various fungi can tolerate and grow in environments where the pH ranges from 2 to 9. Many fungi are less sensitive to high osmotic pressures than are bacteria. As a result, they can grow in concentrated salt solutions or in sugar solutions such as jelly, which discourage or prevent bacterial growth. Fungi also thrive over a wide temperature range. Even refrigerated food may be invaded by fungi.

Fungi absorb food from the environment

Unlike plants, fungi cannot produce their own organic materials from a simple carbon source (carbon dioxide). Like animals, fungi are heterotrophs. They depend on preformed carbon molecules produced by other organisms. However, fungi do not ingest food and then digest it in the body as animals do. Instead, they infiltrate a food source and secrete digestive enzymes onto it. Digestion takes place outside the body. When complex molecules are broken down into smaller compounds, the fungus absorbs the predigested food into its body.

The fungus is very efficient at absorbing nutrients and growing. It rapidly converts nutrients into new cell material. If excessive amounts of nutrients are available, fungi store them, usually as lipid droplets or glycogen.

Fungi have cell walls that contain chitin

Like the cells of bacteria, certain protists, and plants, fungal cells are enclosed by cell walls during at least some stage in their life cycle. Fungal cell walls, however, have a different chemical composition from cell walls of other organisms. In most fungi, the cell wall consists of complex carbohydrates, including **chitin,** a polymer that consists of subunits of a nitrogen-containing sugar (see Fig. 3-11). Chitin is resistant to breakdown by most microorganisms. Chitin is also a component of the external skeletons of insects and other arthropods.

Most fungi have a filamentous body plan

Mycologists, biologists who study fungi, identify two main types of fungi, based on body plan: yeasts and molds. The simplest fungi are the **yeasts,** which are unicellular, with a round or oval shape. Yeasts are widely distributed in the soil; on leaves, fruits, and cured meats; and on and in our bodies. Yeasts are essential in making bread and fermenting alcoholic beverages. Some yeasts have been very important in medicine and as model organisms in modern biology (discussed later in this chapter).

Most fungi are **molds.** The vegetative (nonreproductive) body plan of molds consists of long, branched, threadlike filaments called **hyphae** (sing., *hypha*) (Fig. 26-1a and b). Hyphae are an adaptation to the fungal mode of nutrition. Growth occurs at the tips of the hyphae; as the hyphae elongate, the fungus grows into and infiltrates food sources. The fungus absorbs nutrients through its very large surface area.

A hypha first develops from a unicellular spore. As hyphae grow, they form a tangled mass or tissuelike aggregation known as a **mycelium** (pl., *mycelia*). The cobweblike mold sometimes seen on bread is the mycelium of a fungus. What is not seen is the extensive mycelium that grows into the bread. Depending on environmental conditions, some fungi can alternate between a yeast phase and a phase in which they produce hyphae.

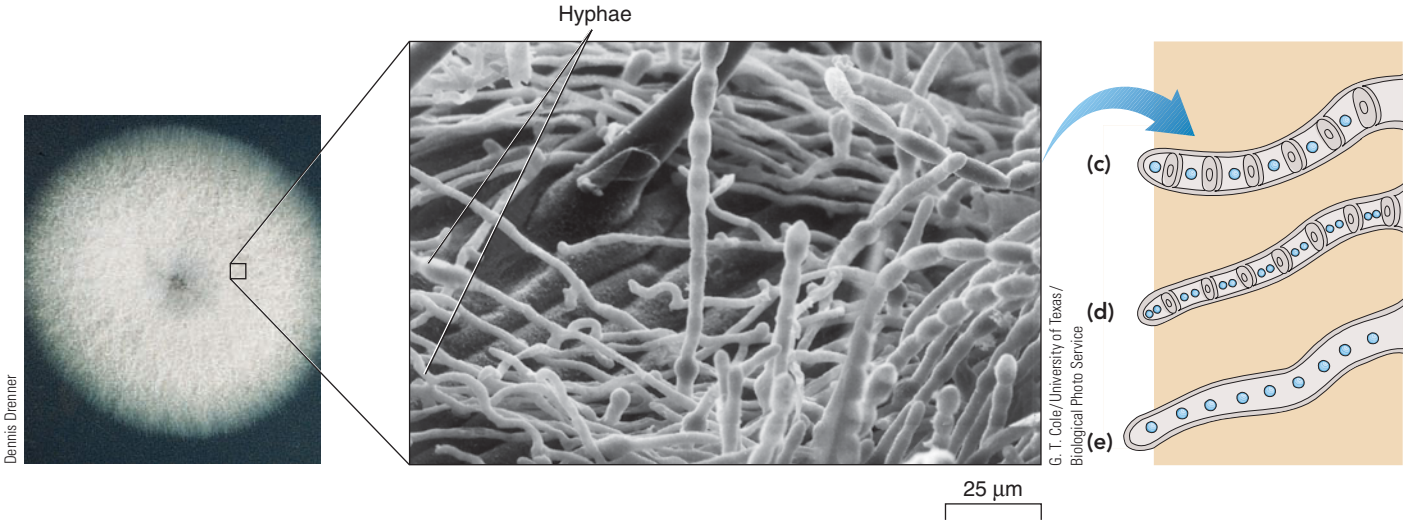
In most fungi, hyphae are divided by cross walls, called **septa** (sing., *septum*), into individual cells containing one or more nuclei (Fig. 26-1c and d). As we will discuss, the presence of septa is an important character in the two largest fungal phyla (which include the most complex fungi). The septa of many fungi are perforated by a pore that may be large enough to permit organelles to flow from cell to cell. Some fungi, called **coenocytic** fungi, lack septa. In these species, nuclear division is not followed by cytoplasmic division. As a result, a coenocytic fungus is one elongated, multinucleated, giant cell (Fig. 26-1e).

Fungi reproduce by spores

Most fungi reproduce by means of microscopic **spores,** reproductive cells that can develop into new organisms (Fig. 26-2). In most groups, spores are nonmotile. They are dispersed by wind, water, or animals. The air we breathe is filled with hundreds of thousands of fungal spores.

Fungi produce spores either sexually or asexually. With asexual reproduction, new fungi are produced quickly, but there is little genetic variability. Sexual reproduction involves meiosis and generates new genotypes.

Spores are usually produced on specialized aerial hyphae or in fruiting structures. Positioned up above the ground, spores can



(a) A fungal mycelium, a mass of threadlike hyphae (10 cm [4 in] wide), growing on agar in a culture dish. In nature, fungal mycelia are rarely so symmetric.

(b) SEM of a mycelium of *Blumeria graminis* growing on a leaf (*darker area underneath the mycelium*).

(c) A hypha divided into cells by septa; each cell is monokaryotic. In some taxa the septa are perforated (*as shown*).

(d) A septate hypha in which each cell is dikaryotic (has two nuclei).

(e) A coenocytic hypha.

Figure 26-1 Fungus body plan

be easily dispersed. Structures in which spores are produced are called **sporangia** (sing., *sporangium*). The aerial hyphae of some fungi produce spores in large, complex reproductive structures, referred to as **fruiting bodies.** The familiar part of a mushroom is a large fruiting body. We do not normally see the bulk of the fungus, a nearly invisible mycelium buried out of sight in the rotting material or soil on which it grows.

Many fungi reproduce asexually

Yeasts reproduce asexually, primarily by forming buds that pinch off from the parent cell (Fig. 26-3). Many species of molds also reproduce asexually. Spores are produced by mitosis and then released into the air or water. **Conidiophores** (from the Greek, meaning "dust-bearers") are specialized hyphae that produce asexual spores called **conidia** (sing., *conidium*). The arrangement of conidia on conidiophores varies from species to species.

Most fungi reproduce sexually

Many mold species reproduce sexually when they come into contact with other mating types. In contrast to the majority of animal and plant cells, most fungal cells contain haploid nuclei. In sexual reproduction, the hyphae of two genetically compatible mating types come together, and their cytoplasm fuses, a process known as **plasmogamy.** The resulting cell has two haploid nuclei, one from each fungus. This cell gives rise by mitosis to other cells with two nuclei. At some point the two haploid nuclei fuse. This process, called **karyogamy,** results in a cell containing a diploid nucleus known as a **zygote nucleus.** In some groups, the zygote nucleus is the only diploid nucleus.

In the two largest fungal phyla, the ascomycetes and basidiomycetes (discussed later in this chapter), plasmogamy occurs (the hyphae fuse), but karyogamy (the fusion of the two different nuclei) does not follow immediately. For a time, the nuclei re-

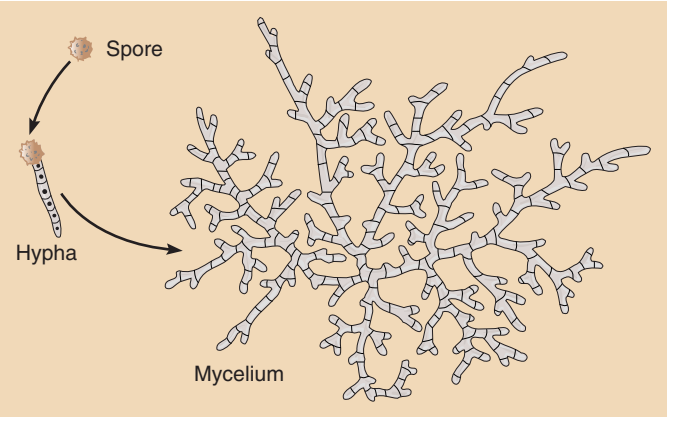


Figure 26-2 ***Animated*** Germination of a spore to form a mycelium

SciMat/Photo Researchers, Inc.

(b) SEM (color enhanced) of *Saccharomyces cerevisiae*. Also known as baker's or brewer's yeast, this fungus can ferment sugar, producing carbon dioxide and alcohol in the process. It is used in brewing beer, in wine production, and in baking bread. Note that several yeast cells are budding, a form of sexual reproduction.

Figure 26-3 Yeasts are unicellular fungi

main separate within the fungal cytoplasm. Hyphae that contain two genetically distinct, sexually compatible nuclei within each cell are described as **dikaryotic** (see Fig. 26-1d). This condition is referred to as $n + n$ rather than $2n$, because there are two separate haploid nuclei. Hyphae that contain only one nucleus per cell are described as **monokaryotic.** The presence of a dikaryotic stage is an important defining character of the ascomycetes and basidiomycetes.

Fungi are a diverse group with many variations in their life cycles. Most fungi (but not all) reproduce both asexually and sexually. Figure 26-4 illustrates a generalized life cycle. When a fungal spore comes into contact with an appropriate food source, the spore germinates and begins to grow. A threadlike hypha emerges from the tiny spore and grows at its tip, branching frequently. In many fungi, cells from individuals of two different mating types fuse (plasmogamy), resulting in a dikaryotic mycelium. In most fungi, karyogamy (fusion of the two nuclei) occurs, producing a zygote nucleus that undergoes meiosis. Each haploid spore produced can germinate and develop into a new mycelium by mitosis. In asexual reproduction, spore-producing structures develop and spores are produced by mitosis.

Fungi communicate chemically by secreting signaling molecules called **pheromones.** At least one pheromone has been identified in each fungal phylum. The pheromone binds with a compatible receptor on a different mating type. For example, in the phylum Zygomycetes, a pheromone induces the formation of specialized aerial hyphae. Another pheromone causes the tips of aerial hyphae of opposite mating types to grow toward each other and fuse prior to sexual reproduction.

Review

- What characteristics distinguish fungi from other organisms?
- How does the body of a yeast differ from that of a mold?
- Draw a generalized life cycle of a fungus.

FUNGAL DIVERSITY

Learning Objectives

4 Give arguments to support the hypothesis that fungi are opisthokonts, more closely related to animals than to plants.

5 Give arguments to support the hypothesis that chytrids may have been the earliest fungal group to evolve from the most recent common ancestor of fungi.

6 List distinguishing characteristics, describe a typical life cycle, and give examples of each of the following fungal groups: chytridiomycetes, zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes.

For centuries, biologists classified fungi in the plant kingdom. However, some systematists disagreed with this classification, arguing that there are important structural differences between fungi and plants. Like plants, fungi have cell walls; but unlike plants, fungal cell walls do not contain cellulose. Rather, they contain chitin, a polysaccharide found in insect skeletons. The fungal mode of nutrition is also very different from that of plants Whereas plants are photosynthetic autotrophs, fungi, like animals, are heterotrophs. In 1969, R. H. Whittaker proposed that fungi be assigned to a separate kingdom—Fungi.

As with systematics for other kingdoms, fungal systematics is a challenging and continuously changing process. For example, slime molds and water molds were formerly classified as fungi but have now been assigned to the protist kingdom (see Chapter 25).

Fungi are assigned to the opisthokont clade

As discussed in Chapter 25, fungi, animals, and a few protists, including the choanoflagellates, form a monophyletic group, the **opisthokonts.** Both genetic and structural similarities sup-

Key Point

Most fungi can reproduce both asexually (rapid proliferation) and sexually (new genotypes).

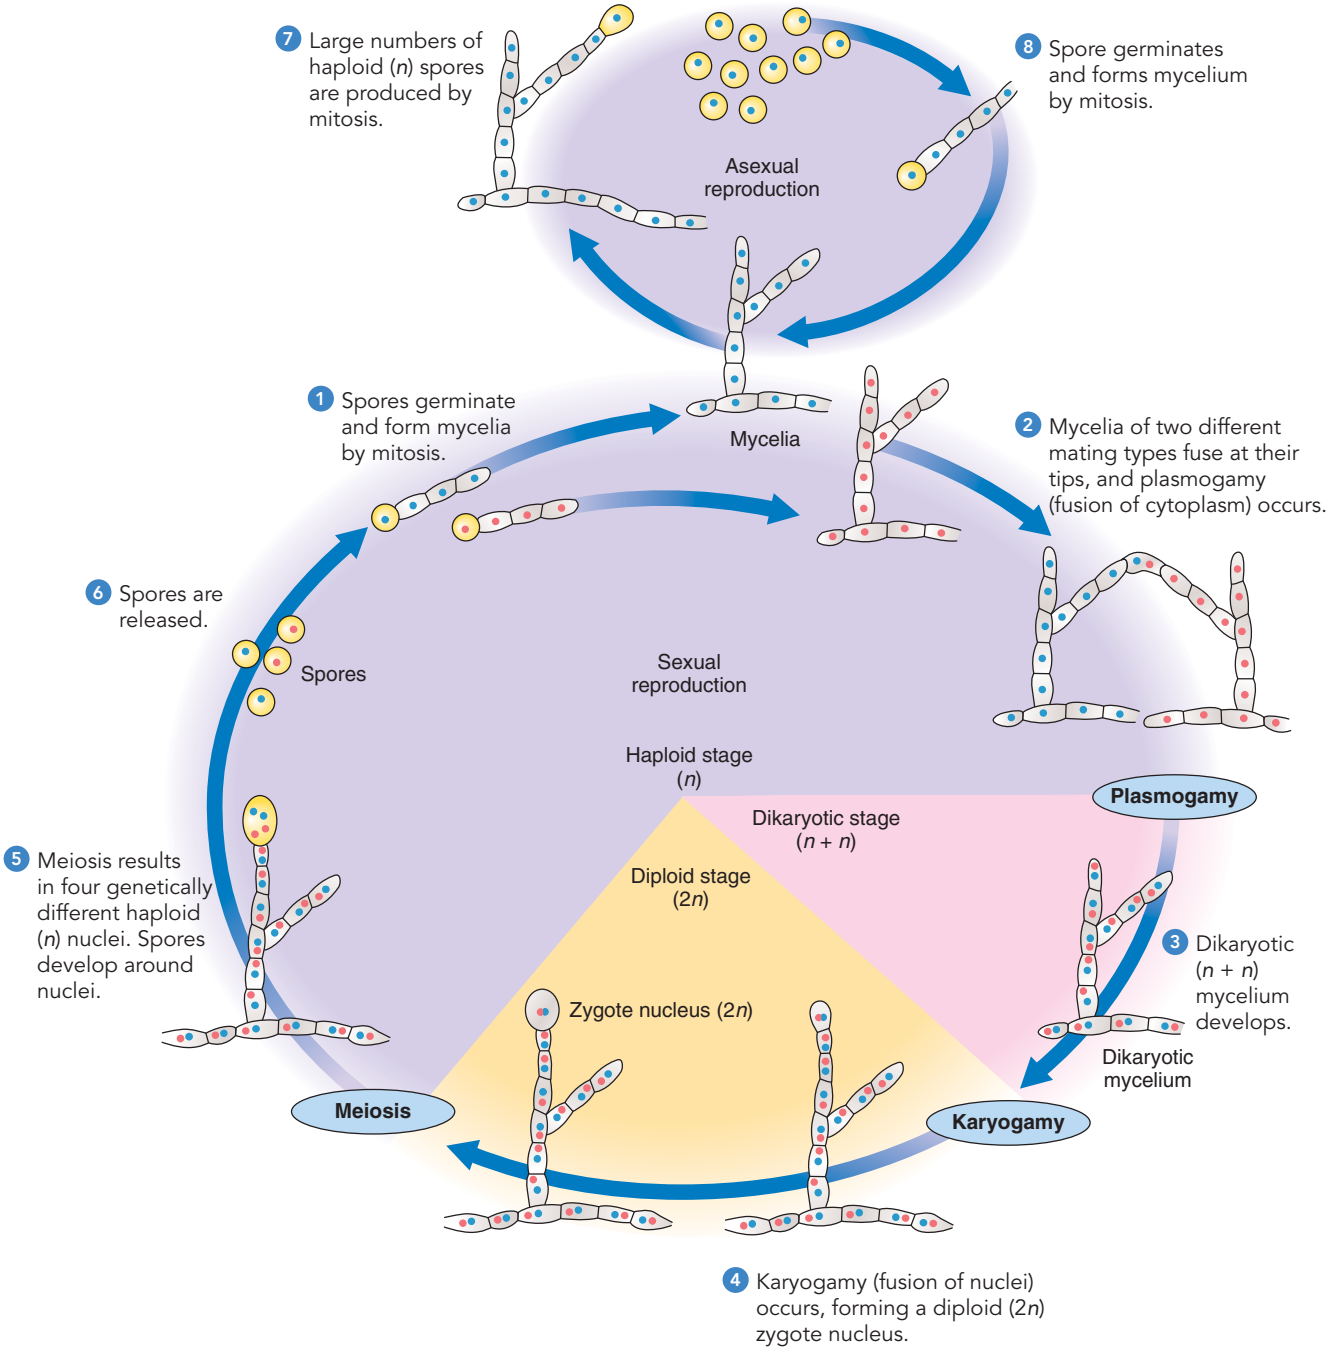

Figure 26-4 The basic sequence of events in most fungal life cycles

port this grouping. Like animals, fungi have platelike cristae in their mitochondria. Another character shared by this clade is that flagellate cells propel themselves with a single posterior flagellum. In other eukaryote groups, flagellate cells move by means of one or more anterior flagella. Based on structural characters and on molecular data, the fungi, once considered part of the plant kingdom, are now viewed as more closely related to animals.

Diverse groups of fungi have evolved

Fossil evidence has not been very helpful to systematists studying evolutionary relationships among different fungal groups. Most fossilized fungi recovered to date have been microscopic. For example, fossilized fungal spores have been found in amber more than 225 million years old, and fossils of hyphae associated with cyanobacteria or algae have been dated as more than 550 million years old. Few large fungal fossils, such as mushrooms, have been found.

Historically, fungi have been classified mainly on the characteristics of their sexual spores and fruiting bodies. More recently, molecular data, such as comparative DNA and RNA sequences, have clarified relationships among fungal groups. Currently, mycologists assign fungi to five main phyla: Chytridiomycota, Zygomycota, Glomeromycota, Ascomycota, and Basidiomycota (Fig. 26-5 and Table 26-1). Microsporidia, a group of intracellular parasites, are classified in this text with the zygomycetes. About 95% of all named fungi have been assigned to phyla Ascomycota and Basidiomycota. These phyla are considered sister taxa because they share a more recent common ancestor with each other than either does with any other group. Fungi of phyla Ascomycota and Basidiomycota have septate hyphae and a dikaryotic stage during the sexual part of their life cycle.

Until recently, mycologists had grouped about 25,000 species of fungi that did not fit into the major groups as deuteromycetes (phylum Deuteromycota). This was a polyphyletic group (they do not share a recent common ancestor) lumped together simply as a matter of convenience. Mycologists classified fungi as deuteromycetes if no sexual stage had been observed for them at any point during their life cycle. Some of these fungi have lost the ability to reproduce sexually, whereas others reproduce sexually only rarely. Most fungi classified as deuteromycetes reproduce only by means of conidia (as ascomycetes do). Mycologists have identified relationships between deuteromycetes and their sexually reproducing relatives, based on DNA comparisons among various species. Most of the deuteromycetes have been reassigned to phylum Ascomycota, and a few reassigned to phylum Basidiomycota. (By convention, the asexual stage is still identified as a deuteromycete.)

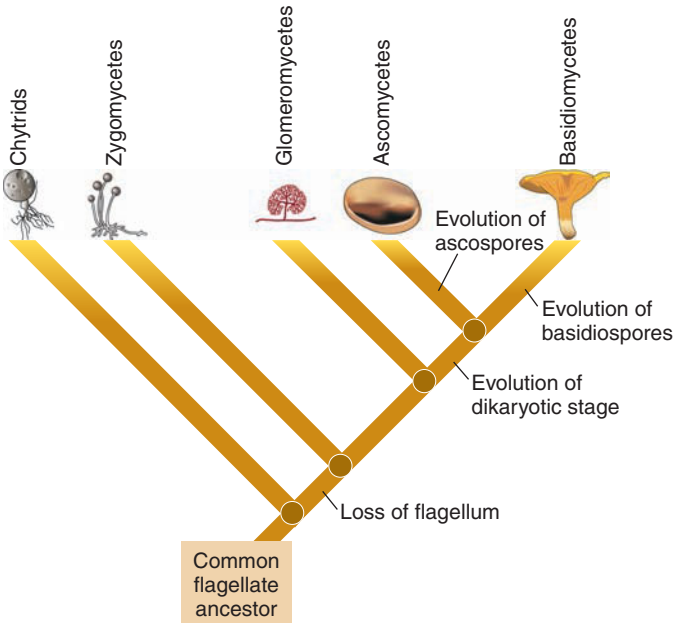

Figure 26-5 Fungal evolution: cladogram of major phyla of fungi

This cladogram shows phylogenetic relationships among living fungi, based on comparisons of ribosomal and nuclear gene sequence data for many species. The chytrids were the lineage that branched off first during fungal evolution. Note that ascomycetes and basidiomycetes are sister clades. Remember that the phylogeny of fungi is a work in process.

Chytrids have flagellate spores

At one time, biologists considered the **chytrids,** also known as **chytridiomycetes** (phylum Chytridiomycota), to be funguslike protists, similar in many respects to the water molds. However, both structural and molecular characters indicate that the approximately 1000 species of chytridiomycetes are members of kingdom Fungi. Like fungi, their cell walls contain chitin. Molecular comparisons, particularly of DNA and RNA sequences, have provided compelling evidence that chytrids are indeed fungi.

Chytrids are small, relatively simple fungi that inhabit ponds and damp soil. A few species have been found in salt water. Most chytrids are decomposers that degrade organic matter. However, a few species cause disease in plants and animals. Although not identified until 1998, a parasitic chytrid has been partly responsible for declining amphibian populations dating back to the 1970s. Infected frogs have been identified in many parts of the world (see *Focus On: Declining Amphibian Populations,* in Chapter 56).

Most chytrids are unicellular or composed of a few cells that form a simple body, called a **thallus.** (The term *thallus* describes the simple body plan of certain algae, fungi, or plants.) The thallus may have slender extensions, called **rhizoids,** that anchor it to a food source and absorb food (Fig. 26-6). Chytrids are the only fungi that have flagellate cells. Their spores bear a single, posterior flagellum. Sexual reproduction has not been identified in most chytrids. Species that reproduce sexually have flagellate gametes.

Some chytrids produce branched, coenocytic mycelia. *Allomyces,* a large, common chytrid, has an unusual life cycle compared to that of most fungi. It undergoes an **alternation of generations** (common in plants, but rare in fungi), spending part of its life as a multicellular haploid (n) thallus and part as a multicellular diploid ($2n$) thallus (Fig. 26-7). The haploid and diploid thalli are similar in appearance. At the tips of its branches, the haploid thallus bears two types of sporangia, structures in which gametes form by mitosis. Each sporangium produces a different type of flagellate gamete.

TABLE 26-1

Characteristics of Currently Recognized Phyla of Kingdom Fungi

Phylum and Common Types	Asexual Reproduction	Sexual Reproduction	Other Key Characters
Chytridiomycota (chytrids or chytridiomycetes) *Allomyces*	Flagellate, diploid zoospores produced by mitosis in zoosporangia	Flagellate, haploid gametes in some species	Haploid zoospores produced in resting sporangia; form haploid thallus
Zygomycota (zygomycetes) Black bread mold. Microsporidia are classified with the zygomycetes	Haploid spores produced in sporangia	Zygospores develop in zygosporangia	Important decomposers; some are insect parasites. Microsporidia are opportunistic pathogens that infect animals.
Glomeromycota (glomeromycetes)	Large, multinucleate blastospores	Has not been observed	Form arbuscular mycorrhizae with plant roots
Ascomycota (ascomycetes) Yeasts, powdery mildews, molds, morels, truffles	Conidia pinch off from conidiophores	Ascospores develop in asci	Have a dikaryotic stage; form important symbiotic relationships as lichens and mycorrhizae
Basidiomycota (basidiomycetes or club fungi) Mushrooms, bracket fungi, puffballs, rusts, smuts	Uncommon	Basidiospores develop on club-shaped basidia	Have a dikaryotic stage; many form mycorrhizae with tree roots

Each type of gamete secretes a pheromone that attracts the other type. The two types of gametes fuse; plasmogamy and karyogamy occur, forming a motile zygote. Each zygote can develop into a diploid thallus. The thallus bears two kinds of spore cases, zoosporangia and resting sporangia. Zoosporangia produce flagellate diploid **zoospores** that develop into new diploid thalli. Meiosis occurs within resting sporangia, producing recombinant haploid zoospores. Each zoospore has the potential to develop into a haploid thallus.

Molecular evidence suggests that chytrids were probably the earliest fungal group to evolve. Scientists hypothesize that the common ancestor of all plants, fungi, and animals was a flagellated ancient protist. Chytrids, which produce flagellate cells at some stage in their life history, have retained this feature of their protist ancestor. No other fungal group has flagellate cells. At some point in their evolutionary history, other fungal groups apparently lost the ability to produce motile cells, perhaps during the transition from aquatic to terrestrial habitats.

Zygomycetes reproduce sexually by forming zygospores

Mycologists have named more than 1100 species of **zygomycetes** (phylum Zygomycota). Of all the fungi, members of this taxon appear most closely related to the chytrids. However, zygomycetes are not a monophyletic group, and as mycologists learn more about fungal relationships, they may divide this phylum into several taxa or reassign some of its members to other existing phyla.

Most zygomycetes are decomposers that live in the soil on decaying plant or animal matter (Fig. 26-8). Some zygomycetes form mycorrhizal relationships with plant roots. A few species cause disease in plants and animals, including humans.

Figure 26-6 Chytrid

Nomarski differential interference micrograph of a common chytrid (*Chytridium convervae*). Many chytrids have a microscopic body form consisting of a rounded, coenocytic thallus and branched rhizoids that superficially resemble roots. The rhizoids may anchor the chytrid thallus and absorb predigested food.

Key Point

Chytrids have flagellate reproductive cells.

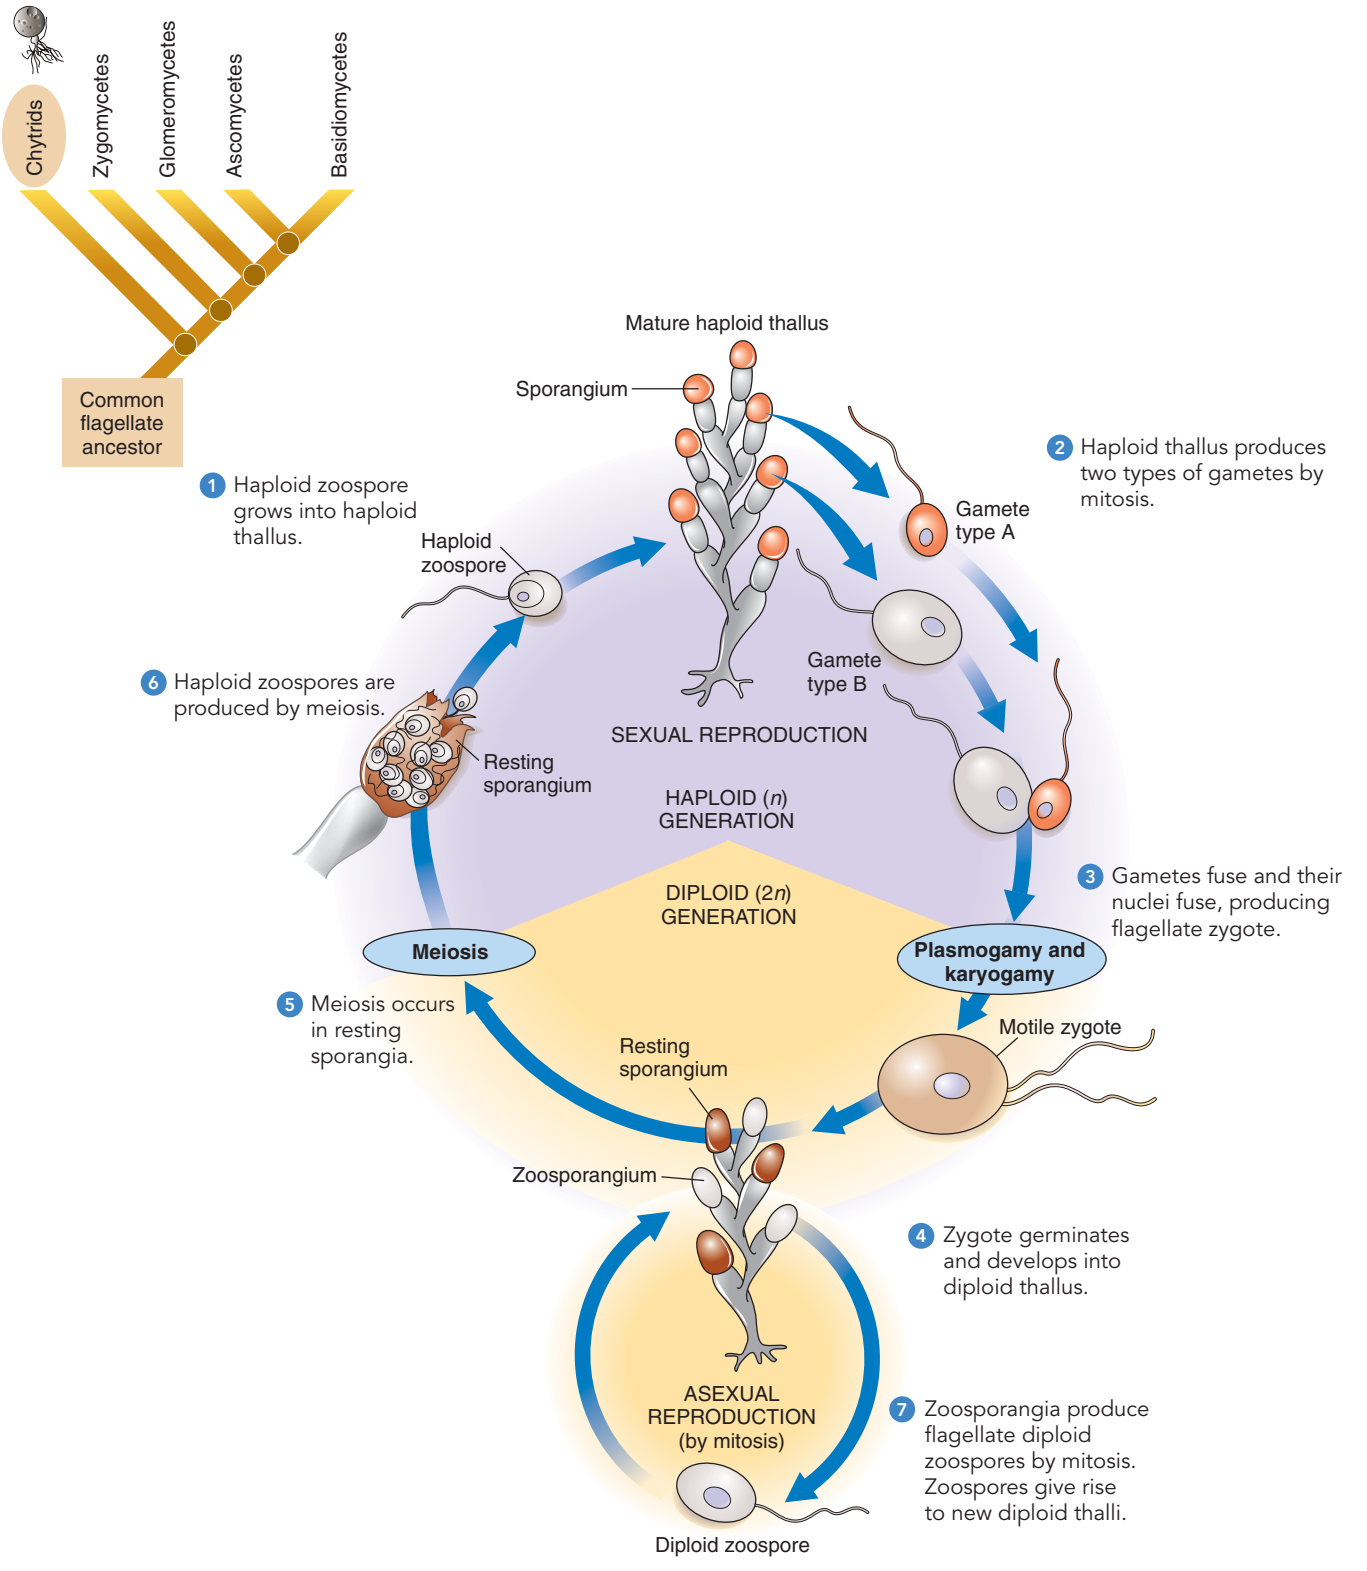

Figure 26-7 Life cycle of *Allomyces arbuscula*, a chytrid

Allomyces alternates between haploid and diploid stages, which are similar in appearance.

Cabisco/Visuals Unlimited

Figure 26-8 *Pilobolus,* a zygomycete that grows in animal dung

Stalked sporangia of *Pilobolus* protruding from a pile of dung, which contains an extensive mycelium of the fungus. The stalked sporangia, which are 5 to 10 mm tall, act like shotguns and forcefully discharge sporangia (the black tips) away from the dung onto nearby grass. When animals such as cattle or horses eat the grass, the spores pass unharmed through the animal's digestive tract and are deposited in a fresh pile of dung.

During sexual reproduction, zygomycetes produce sexual spores, called **zygospores.** The zygospores are typically produced in spore sacs called sporangia. The hyphae in zygomycetes are coenocytic; that is, they lack regularly spaced septa. However, septa do form to separate the hyphae from reproductive structures.

Perhaps the most familiar zygomycete is the black bread mold, *Rhizopus stolonifer,* a decomposer that breaks down bread and other foods. If preservatives are not added, bread left at room temperature often becomes covered with a black, fuzzy growth in a few days. Bread becomes moldy when a spore falls on it and then germinates and grows into a mycelium (Fig. 26-9). Hyphae penetrate the bread and absorb nutrients. Eventually, certain hyphae grow upward and develop sporangia at their tips. Clusters of more than 50,000 black asexual spores can develop within each sporangium. The spores are released when the delicate sporangium ruptures. The spores give the black bread mold its characteristic color.

Sexual reproduction in the black bread mold occurs when the hyphae of two different mating types, designated plus (+) and minus (−), grow into contact with one another. The bread mold is **heterothallic,** meaning that an individual fungal hypha is self-sterile and mates only with a hypha of a different mating type. That is, sexual reproduction occurs only between a member of a (+) strain and one of a (−) strain, not between members of two (+) strains or members of two (−) strains. Because there are no physical differences between the two mating types, it is not appropriate to refer to them as "male" and "female."

When hyphae of opposite mating types grow in close proximity, they signal one another with pheromones. In response to these chemical signals, the tips of the hyphae come together and form **gametangia,** which serve as gametes. Plasmogamy occurs as the gametangia fuse. Then karyogamy occurs as the (+) and (−) nuclei fuse to form the diploid zygote nucleus. The zygote develops into a zygospore. Zygospores are surrounded by a thick protective covering called a **zygosporangium,** which contains many diploid nuclei.

The zygospore may lie dormant for several months and can survive desiccation and extreme temperatures. Meiosis probably occurs at or just before germination of the zygospore.

When the zygospore germinates, an aerial hypha develops with a sporangium at the tip. Mitosis within the sporangium produces haploid spores. These spores may be all (+) spores, all (−) spores, or a mixture of (+) and (−) spores. When released, the spores germinate to form new hyphae. Only the zygote and zygospore of a black bread mold are diploid; all the hyphae and the asexual spores are haploid.

Microsporidia have been a taxonomic mystery

Microsporidia are small, unicellular parasites that infect eukaryotic cells. At present, these common pathogens are classified with the zygomycetes. They are opportunistic pathogens that infect animals. For example, microsporidia infect people with compromised immune systems, such as those with AIDS. Microsporidia cause a variety of diseases involving many organ systems, and some species cause lethal infections. Some species of microsporidia appear to be host specific.

Microsporidia have two developmental stages inside their host: a feeding stage and a reproductive stage. Some microsporidian species divide by binary fission, and others divide into several cells. Some species undergo nuclear fusion and meiosis before producing spores. The spores, which have thick protective walls, can pass from cell to cell inside the host or can be excreted in urine or through the skin. The spores, the only stage with distinct characters, are used to identify groups.

Each spore is equipped with a unique structure, a long, threadlike **polar tube.** When the spore enters the gut of a new host, it discharges its polar tube and penetrates the lining of the gut. Acting as a hypodermic needle, the polar tube injects the contents of the spore into the host cell (Fig. 26-10).

Microbiologists estimate that there may be more than a million species of microsporidia, but only about 1500 species have been named. Microsporidia were originally classified with yeasts and bacteria. In 1976, they were assigned to the protozoa. In the 1980s, biologists viewed microsporidia as the most primitive example of a eukaryote. They were the smallest and simplest known eukaryotes, and the genomes of some species are smaller than most bacterial genomes. Microsporidia lack mitochondria, flagella, and Golgi complexes. Their ribosomes resemble those of prokaryotes.

In 1998, British biologist Thomas Cavalier-Smith reassigned microsporidia to kingdom Fungi. Molecular studies show that microsporidia have gene sequences indicating that they originally had mitochondria. Microbiologists now generally agree that these organisms have become simpler as they adapted to their parasitic way of life. Other molecular studies have provided additional evidence for their taxonomic relationship with fungi.

Key Point

Like most fungi, most zygomycetes reproduce both asexually and sexually.

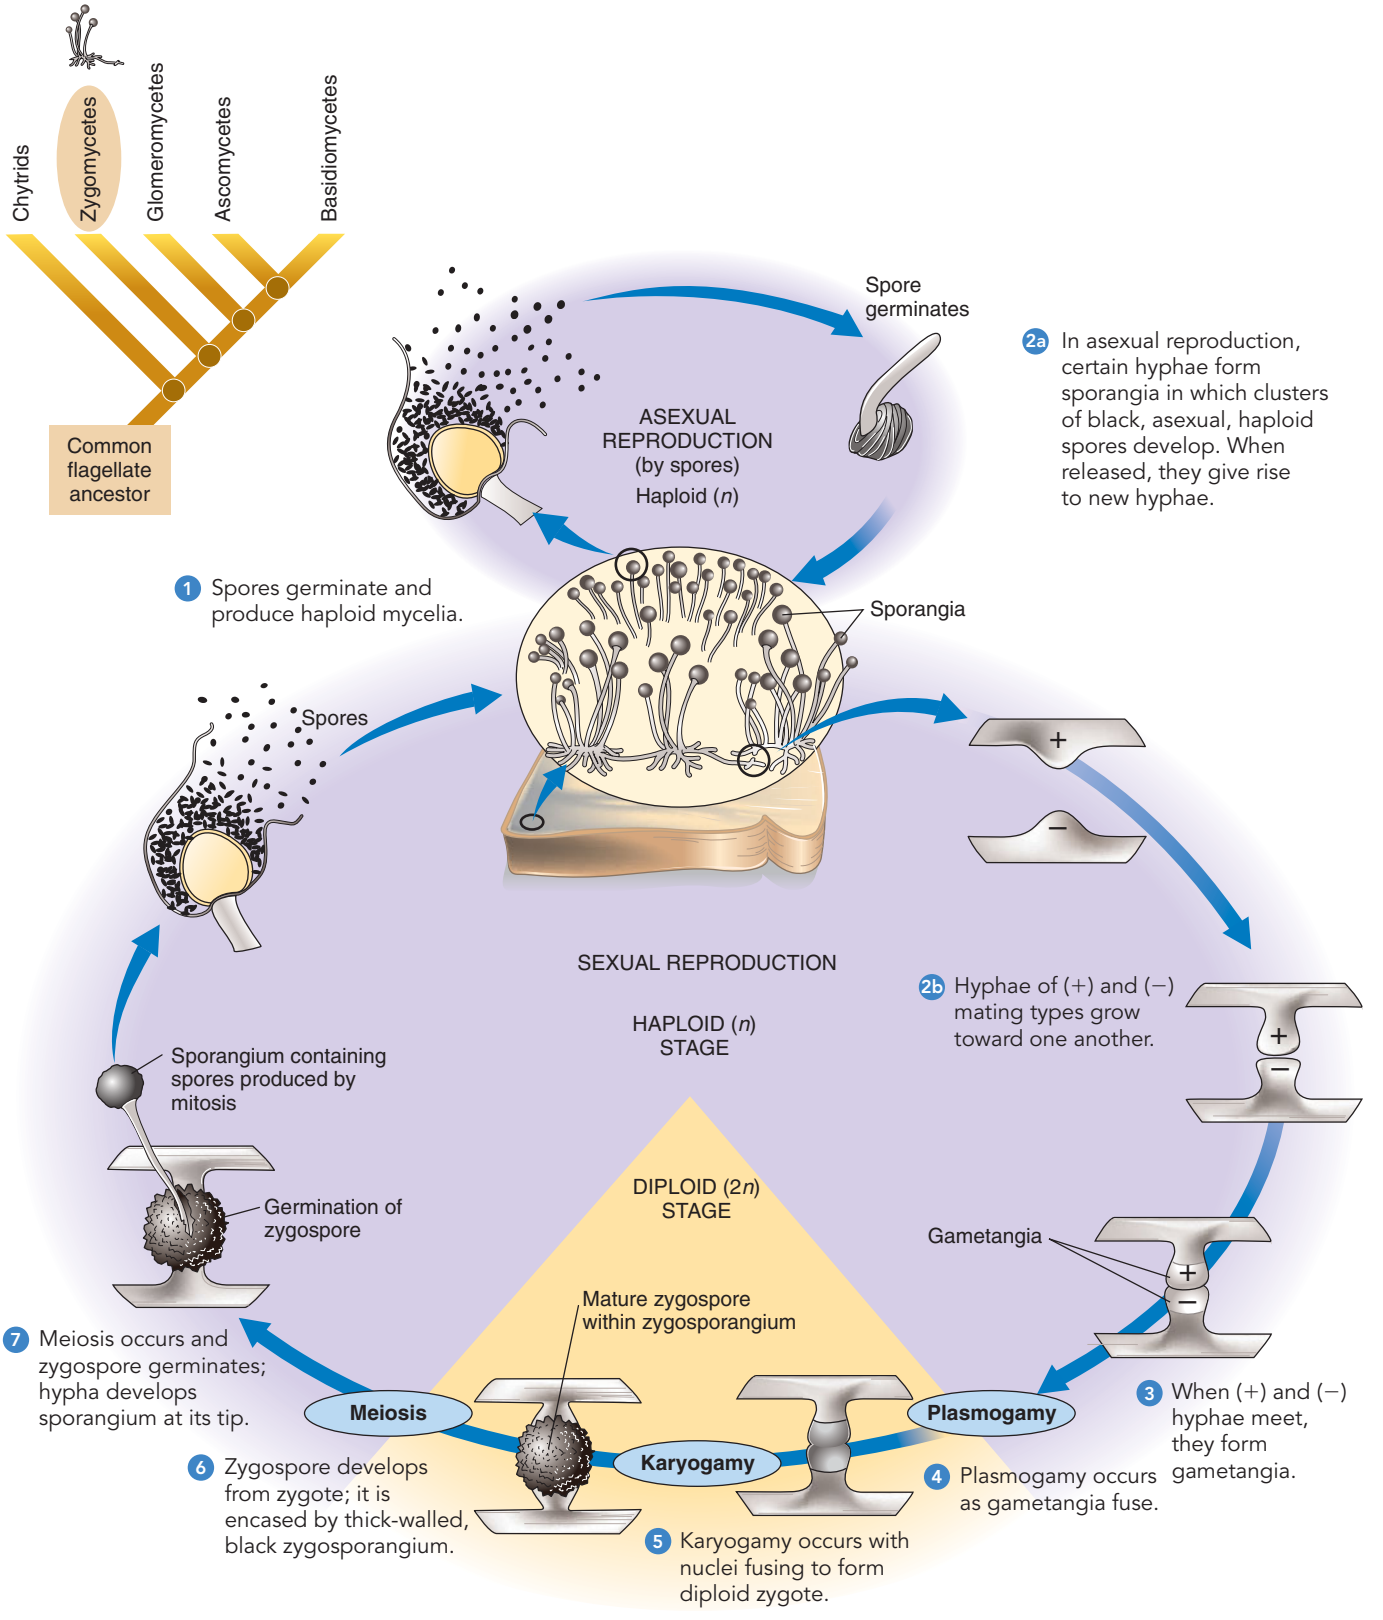

Figure 26-9 ***Animated*** Life cycle of the black bread mold (*Rhizopus stolonifer*), a zygomycete

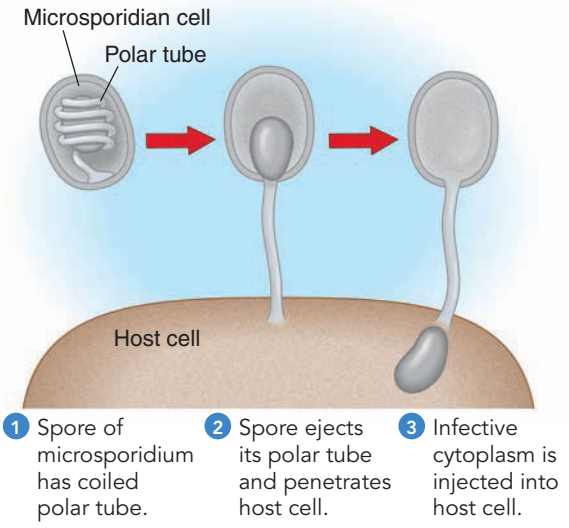

Figure 26-10 Infection by microsporidium

Establishing that they are closely related to fungi is important in developing medications that will be effective in treating microsporidian infections.

Glomeromycetes are symbionts with plant roots

Glomeromycetes (phylum Glomeromycota) are symbionts that form intracellular associations within the roots of most trees and herbaceous plants. (Recall that a symbiotic association is an intimate relationship between organisms of different species.) Glomeromycetes were previously considered zygomycetes, but in 2002 taxonomists concluded that they form a separate monophyletic group. This phylogeny is based on comparison of ssRNA genes.

Glomeromycetes have coenocytic (no septa) hyphae. They reproduce asexually with large, multinucleate spores called *blastospores*. Sexual reproduction has not been documented.

The symbiotic relationships between fungi and the roots of plants are called **mycorrhizae** (from Greek words meaning "fungus roots") (Fig. 26-11; also see Fig. 35-10). The roots supply the fungus with sugars, amino acids, and other organic substances. The mycorrhizal fungus decomposes organic material in the soil and also benefits the plant by extending the reach of its roots. The slender mycelia are far thinner than roots and can extend into narrow spaces, absorbing nutrients that the plant could not capture on its own. Thus, with the help of the mycorrhizal fungus, the plant can take in more water and nutrient minerals such as phosphorus and nitrogen.

What we have just described is a mutualistic symbiotic relationship: both partners benefit. Studies show that if a plant grows in phosphate-deficient soil or if it has a limited root system, its growth is enhanced by having a fungal partner. However, a plant in a phosphate-rich soil with a well-developed root system may not need fungal partners. For these plants, the fungus may be a parasite.

Much remains to be learned about mycorrhizal relationships. Other, yet unknown, benefits of the symbiosis may define the relationship as mutualistic. For example, some fungi release alkaloids that protect the plants from herbivores and pathogens. Plants also exchange nutrients with one another through fungi that connect them.

Glomeromycetes extend their hyphae through the cell walls of root cells but do not penetrate the plasma membrane. As the hyphae push forward, the root plasma membrane surrounds them. Thus, the hyphae can be thought of as fingers pushing into a glove formed by the plasma membrane. Because they appear intracellular, these fungi are referred to as **endomycorrhizal fungi.** The most widespread endomycorrhizae are called **arbuscular mycorrhizae** because the hyphae inside the root cells form branched, tree-shaped structures known as arbuscules (see Fig. 26-11). The arbuscules are the sites of nutrient exchange between the plant and the fungus. Arbuscular mycorrhizae live entirely underground.

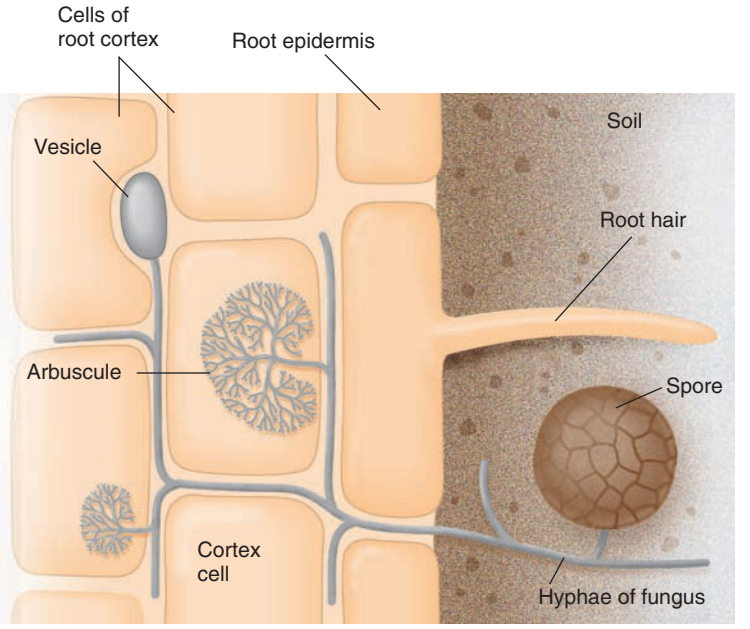

Figure 26-11 Arbuscular mycorrhizae

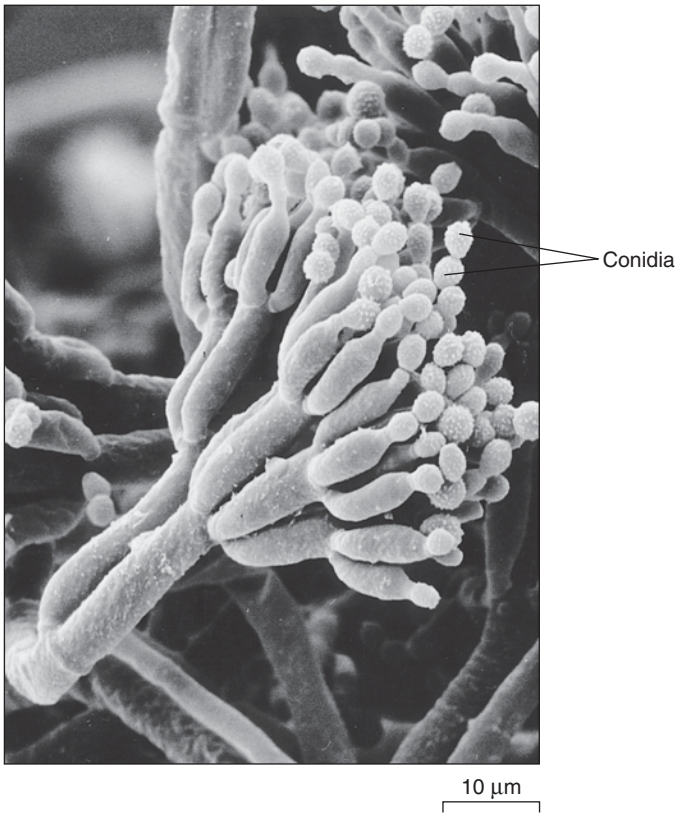
This mycelium has grown into the root. Its hyphae branch between the cells of the root. Hyphae have penetrated through the cell walls of two root cells and have branched extensively to form arbuscules. The tip of one hypha between root cells has enlarged and serves as a vesicle that stores food. The tip of a hypha in the soil has enlarged, forming a spore. The spaces between the root cells have been magnified.



Biophoto Associates/Photo Researchers, Inc.

Figure 26-12 Conidia

Conidia are asexual reproductive cells produced by ascomycetes and some basidiomycetes. Biologists use the arrangement of conidia on conidiophores to identify species of these fungi. Shown is a SEM of *Penicillium* conidiophores, which resemble paintbrushes. Note the conidia pinching off the tips of the "brushes."

Scientists have discovered mycorrhizal fungi within ancient plant fossils in rocks that are about 400 million years old. These findings suggest that when plants moved onto the land, their fungal partners moved with them. In fact, botanists have suggested that fungal hyphae may have provided plants with water and minerals before their own root systems evolved.

Ascomycetes reproduce sexually by forming ascospores

Ascomycetes (phylum Ascomycota) comprise a large group of fungi consisting of more than 32,000 described species. The diverse ascomycetes include most yeasts; the powdery mildews; most of the blue-green, pink, and brown molds that cause food to spoil; decomposer cup fungi; and the edible morels and truffles.

The ascomycetes, more than any other group of fungi, impact humans. As we will discuss in a later section, ascomycetes are used to flavor cheeses, to bake bread (yeast), and to ferment alcohol. Some are enjoyed as foods (morels and truffles). Ascomycetes are used to produce antibiotics. They have also served as valuable model organisms for biologists studying cellular processes, including protein synthesis. Many fungi in this group form mycorrhizae with tree roots, and about 40% join with green algae or cyanobacteria to form lichens. On the negative side, ascomycetes cause most fungal diseases of plants and animals, including humans. For example, ascomycetes cause serious plant diseases such as Dutch elm disease, ergot disease on rye, powdery mildew on fruits and ornamental plants, and chestnut blight.

Ascomycetes are sometimes referred to as *sac fungi* because their sexual spores are produced in microscopic sacs called **asci** (sing., *ascus*). Their hyphae usually have septa, but these cross walls have pores so that cytoplasm is continuous from one cell compartment to another.

In most ascomycetes, asexual reproduction involves production of spores called conidia, which form at the tips of certain specialized hyphae known as conidiophores (Fig. 26-12). Production of these spores is a means of rapidly propagating new mycelia when environmental conditions are favorable. Conidia occur in various shapes, sizes, and colors in different species. The color of the conidia produces the characteristic brown, blue-green, pink, or other tints of many of these molds.

Some species of ascomycetes are heterothallic and have different mating strains. Others are **homothallic,** which means they are self-fertile and have the ability to mate with themselves. In both heterothallic and homothallic ascomycetes, sexual reproduction takes place after two gametangia come together and their cytoplasm mingles.

Let us examine the life cycle of a typical ascomycete (Fig. 26-13). In our example, plasmogamy takes place as hyphae of two different mating types come together and fuse. Within this fused structure, pairs of haploid nuclei, one from each parent hypha, associate but do not fuse. New hyphae, with dikaryotic cells, develop from the fused structure. The hyphae branch repeatedly until the hyphal tips reach the site where asci will be produced. As the many sac-shaped asci develop, each containing two dissimilar nuclei (one from each parent), they are surrounded by intertwining haploid (monokaryotic) hyphae. These hyphae help make a fruiting body known as an **ascocarp** (Fig. 26-14a).

Karyogamy occurs in each ascus. The two nuclei fuse and form a diploid zygote nucleus. The zygote nucleus then undergoes meiosis to form four haploid nuclei with different genotypes. One mitotic division of each of the four nuclei usually follows, resulting in eight haploid nuclei. Each haploid nucleus becomes incorporated into a thick-walled **ascospore;** thus, there are typically eight haploid ascospores within the ascus (Fig. 26-14b). The ascospores are usually released through a pore, slit, or hinged lid at the tip of the ascus. Air currents carry individual ascospores, often for long distances. If one lands in a suitable location, it germinates and forms a new mycelium. The fungus can reproduce asexually by producing conidia that can develop into new mycelia.

Phylum Ascomycota includes more than 300 species of unicellular yeasts. Asexual reproduction of yeasts is mainly by **budding;** in this process a small protuberance (bud) grows and

Key Point

Ascomycetes produce asexual spores called conidia and sexual spores called ascospores.

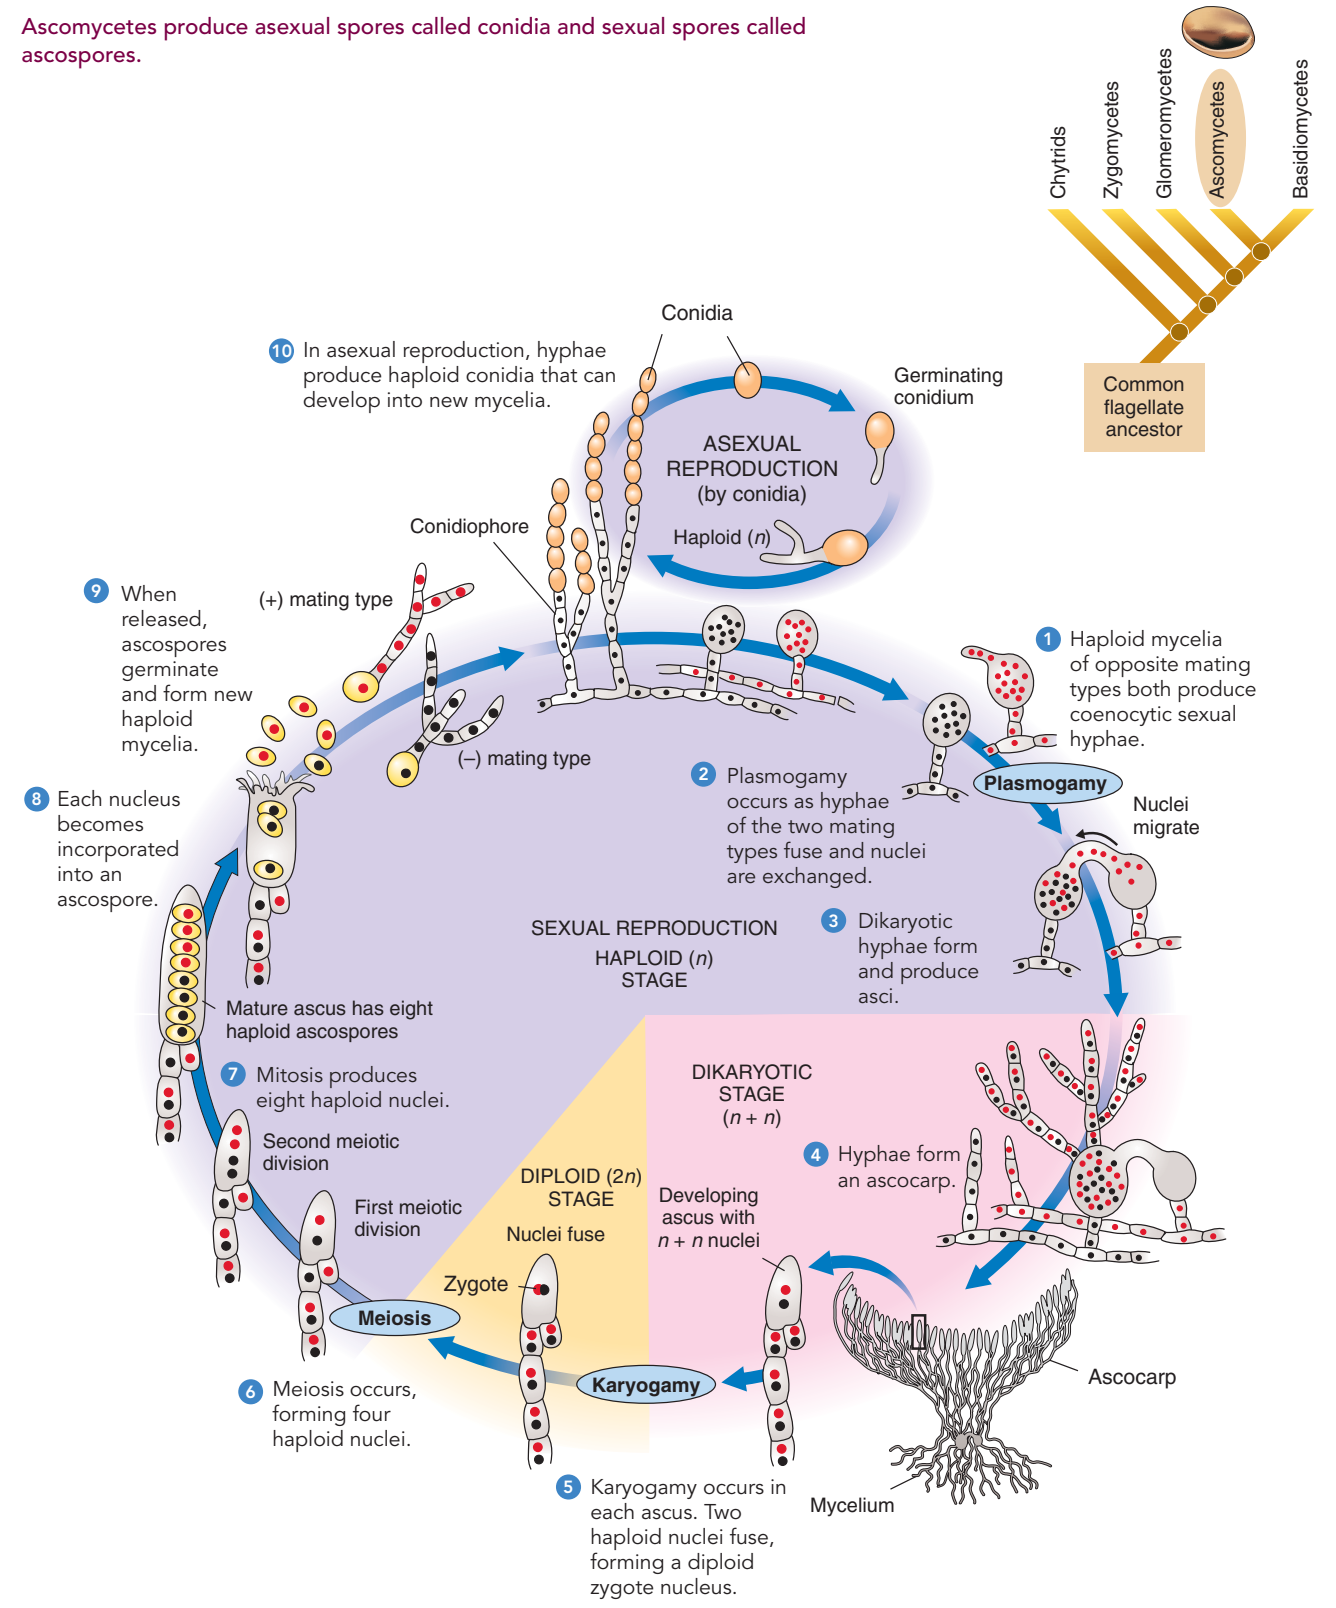


Figure 26-13 Life cycle of a typical ascomycete

Sexual reproduction requires haploid mycelia of different mating types. Note the dikaryotic stage and the separation of plasmogamy and karyogamy. Steps 5–8 take place within an ascus in the ascocarp.

(b) Asci, each containing eight ascospores, line the inner portion of the ascocarp.

Figure 26-14 ***Animated*** Sexual reproduction in the ascomycetes

eventually separates from the parent cell (see Fig. 26-3). Each bud can grow into a new yeast cell.

Yeasts reproduce sexually by forming ascospores. During sexual reproduction, two haploid yeasts fuse, forming a diploid zygote. The zygote undergoes meiosis, and the resulting haploid nuclei are incorporated into ascospores. These spores remain enclosed for a time within the original cell wall, which corresponds to an ascus.

Basidiomycetes reproduce sexually by forming basidiospores

The more than 30,000 species of **basidiomycetes** (phylum Basidiomycota) include the largest and most familiar of the fungi: the mushrooms, bracket fungi, and puffballs (Fig. 26-15). Many basidiomycetes are decomposers that obtain nutrients by breaking down organic matter. Some species cause great economic loss because they cause dry rot in buildings. Certain basidiomycetes form mycorrhizae. Others, such as wheat rust and corn smut, infect important crops. A few basidiomycetes cause human disease.

Sometimes called *club fungi,* basidiomycetes derive their name from their microscopic club-shaped **basidia** (sing., *basidium*). Basidia are comparable in function to the asci of ascomycetes. Each basidium is an enlarged hyphal cell that undergoes meiosis to form four **basidiospores** (Fig. 26-16). Note that basidiospores develop on the *outside* of a basidium, whereas ascospores develop *within* an ascus.

Each individual fungus produces millions of basidiospores, and each basidiospore has the potential to give rise to a new **primary mycelium.** Hyphae of a primary mycelium consist of monokaryotic cells. The mycelium of a basidiomycete, such as the commonly cultivated mushroom *Agaricus brunnescens,* consists of a mass of white, branching, threadlike hyphae that live mostly underground. Septa divide the hyphae into cells, but as in ascomycetes, the septa are perforated and allow cytoplasmic streaming between cells.

Let us examine the life cycle of a typical basidiomycete. Asexual reproduction is less common in basidiomycetes than in other groups, so we will focus here on sexual reproduction. We begin with two compatible primary mycelia (Fig. 26-17 on page 571). When in the course of its growth a hypha of a primary mycelium encounters a compatible monokaryotic hypha, typically of a different mating type, the two hyphae fuse (plasmogamy). As in the ascomycetes, the two haploid nuclei remain separate within each cell. In this way a **secondary mycelium** with dikaryotic hyphae is produced, in which each cell contains two haploid nuclei. The $n + n$ hyphae of the secondary mycelium grow rapidly and extensively.

When environmental conditions are favorable, the hyphae form compact masses, called *buttons,* along the mycelium. Each button grows into a fruiting body that we know as a mushroom. A mushroom, which consists of a stalk and a cap, is more formally referred to as a **basidiocarp.** Each basidiocarp consists of intertwined, matted hyphae. The lower surface of the cap usually consists of many thin, perpendicular plates called **gills** that radiate from the stalk to the edge of the cap.

Karyogamy takes place within the young basidia on the gills of the mushroom. The haploid nuclei fuse in the dikaryotic cells, forming diploid zygote nuclei. These are the only diploid cells that form during a basidiomycete's life history. Meiosis then takes place, forming four haploid nuclei with different genotypes. These nuclei move to the outer edge of the basidium. Fingerlike extensions of the basidium develop, into which the nuclei and some cytoplasm move; each of these extensions becomes a basidiospore. A septum forms that separates the basidiospore from the rest of the basidium by a delicate stalk that breaks when the basidiospore is forcibly discharged. Each basidiospore can germinate and give rise to a primary mycelium.

Many basiodmycetes produce "fairy rings" in lawns and forests (Fig. 26-18). A fairy ring may first appear as a dark green ring surrounding an inner brown circle. The size of the ring ranges from a few centimeters to more than 15 m (about 51 ft) in diameter. The green ring consists of grass, well nourished by the nutrients released as the fungi decompose organic material. Grass dies, producing the inner brown circle, because the mass of mycelia decreases the movement of water into the area. As the fungi grow outward, the circle widens. The rings grow at a rate of a few centimeters to more than a meter per year. After rainfall or irrigation, a ring of mushrooms may appear just outside the green circle. The name "fairy ring" comes from a legend that a ring of mushrooms appeared where fairies had danced in a circle the night before.

Review

- What evidence supports the hypothesis that chytrids were the earliest fungal group to evolve from the common ancestor of fungi?
- What are the distinguishing characteristics of each of the following fungal groups: (1) zygomycetes, (2) glomeromycetes, (3) ascomycetes, and (4) basidiomycetes?
- How does the life cycle of a typical basidiomycete differ from that of a typical ascomycete? (Draw diagrams to support your answer.)
- Distinguish among (1) ascocarp, ascus, and ascospore and among (2) basidiocarp, basidium, and basidiospore.

Dennis Drenner

(a) Basidia line the gills of the Jack-o'-lantern mushroom (*Omphalotus olearius*), a poisonous species whose gills produce a greenish glow in the dark. Each cap is about 15 cm (6 in) wide. Photographed at the base of an oak tree in Maryland, the Jack-o'-lantern occurs throughout eastern North America and California.

Richard D. Poe/Visuals Unlimited

(b) The elegant stinkhorn (*Phallus ravenelii*) has a foul smell that attracts flies. The flies help disperse the slimy mass of basidiospores. Fruiting bodies of elegant stinkhorns grow to 18 cm (7 in) tall. Photographed in Pennsylvania.

J. L. Lepore/Photo Researchers, Inc.

(c) Turkey-tail (*Trametes versicolor*) is a common bracket fungus. Bracket fungi grow on both dead and living trees and produce shelflike fruiting bodies. Basidiospores are produced in pores located underneath each shelf.

ECOLOGICAL IMPORTANCE OF FUNGI

Learning Objectives

7 Explain the ecological significance of fungi as decomposers.
8 Describe the important ecological role of mycorrhizae.
9 Characterize the unique nature of a lichen.

Fungi make vital contributions to the ecological balance of our planet. Like bacteria, most fungi are free-living decomposers, chemoheterotrophs that absorb nutrients from organic wastes and dead organisms. For example, many fungal decomposers degrade cellulose and lignin, the main components of plant cell walls. When fungi degrade wastes and dead organisms, they release water, carbon (as CO_2), and mineral components of organic compounds, and these elements are recycled (see biogeochemical cycles in Chapter 54).Without this continuous decomposition, essential nutrients would remain locked up in huge mounds of animal carcasses, feces, branches, logs, and leaves. The nutrients would be unavailable for use by new generations of organisms, and life would eventually cease.

Fungi form important symbiotic relationships with animals, plants, bacteria, and protists. These symbioses have major effects on ecosystems.

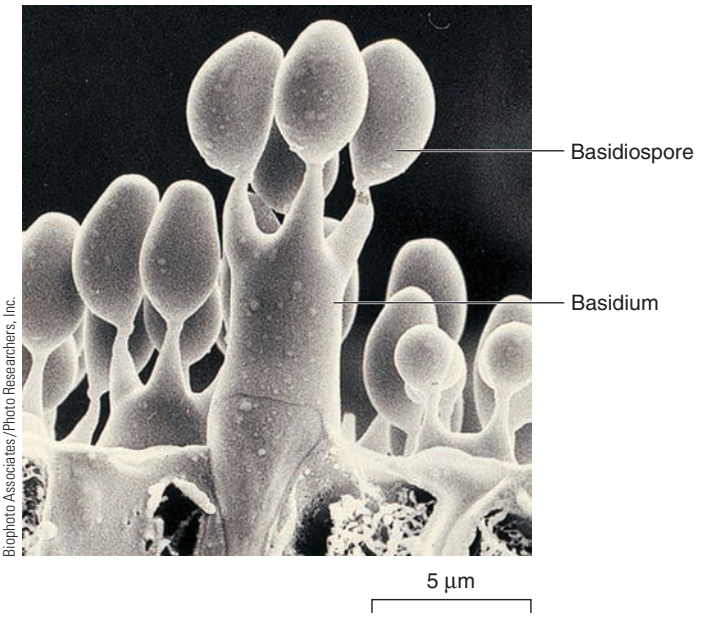
Fungi form symbiotic relationships with some animals

Because animals do not have the enzymes necessary to digest cellulose and lignin, cattle and other grazing animals cannot, by themselves, obtain needed nutrients from the plant material they eat. Their survival depends on fungi that inhabit their guts because fungi, like many other microorganisms, do have the enzymes that break down these organic compounds. The fungi benefit by living in a nutrient-rich environment.

Fungi also form symbiotic associations with ants and termites. More than 200 species of ants farm fungi. Leaf-cutting ants bring leaves to their fungi and protect them from competitors and predators. The ants also disperse the fungi to new locations. In exchange, the fungi digest the leaves, providing nutrients for the ants. This symbiosis can involve other organisms. The farmed fungi can be infested by fungal parasites. In response, the ants culture bacteria (actinomycetes) that produce antibiotics to control these parasites. These symbiotic relationships, the most complex known, are the product of 50 million years of coevolution.

Mycorrhizae are symbiotic relationships between fungi and plant roots

Mycorrhizae occur in about 80% of plants (and more than 90% of all plant families). As discussed in the section on glomeromycetes, mycorrhizal fungi decompose organic material in the soil and increase the surface area of a plant's roots so that the plant can absorb more water and nutrient minerals. In exchange, the roots supply the fungus with organic nutrients.



Biophoto Associates/Photo Researchers, Inc.

Figure 26-16 SEM of a basidium
Each basidium produces four basidiospores.

The importance of mycorrhizae first became evident when horticulturalists observed that orchids do not grow unless an appropriate fungus lives with them. Similarly, many forest trees, such as pines, decline and eventually die from mineral deficiencies when transplanted to mineral-rich grassland soils that lack the appropriate mycorrhizal fungi. When forest soil containing the appropriate fungi or their spores is added to the soil around these trees, they quickly resume normal growth. Studies performed with various types of plants, including cedar, have confirmed the role of mycorrhizae in plant growth (Fig. 26-19).

As we have discussed, glomeromycetes form *endomycorrhizal* connections; they infiltrate the cells of plant roots. At least 5000 species of ascomycetes and basidiomycetes also form mycorrhizal connections, but their hyphae coat the plant root rather than penetrate its cells. They are referred to as **ectomycorrhizae.** Interestingly, researchers have shown that some mycorrhizal fungi harbor bacteria in their cytoplasm. Although the role of the bacteria is not yet clear, their presence suggests that they may be members of a three-domain partnership: fungus, plant, and bacteria.

Mycorrhizal fungi connect plants, allowing nutrient transfer among them. Scientists have measured the movement of organic materials from one tree species to another through shared mycorrhizal connections. Mycorrhizal fungi also release chemicals that protect the plant against herbivores and pathogens.

Mycorrhizae improve the soil by decreasing water loss and erosion. Ecologists are studying the role of mycorrhizal fungi

in reclaiming soils damaged by pollution. For example, mycorrhizae can modify toxic heavy metals, such as cadmium, so that plants cannot absorb them.

Lichens are symbiotic relationships between a fungus and a photoautotroph

Although a **lichen** looks like a single organism, it is actually a dual organism. A lichen is a symbiotic association between two organisms: a fungus and a *photoautotroph* (Fig. 26-20a). Almost one fifth of all known fungal species form these symbiotic relationships; about 14,000 kinds of lichens have been described. Fossils suggest that fungi developed symbiotic partnerships with photoautotrophs before the evolution of vascular plants.

The photoautotrophic component of a lichen is either a green alga, a cyanobacterium, or both. The fungus is most often an ascomycete, although in some tropical lichens the fungal partner is a basidiomycete. Most photoautotrophic organisms found in lichens also occur as free-living species in nature, but the fungal components are generally found only as a part of the lichen. Typically, the fungus forms most of the lichen thallus (body). The fungus surrounds hundreds of photosynthetic partners and holds them in place. Lichens are named for the fungal component.

In the laboratory, researchers can isolate the fungal and photoautotrophic components of some lichens and grow them separately in appropriate culture media. The photoautotroph grows more rapidly when separated, whereas the fungus grows more slowly and requires many complex carbohydrates. Neither organism resembles a lichen in appearance when grown separately. The photoautotroph and fungus can be reassembled as a lichen thallus, but only if they are placed in a culture medium under conditions that cannot support either of them independently.

What is the nature of this partnership? The lichen was originally considered a definitive example of mutualism. The photoautotroph carries on photosynthesis, producing energy-rich carbon compounds for both members of the lichen, but it is unclear how the photoautotroph benefits from the relationship. It has been suggested that the photoautotroph obtains water and nutrient minerals from the fungus as well as protection against desiccation. More recently, some biologists have suggested that the lichen partnership is not really a case of mutualism but one of controlled parasitism of the photoautotroph by the fungus.

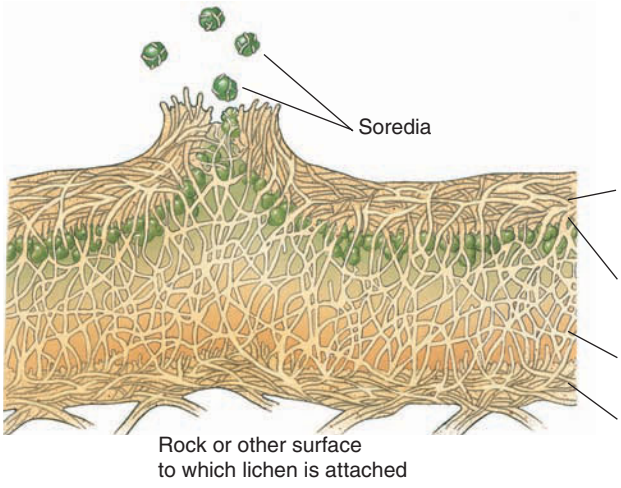
(b) These seedlings are the same age as the control plants and were grown under conditions identical to those of the control, except that their roots have formed mycorrhizal associations.

Figure 26-19 The effect of mycorrhizae on western red cedar (*Thuja plicata*) seedlings



(a) This cross section of a typical lichen shows distinct layers. The soredium (pl., *soredia*), an asexual reproductive structure, consists of clusters of algal or cyanobacterial cells enclosed by fungal hyphae.

(b) Lichens vary in color, shape, and overall appearance. Three growth forms—crustose, foliose, and fruticose—are shown on a maple branch in Washington State.

Figure 26-20 ***Animated*** Lichens

Lichens typically exhibit one of three different growth forms (Fig. 26-20b). *Crustose lichens* are flat and grow tightly against their substrate (the surface they are growing on); *foliose lichens* are also flat, but they have leaflike lobes and are not so tightly pressed to the substrate; and *fruticose lichens* grow erect and have many branches.

Able to tolerate extremes of temperature and moisture, lichens grow in almost all terrestrial environments except polluted cities. They exist farther north than any plants of the arctic region and are equally at home in the steaming equatorial rain forest. They grow on tree bark, leaves, and exposed rock surfaces, from solidified lava to tombstones. In fact, lichens are often the first organisms to inhabit rocky areas, and their growth in these areas is important in forming soil from rock. They secrete acid that gradually etches tiny cracks in the rock, releasing minerals. This process sets the stage for further disintegration of the rock by wind and rain. When the lichens themselves die and are decomposed, they become part of the soil.

Reindeer mosses of the arctic region, which serve as the main source of food for migrating herds of caribou, are actually lichens, not mosses. Some lichens produce colored pigments. One of them, orchil, is used to dye woolens, and another, litmus, is widely used in chemistry laboratories as an acid–base (pH) indicator.

Lichens vary greatly in size. Some are almost invisible, whereas others, such as the reindeer mosses, may cover many square kilometers of land with an ankle-deep growth. Growth proceeds slowly; the radius of a lichen may increase by less than 1 mm each year. Some mature lichens are thought to be thousands of years old.

Lichens absorb minerals from the air, rainwater, and the surface on which they grow. They cannot excrete the elements they absorb, and perhaps for this reason they are extremely sensitive to toxic compounds. This sensitivity was first reported in 1866 by a Finnish biologist who observed that lichens growing on tree trunks in Paris were poorly developed or sterile. He deduced that lichens could be used to measure air purity. Today, reduction in lichen growth is used as a sensitive indicator of air pollution, particularly from sulfur dioxide. Investigators demonstrated a relationship between lung cancer and air pollution by comparing the locations of low lichen biodiversity (and therefore of air pollution) with the locations of lung cancer deaths in young males. The return of lichens to an area indicates an improvement in air quality.

Lichens reproduce mainly by asexual means, usually by fragmentation, a process in which special dispersal units of the lichen, called **soredia,** break off and, if they land on a suitable surface, establish themselves as new lichens. Soredia contain cells of both

partners. In some lichens, the fungus produces ascospores, which may be dispersed by wind and find an appropriate algal partner only by chance.

ECONOMIC, BIOLOGICAL, AND MEDICAL IMPACT OF FUNGI

Learning Objectives

10 Summarize some of the ways that fungi impact humans economically.

11 Summarize the importance of fungi to biology and medicine; describe how fungi infect plants and humans, identifying at least three fungal plant diseases and three fungal animal diseases.

The same powerful digestive enzymes that fungi use to decompose wastes and dead organisms can also be used with great efficiency to reduce wood, fiber, and food to their basic components. Many species of basidiomycetes have enzymes that break down the lignin in wood. (Lignin is the second most abundant organic compound on Earth, second only to cellulose.) From the human perspective, various fungi cause incalculable damage to stored goods and building materials each year. Bracket fungi, for example, cause enormous losses by decaying wood, both in living trees and in stored lumber.

Fungi are more destructive to plants than any other disease-causing organism. Their activities cost billions of dollars in agricultural damage yearly. Some fungi cause diseases in humans and other animals. Yet fungi also contribute to our quality of life. They are responsible for economic gains as well as losses. People eat them and grow them to make various chemicals, such as citric acid and other industrial chemicals.

Fungi provide beverages and food

Humans exploit the capability of yeasts to produce ethyl alcohol and carbon dioxide from sugars such as glucose by fermentation (see Chapter 8) to make wine, beer, and other fermented beverages, as well as bread. Wine is produced when yeasts ferment fruit sugars, and beer results when yeasts ferment sugars derived from starch in grains (usually barley). During the process of making bread, carbon dioxide produced by yeast becomes trapped in dough as bubbles, causing the dough to rise; this gives leavened bread its light texture. Both the carbon dioxide and the alcohol produced by the yeast escape during baking.

The unique flavor of cheeses such as Roquefort, Brie, Gorgonzola, and Camembert is produced by species of *Penicillium.* For example, *P. roquefortii,* found in caves near the French village of Roquefort, is used to make Roquefort cheese. By French law, only cheeses produced in this area can be called Roquefort cheese. (The blue spots in Roquefort and certain other cheeses are masses of conidia.)

Aspergillus tamarii and certain other fungi are used to produce soy sauce by fermenting soybeans with the fungi for at least 3 months. (In the United States soy sauce is often made by adding flavoring to salt water rather than by soaking fermented soybeans.) Soy sauce enriches other foods with more than just its special flavor. It also adds vital amino acids from both the soybeans and the fungi themselves, which, in some parts of the world, supplement a low-protein rice diet.

Among the basidiomycetes, there are some 200 kinds of edible mushrooms and about 70 species of poisonous ones. Some edible mushrooms are cultivated commercially. The mushroom *Agaricus brunnescens* is the principal fungal species grown extensively for food. About 30 other mushroom species, such as oyster, shiitake, portobello, and straw mushrooms, are available in supermarkets. Morels, which superficially resemble mushrooms, and truffles, which produce underground fruiting bodies, are ascomycetes (Fig. 26-21). These gourmet delights are now being cultivated as mycorrhizal fungi on the roots of tree seedlings.

Edible and poisonous mushrooms can look very much alike and may even belong to the same genus. There is no simple way to tell them apart; an expert must identify them. Some of the most poisonous mushrooms belong to the genus *Amanita* (Fig. 26-22). Toxic species of this genus have been appropriately called such names as "destroying angel" (*A. virosa*) and "death cap" (*A. phalloides*). Eating a single mushroom of either species can be fatal.

Certain species of mushrooms cause intoxication and hallucinations. The sacred mushrooms of the Aztecs—*Conocybe* and *Psilocybe*—are still used in religious ceremonies by native peoples of Central America for their hallucinogenic properties. The chemical ingredient *psilocybin* is responsible for the trances and visions experienced by those who eat these mushrooms. Psilocybin is related to lysergic acid diethylamide (LSD). Ingestion of psychoactive mushrooms is dangerous because negative reactions vary considerably, from mild indigestion, sweating, and heart palpitations, to death. In addition, the possession and use of such mushrooms are illegal in the United States and some other countries.

Fungi are important to modern biology and medicine

The yeast *Saccharomyces cerevisiae* (baker's yeast), an ascomycete, has served as a model eukaryotic cell. It was the first eukaryote whose genome was sequenced, and with its 6000 genes, it has the smallest genome of any eukaryotic model organism. Molecular biologists are in the process of determining the functions of the proteins encoded by its genes. Biologists have used *S. cerevisiae* to study molecular genetics, including how genes regulate cell division. Researchers continue to use this yeast to study such problems as genetic recombination, and the correlation between cell

(b) The Oregon white truffle (*Tuber gibbosum*), which is found underground near Douglas firs and possibly oak trees in British Columbia and Northern California, is 1 to 5 cm (0.4 to 2 in) wide. People find these subterranean ascocarps with the help of trained dogs or pigs. Here, truffles are shown whole and sectioned to show the conspicuous white, marbled tissue.

Figure 26-21 Edible ascomycetes

age and cancer. *S. cerevisiae* is also being used to study the mechanism of action of antifungal drugs and resistance to these drugs.

Biologists have used the ascomycete *Aspergillus nidulans,* an opportunistic pathogen of humans, to study mitosis and other cell processes. This fungus has provided valuable knowledge about the genetics of microtubules. Biologists are using recombinant DNA techniques to manipulate yeasts and certain filamentous fungi to produce important biological molecules, such as hormones. Among the many genes that have been cloned in yeast are those for insulin, human growth hormone, and molecules important in immune function. These procedures allow researchers to produce unlimited amounts of these compounds for study and eventual medical use.

Researchers are investigating fungi—for example, certain species of microsporidia—for the biological control of pathogens and insect pests. Some of these species are already being used to parasitize insect pests. In some cases, they interfere with reproduction in their insect host. Other microsporidia completely control the metabolism and reproduction of the host. Researchers are studying the use of microsporidia in controlling the spread of malaria. A recent study showed that when female *Anopheles* mosquitoes are infected with microsporidia, their blood feeding is decreased. Fungal infection of the mosquito also interferes with development of *Plasmodium,* the protist that causes malaria.

Fungi produce useful drugs and chemicals. Discovered in 1928 by the British bacteriologist Alexander Fleming, penicillin, produced by the mold *Penicillium notatum,* is still among the most widely used and effective antibiotics (see Chapter 1). Other drugs derived from fungi include the cephalosporin antibiotics (produced by *Cephalosporium*), statins (used to lower blood cholesterol levels), and cyclosporine (used to suppress immune responses in patients who receive organ transplants). Fumagillin, a chemical produced by the ascomycete *Aspergillus fumigatus,* inhibits the formation of new blood vessels. Because solid tumors need a rich blood supply, fumagillin shows promise as an anticancer agent. Fumagillin is also used to treat diseases caused by microsporidia.

The ascomycete *Claviceps purpurea* infects the flowers of rye plants and other cereals. It produces a structure called an *ergot* where a seed would normally form in the grain head. When live-

Figure 26-22 Poisonous mushrooms

The destroying angel (*Amanita virosa*) is an extremely poisonous mushroom that is distinguished, as are other amanitas, by the ring of tissue around its stalk and by the underground cup from which the stalk protrudes. About 50 g (2 oz) of this mushroom can kill an adult man. The destroying angel, which is 7.5 to 20 cm (3 to 8 in) tall, is found in grass or near trees throughout North America.

stock eat this grain or when humans eat bread made from ergot-contaminated rye flour, they may be poisoned by the extremely toxic substances in the ergot. However, some ergot compounds are now used clinically in small quantities as drugs to induce labor, to stop uterine bleeding, to treat high blood pressure, and to relieve one type of migraine headache.

Some fungi cause animal diseases

Some fungi cause superficial infections in which only the skin, hair, or nails are infected. Ringworm, athlete's foot, and jock itch are examples of superficial fungal infections. Because these fungi infect dead layers of skin that are not fed by capillaries, the immune system cannot launch an effective response. Ascomycetes cause these types of infections.

Many pathogenic fungi are opportunists that cause infections only when the body's immune system is compromised, for example, in patients with HIV. Cancer patients and organ transplant recipients who are given medication to suppress their immune systems are also at risk. *Candida* is an ascomycete that inhabits the human mouth and vagina. The immune system and the normal bacteria of these regions normally prevent this yeast from causing infection. However, when the immune system is compromised, *Candida* multiplies, causing thrush, a painful yeast infection of the mouth, throat, and vagina.

The ascomycete *Aspergillus fumigatus* is usually harmless but causes aspergillosis in people with lowered immune function. During the course of aspergillosis, the fungus can invade the lungs, heart, brain, kidneys, and other vital organs and cause death.

Other fungi infect internal tissues and organs and may spread through many regions of the body. Histoplasmosis, for example, is a serious infection of the lungs caused by inhaling spores of a fungus common in soil contaminated with bird feces. Most people in the Eastern and Midwestern parts of the United States have been exposed to this fungus at some time, and an estimated 40 million Americans have had mild infections. Fortunately, the infection is usually confined to the lungs and is of short duration, but if the infection spreads through the blood to the heart, brain, or other parts of the body, it can be serious and sometimes fatal.

Some fungi produce poisonous compounds collectively called **mycotoxins.** A few species of *Aspergillus,* for example, produce potent mycotoxins called **aflatoxins** that harm the liver and are known carcinogens. Foods on which aflatoxin-producing fungi commonly grow include peanuts, pecans, corn, and other grains. Other foods that may contain traces of aflatoxins include animal products such as milk, eggs, and meat (from animals that consumed feed contaminated by aflatoxin). Avoiding aflatoxin in the diet is impossible, but exposure should be minimized as much as possible. Any human food or animal forage product that has become moldy should be suspected of aflatoxin contamination and be discarded.

Fungi contribute to sick-building syndrome, a situation in which occupants of a building experience acute adverse health effects linked to the time they spend in a given building. Mold-related insurance claims amount to hundreds of millions of dollars each year. When conditions are moist, molds can grow on carpets, leather, cloth, wood, insulation, and food. Mold spores, fragments, and mold products make their way into the air, and people are exposed through inhalation as well as by skin contact. Exposure to molds and their toxins has been linked to depressed immune function, irritation of the throat and respiratory passageways, infection, and toxicity. The most common responses to mold exposure are allergic reactions that range from mild to severe illnesses, including hay fever, sinusitis, asthma, and dermatitis.

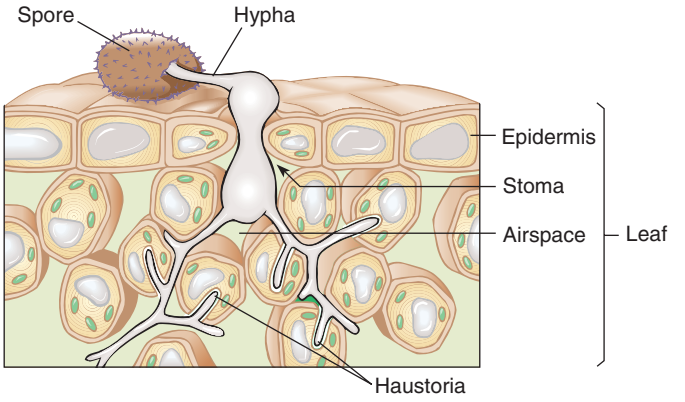

Figure 26-23 How a fungus parasitizes a plant

In this example, the hypha enters the leaf through a stoma. The hypha grows, branching extensively through the internal air spaces, and penetrates plant cells with specialized hyphal extensions called haustoria.

Fungi cause many important plant diseases

Fungi are responsible for about 70% of all major crop diseases. They cause serious epidemic diseases that spread rapidly and often result in complete crop failure. All plants are apparently susceptible to some fungal infection. Damage may be localized in certain tissues or structures of the plant, or the disease may be systemic and spread throughout the entire plant. Fungal infections may cause stunting of plant parts or of the plant; they may cause wartlike growths or kill the plant.

A plant often becomes infected after hyphae enter through stomata (pores) in the leaf or stem or through wounds in the plant body (Fig. 26-23). Alternatively, the fungus may produce *cutinase,* an enzyme that dissolves the waxy cuticle that covers the surface of leaves and stems. After dissolving the cuticle, the fungus easily invades the plant tissues. As the mycelium grows, it may stay mainly between the plant cells or it may penetrate the cells. Parasitic fungi often produce special hyphal branches called **haustoria** (sing., *haustorium*) that penetrate the host cells and obtain nourishment from the cytoplasm.

Ascomycetes cause important plant diseases, including powdery mildew, chestnut blight, Dutch elm disease, apple scab, wilt on potatoes, and brown rot, which attacks cherries, peaches, plums, and apricots (Fig. 26-24a). Early in the 20th century the chestnut blight fungus (*Cryphonectria parasitica*) was accidentally imported on diseased Asian chestnuts and quickly at-

Figure 26-24 Fungi that cause plant diseases

tacked native American chestnut trees, which had no resistance to the fungus. By the late 1940s, the blight had killed or damaged several billion mature trees—almost every North American chestnut tree throughout its entire natural range. Plant biologists are working to save the American chestnut tree from extinction. One approach has been to develop a disease-resistant variety by breeding the American chestnut with the Chinese chestnut, a related species that is resistant to chestnut blight. Other biologists are genetically engineering a virus that infects the chestnut blight fungus and reduces its virulence.

Basidiomycetes cause smuts and rusts that attack corn, wheat, oats, and other grains (▮ Fig. 26-24b). Some fungal parasites, such as the stem rust of wheat, have complex life cycles that involve two or more different host plants and the production of several kinds of spores. For example, wheat rust must infect a barberry plant at one stage in its life cycle. As a result of this discovery, the eradication of barberry plants in wheat-growing regions has reduced infection with wheat rust. Eradication of the barberry has not eliminated wheat rust, however, because the fungus overwinters on wheat at the southern end of the Grain Belt and forms asexual spores. During the spring, wind blows these spores for hundreds of kilometers, reinfecting northern areas of the United States and Canada.

Review

- Some dictionaries erroneously define a morel as a type of mushroom. Why is this definition incorrect?
- How are fungi important in modern biology and medicine?
- What are three important fungal diseases of humans?
- What are three important fungal diseases of plants?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Describe the distinguishing characteristics of kingdom Fungi (page 556).

- **Fungi** are eukaryotic heterotrophs that secrete digestive enzymes onto their food source and then absorb the predigested food.
- Fungi are characterized by cell walls that contain **chitin.**

2 Describe the body plan of a fungus (page 556).

- A fungus may be a unicellular **yeast** or a filamentous, multicellular **mold.** The body of most multicellular fungi consists of long, threadlike filaments called **hyphae** that branch and form a tangled mass called a **mycelium.**

ThomsonNOW™ **Learn more about mycelium by clicking on the figure in ThomsonNOW.**

- In most fungi, perforated **septa,** or cross walls, divide the hyphae into individual cells. In some fungi (zygomycetes and glomeromycetes), the hyphae are **coenocytic,** that is, they form an elongated, multinuclear cell.

3 Describe the life cycle of a typical fungus, including sexual and asexual reproduction (page 556).

- Most fungi reproduce both sexually and asexually by means of **spores.** Spores are produced on aerial hyphae.

When a fungal spore lands in a suitable spot, the spore germinates.

- When fungi of two different mating types meet, their hyphae fuse, a process called **plasmogamy.** The cytoplasm fuses, but the nuclei remain separate. The fungi enter a **dikaryotic** ($n + n$) stage in which each new cell formed has one nucleus of each type.
- **Karyogamy,** fusion of the nuclei, takes place in the hyphal tip and results in a diploid ($2n$) **zygote nucleus.**
- Meiosis takes place, producing four genetically different haploid (n) nuclei. Each nucleus becomes part of a spore. When the spores germinate, they form new mycelia by mitosis.
- Genetically similar asexual spores can be produced by mitosis. When these spores germinate, they also develop into mycelia.

4 Give arguments to support the hypothesis that fungi are opisthokonts, more closely related to animals than to plants (page 558).

- Like animals, some fungi have flagellate cells—for example, chytrid gametes and spores; the flagellate cells propel themselves with a single posterior flagellum.
- Like animal cells, fungal cells have platelike cristae in their mitochondria.
- Based on chemical and structural characters, fungi are classified, along with animals and choanoflagellates, as **opisthokonts.**

5 Give arguments to support the hypothesis that chytrids may have been the earliest fungal group to evolve from the most recent common ancestor of fungi (page 558).

- **Chytrids,** or **chytridiomycetes,** produce flagellate cells at some stage in their life cycle. No other fungi have flagella. Thus, chytrids probably were the earliest fungi to evolve from a flagellate protist, the common ancestor of all fungi.

6 List distinguishing characteristics, describe a typical life cycle, and give examples of each of the following fungal groups: chytridiomycetes, zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes (page 558).

- Chytrids reproduce both asexually and sexually. Their gametes and zoospores are flagellate. *Allomyces,* a common chytrid, spends part of its life as a multicellular haploid **thallus** and part as a multicellular diploid thallus. The haploid thallus produces two types of flagellate gametes that fuse. Both plasmogamy and karyogamy occur, producing a flagellate zygote. The diploid thallus bears zoosporangia that produce diploid **zoospores** and resting sporangia in which haploid zoospores form by meiosis. The haploid zoospores form new haploid thalli.
- **Zygomycetes,** such as the black bread mold, *Rhizopus,* form a haploid thallus that produces both asexual spores and sexual spores. Asexual spores germinate and form new thalli. In sexual reproduction, hyphae of two different haploid mating types form gametangia. Plasmogamy occurs as the gametangia fuse. Karyogamy occurs, and a diploid zygote is formed, from which a **zygospore** develops. Meiosis produces recombinant haploid zygospores. When zygospores germinate, each hypha develops a sporangium at its tip. Spores are released and develop into new hyphae. **Microsporidia,** now considered zygomycetes, are opportunistic pathogens that penetrate and infect animal cells with their long, threadlike **polar tubes.**
- **Glomeromycetes** (phylum Glomeromycota) are symbionts that form intracellular associations called **mycorrhizae** with the roots of many plants. Because they extend their hyphae into root cells, glomeromycetes are **endomycorrhizal fungi.** The most common endomycorrhizae are called **arbuscular mycorrhizae** because the hyphae inside the root cells form branched, tree-shaped structures known as **arbuscules.** Glomeromycetes have coenocytic hyphae. They reproduce asexually with large, multinucleate spores called blastospores.
- **Ascomycetes** produce asexual spores called **conidia;** sexual spores called **ascospores** are produced in **asci.** The asci line a fruiting body called an **ascocarp.** Haploid mycelia of opposite mating types produce septate hyphae. Plasmogamy occurs, and nuclei are exchanged. A dikaryotic $n + n$ stage occurs in which hyphae form and produce asci and an ascocarp. Karyogamy occurs, followed by meiosis. The recombinant nuclei divide by mitosis, producing eight haploid nuclei that develop into ascospores. When the ascospores germinate, they can form new mycelia. Ascomycetes include yeasts, cup fungi, morels, truffles, and pink, brown, and blue-green molds. Some ascomycetes form mycorrhizae; others form lichens.
- **Basidiomycetes** produce sexual spores called **basidiospores** on the outside of a **basidium.** Basidia develop on the surface of **gills** in mushrooms, a type of **basidiocarp** (a fruiting body). Hyphae in this phylum have septa. Plasmogamy occurs with the fusion of two hyphae of different mating types. A dikaryotic secondary mycelium forms. Then a basidiocarp develops, and basidia form. Karyogamy occurs, producing a diploid zygote nucleus. Meiosis produces four haploid nuclei that become basidiospores. When basidiospores germinate, they form haploid primary mycelia. Basidiomycetes include mushrooms, puffballs, bracket fungi, rusts, and smuts.

ThomsonNOW™ Explore fungus life cycles by clicking on the figures in ThomsonNOW.

7 Explain the ecological significance of fungi as decomposers (page 570).

- Most fungi are decomposers that break down organic compounds in dead organisms, leaves, garbage, and wastes into simpler nutrients that can be recycled.

8 Describe the important ecological role of mycorrhizae (page 570).

- Mycorrhizae are mutualistic relationships between fungi and the roots of plants. The fungus supplies water and nutrient minerals to the plant, and the plant secretes organic compounds needed by the fungus. Glomeromycetes form endomycorrhizal associations with roots. Ascomycetes and basidiomycetes form **ectomycorrhizae** with tree roots; they do not penetrate the root cells.

9 Characterize the unique nature of a lichen (page 570).

- A **lichen** is a symbiotic combination of a fungus and a photoautotroph (an alga or cyanobacterium). The photoautotroph provides the fungus with organic compounds, shelter, water, and minerals. Lichens have three main growth forms: crustose, foliose, and fruticose.

ThomsonNOW™ Learn more about lichens by clicking on the figure in ThomsonNOW.

10 Summarize some of the ways that fungi impact humans economically (page 574).

- Mushrooms, morels, and truffles are foods; yeasts are vital in the production of beer, wine, and bread; certain fungi are used to produce cheeses and soy sauce. Fungi are also used to make citric acid and other industrial chemicals.

11 Summarize the importance of fungi to biology and medicine; describe how fungi infect plants and humans, identifying at least three fungal plant diseases and three fungal animal diseases (page 574).

- Modern biologists use the yeast *Saccharomyces cerevisiae* and other fungi as model organisms for research in molecular biology and genetics. Fungi are also being investigated for the biological control of insects, such as the mosquitoes that transmit malaria.
- Fungi are used to make many medications, including penicillin and other antibiotics.
- Fungi are opportunistic pathogens in humans. They cause human diseases, including ringworm, athlete's foot, candidiasis, and histoplasmosis.
- Some fungi produce **mycotoxins,** such as **aflatoxins,** which can cause liver damage and cancer.
- Fungal hyphae infect plants through stomata. Hyphal branches called **haustoria** penetrate plant cells and obtain nourishment from the cytoplasm. Fungi cause many important plant diseases, including wheat rust, Dutch elm disease, and chestnut blight.

TEST YOUR UNDERSTANDING

1. Fungi produce cell walls containing the polymer _____. (a) chitin (b) cyclosporine (c) cellulose (d) peptidoglycan (e) lysergic acid
2. Which of the following fungi does *not* have a mycelium? (a) black bread mold (b) yeast (c) decomposer cup fungus (d) cultivated mushroom (e) *Penicillium*
3. The condition described as $n + n$ is (a) monokaryotic (b) diploid (c) a primary mycelium (d) coenocytic (e) dikaryotic
4. With the exception of chytridiomycetes, fungi are generally disseminated by (a) water currents (b) fragmentation of hyphae (c) soredia (d) airborne spores (e) flagellate zoospores
5. Which statement is *not* true of the chytrids? (a) they are simple aquatic fungi (b) they produce motile cells with single, posterior flagella (c) they undergo both sexual and asexual reproduction (d) the black bread mold is a representative of this group (e) they were the earliest fungi to evolve
6. Which statement is *not* true of the zygomycetes? (a) many members of this group form endomycorrhizae with tree roots (b) their sexual spores are called zygospores (c) they undergo both sexual and asexual reproduction (d) plasmogamy and karyogamy occur (e) they have coenocytic hyphae
7. Which statement is *not* true of the ascomycetes? (a) their sexual spores are produced in asci (b) their asexual spores are produced in basidia (c) some species in this group are yeasts (d) their asexual spores are called conidia (e) some species cause serious plant diseases
8. The ascomycete life cycle typically includes (a) mainly diploid thalli (b) the formation of a thick zygosporangium (c) the production of eight haploid ascospores within an ascus (d) production of microsporidia (e) the production of ascospores, zoospores, and conidia at different stages
9. Which statement is *not* true of the basidiomycetes? (a) they have a diploid thallus that produces zoospores (b) their sexual spores are called basidiospores (c) they produce a secondary mycelium with $n + n$ hyphae (d) mushrooms and bracket fungi are examples of this group (e) this group includes both edible and poisonous species
10. The familiar portion of a mushroom is actually a large fruiting body called a(an) (a) ascocarp (b) basidium (c) basidiocarp (d) gametangium (e) ascus
11. Glomeromycetes (a) reproduce mainly by sexual spores called glomerospores (b) are characterized by unique structures called polar tubes (c) include some species that associate with cyanobacteria to form lichens (d) include many opportunistic pathogens that cause human disease (e) form arbuscular endomycorrhizae with tree roots
12. A symbiotic association between a photoautotroph and a fungus is called a(an) _____ (a) arbuscular endomycorrhiza (b) ectomycorrhiza (c) lichen (d) pathogenic agent (e) lignin decomposing agent
13. Fungi are (a) eukaryotes and opisthokonts (b) prokaryotes and opisthokonts (c) flagellate and dikaryotic (d) prokaryotic pathogens (e) heterotrophs with cellulose cell walls
14. Mutualistic relationships between fungi and the roots of plants are called (a) lichens (b) mycorrhizae (c) pathogenic associations (d) parasitic haustoria (e) mycotoxic symbioses
15. *Amanita virosa* (a) is the mushroom commonly cultivated for food (b) is the yeast that ferments wine and beer (c) produces the unique flavor of many cheeses (d) is a highly toxic mushroom (e) has been ingested for its hallucinogenic properties
16. Which of the following describes how a fungus infects a plant? (a) it infiltrates leaves with lichens (b) it forms relationships by attaching mycorrhizae to stems (c) it secretes powerful digestive juices onto the leaves (d) it uses haustoria to penetrate stem tissue (e) its hyphae enter leaves through a stoma
17. Mycotoxins (a) are released by most lichens (b) typically cause mild allergic reactions (c) can harm the liver (d) reduce the effects of sick-building syndrome (e) are produced mainly by chytrids
18. *Saccharomyces cerevisiae* (a) is used by biologists as a model eukaryotic cell (b) was the first prokaryote whose genome was sequenced (c) has an extremely complex genome with more than 6 million genes (d) is a mold used to produce antibiotics (e) is a common chytrid

CRITICAL THINKING

1. Explain the statement "Mushrooms are like the tips of icebergs." If you do not see mushrooms in your lawn, can you conclude that no fungi live there? Why or why not?
2. Biologists have discovered that many mycorrhizal fungi are sensitive to a low pH. What human-caused environmental problem may prove catastrophic for these fungi? How may this problem affect their plant partners?
3. **Evolution Link.** How are the life cycles of the marine alga *Ulva* (see Fig. 25-18) and *Allomyces* similar? What hypotheses do these similarities suggest about their evolutionary relationship?
4. **Evolution Link.** Justify (a) classifying fungi as opisthokonts; (b) classifying microsporidia as fungi; (c) grouping ascomycetes and basidiomycetes as sister clades.

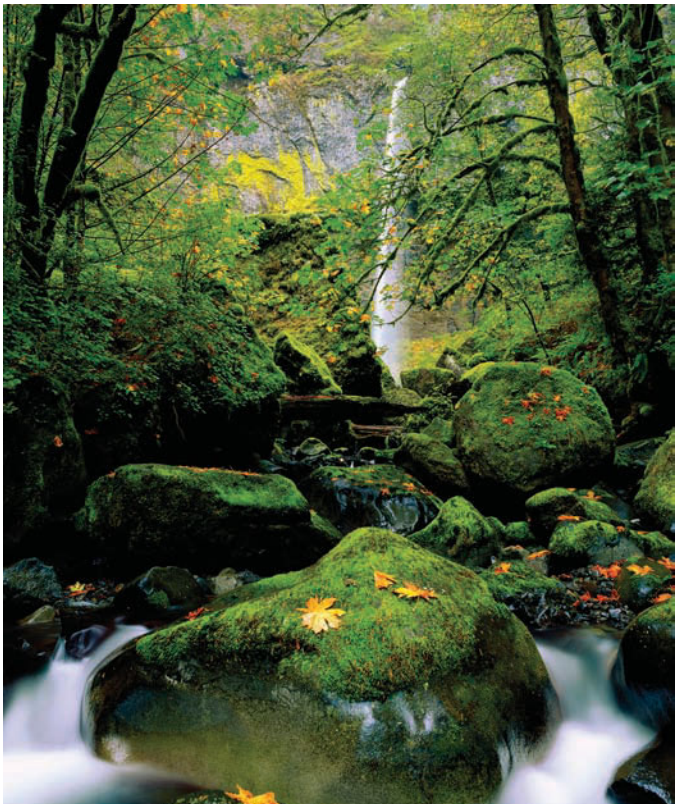
The Plant Kingdom: Seedless Plants



Darrell Gulin /Getty Images

Moss-covered rocks.
Shown is Elowa Falls, Columbia River Gorge, Oregon.

KEY CONCEPTS

Biologists infer that plants evolved from aquatic green algal ancestors known as a charophytes.

Adaptations to life on land that have evolved in plants include a waxy cuticle to prevent water loss; multicellular gametangia; stomata; and for most plants, vascular tissues containing lignin.

Plants undergo an alternation of generations between multicellular gametophyte and sporophyte generations.

Mosses and other bryophytes lack vascular tissues and do not form true roots, stems, or leaves.

In club mosses and ferns, lignin-hardened vascular tissues that transport water and dissolved substances throughout the plant body have evolved.

About 445 million years ago (mya), the ocean was filled with vast numbers of fishes, mollusks, and crustaceans as well as countless microscopic algae, and the water along rocky coastlines was home to large seaweeds. Occasionally, perhaps, an animal would crawl out of the water onto land, but it never stayed there permanently because there was little to eat on land—not a single blade of grass, no fruit, and no seeds.

During the next 30 million years, a time corresponding roughly to the Silurian period (see Table 21-1), plants appeared in abundance and colonized the land. Where did they come from? Although plants living today exhibit great diversity in size, form, and habitat (see photograph), biologists hypothesize that they all evolved from a common ancestor that was an ancient green alga. Recall from Chapter 25 that red algae, green algae, and land plants are collectively classified as "plants." Biologists infer this common ancestor because modern green algae share many biochemical and metabolic traits with modern plants. Both green algae and plants contain the same photosynthetic pigments: chlorophylls *a* and *b* and carotenoids, including xanthophylls (yellow pigments) and carotenes (orange pigments). Both store excess carbohydrates as starch and have cellulose as a major component of their cell walls. In addition, plants and some green algae share certain details of cell division, including formation of a cell plate during cytokinesis (see Chapter 10).

Land plants are complex multicellular organisms that range in size from minute, almost microscopic duckweeds to massive giant sequoias, some of the largest organisms that have ever lived. The plant kingdom consists of hundreds of thousands of species that live in varied habitats, from frozen arctic tundra to lush tropical rain forests to harsh deserts to moist stream banks. ■

ADAPTATIONS OF PLANTS

Learning Objectives

1 Discuss some environmental challenges of living on land, and describe how several plant adaptations meet these challenges.

2 Name the green algal group from which plants are hypothesized to have descended, and describe supporting evidence.

What are some features of plants that have let them colonize so many types of environments? One important difference between plants and algae is that a waxy **cuticle** covers the aerial portion of a plant. Essential for existence on land, the cuticle helps prevent desiccation, or drying out, of plant tissues by evaporation. Plants that are adapted to moister habitats may have a very thin layer of wax, whereas those adapted to drier environments often have a thick, crusty cuticle. (Many desert plants also have a reduced surface area, particularly of leaves, which minimizes water loss.)

Plants obtain the carbon they need for photosynthesis from the atmosphere as carbon dioxide (CO_2). To be fixed into organic molecules such as sugar, CO_2 must first diffuse into the chloroplasts that are inside green plant cells. Because a waxy cuticle covers the external surfaces of leaves and stems, however, gas exchange through the cuticle between the atmosphere and the interior of cells is negligible. Tiny pores called **stomata** (sing., *stoma*), which dot the surfaces of leaves and stems of almost all plants, facilitate gas exchange; algae lack stomata.

The sex organs, or **gametangia** (sing., *gametangium*), of most plants are multicellular, whereas the gametangia of algae are unicellular (Fig. 27-1). Each plant gametangium has a layer of sterile (nonreproductive) cells that surrounds and protects the delicate gametes (eggs and sperm cells). In plants, the fertilized egg develops into a multicellular **embryo** (young plant) within the female gametangium. Thus, the embryo is protected during its development. In algae, the fertilized egg develops away from its gametangium; in some algae, the gametes are released before fertilization, whereas in others the fertilized egg is released.

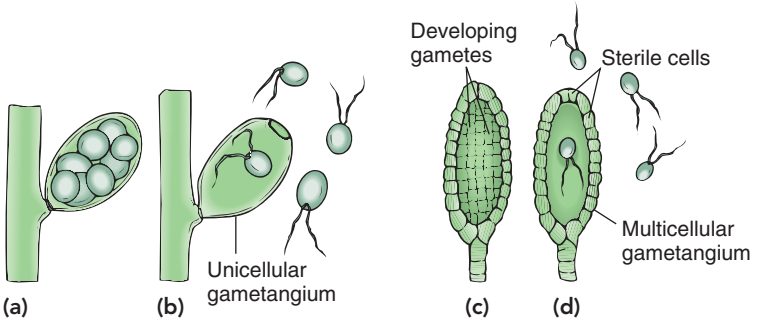


Figure 27-1 Generalized reproductive structures of algae and plants

(a, b) In algae, gametangia are generally unicellular. When the gametes are released, only the wall of the original cell remains. **(c, d)** In plants, the gametangia are multicellular, but only the inner cells become gametes. The gametes are surrounded by a protective layer of sterile (nonreproductive) cells.

The plant life cycle alternates haploid and diploid generations

Plants have a clearly defined **alternation of generations** in which they spend part of their lives in a multicellular haploid stage and part in a multicellular diploid stage (Fig. 27-2).[1] The haploid portion of the life cycle is called the **gametophyte generation** because it gives rise to haploid gametes by mitosis. When two gametes fuse, the diploid portion of the life cycle, called the **sporophyte generation,** begins. The sporophyte generation produces haploid spores by the process of meiosis; these spores represent the first stage in the gametophyte generation.

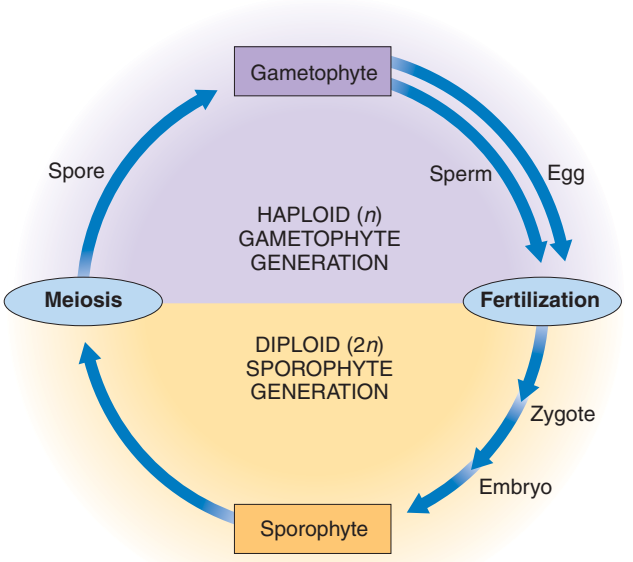

Figure 27-2 The basic plant life cycle

Plants have an alternation of generations, spending part of the cycle in a haploid gametophyte stage and part in a diploid sporophyte stage. Depending on the plant group, the haploid or the diploid stage may be greatly reduced.

[1]For convenience we limit our discussion to plants that are not polyploid, although polyploidy is very common in the plant kingdom. We therefore use the terms *diploid* and 2*n* (and *haploid* and *n*) interchangeably, although these terms are not actually synonymous.

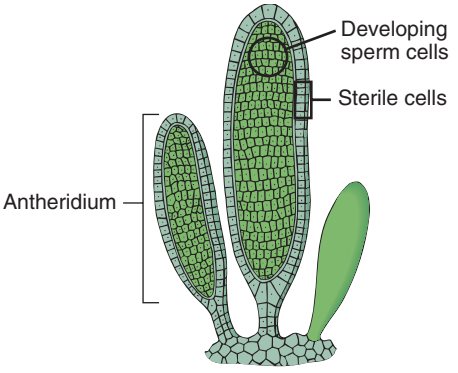
Let us examine alternation of generations more closely. The haploid gametophytes produce male gametangia, known as **antheridia** (sing., *antheridium*), in which sperm cells form, and/or female gametangia, known as **archegonia** (sing., *archegonium*), each bearing a single egg (Fig. 27-3). Sperm cells reach the female gametangium in a variety of ways, and one sperm cell fertilizes the egg to form a **zygote,** or fertilized egg.

The diploid zygote is the first stage in the sporophyte generation. The zygote divides by mitosis and develops into a multicellular embryo, the young sporophyte plant. Embryo development takes place within the archegonium; thus, the embryo is protected as it develops. Eventually the embryo grows into a mature sporophyte plant. The mature sporophyte has special cells called *sporogenous cells* (spore-producing cells, also called *spore mother cells*) that divide by meiosis to form haploid **spores.**

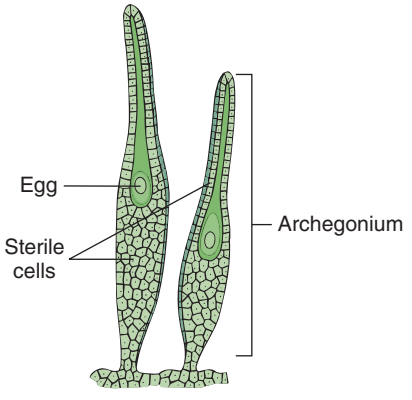
Fertilization of egg by sperm cell ⟶ zygote ⟶ embryo ⟶ mature sporophyte plant ⟶ sporogenous cells ⟶ meiosis ⟶ spores

All plants produce spores by meiosis, in contrast with algae and fungi, which may produce spores by meiosis or mitosis. The spores represent the first stage in the gametophyte generation. Each spore divides by mitosis to produce a multicellular gametophyte, and the cycle continues. Plants therefore alternate between a haploid gametophyte generation and a diploid sporophyte generation.

Spores ⟶ mature gametophyte plants ⟶ archegonia ⟶ eggs; antheridia ⟶ sperm cells



(a) Each antheridium, the male gametangium, produces numerous sperm cells.



(b) Each archegonium, the female gametangium, produces a single egg.

Figure 27-3 Plant gametangia
Shown are generalized moss gametangia.

Four major groups of plants evolved

Recent ultrastructural and molecular data indicate that land plants probably descended from a group of green algae called **charophytes** or **stoneworts** (see Fig. 25-16d). Molecular comparisons, particularly of DNA and RNA sequences, provide compelling evidence that charophytes are closely allied to plants. These comparisons among plants and various green algae include sequences of chloroplast DNA, certain nuclear genes, and ribosomal RNA. In each case, the closest match occurs between charophytes and plants, indicating that modern charophytes and plants probably share a recent common ancestor.

The plant kingdom consists of four major groups: bryophytes, seedless vascular plants, and two groups of seeded vascular plants: gymnosperms and angiosperms (flowering plants) (Fig. 27-4; see also Table 27-1, which is an overview of plant phyla). The mosses and other bryophytes are small nonvascular plants that lack a specialized vascular, or conducting, system to transport nutrients, water, and essential minerals (inorganic nutrients) throughout the plant body. In the absence of such a system, bryophytes rely on diffusion and osmosis to obtain needed

TABLE 27-1

The Plant Kingdom

Nonvascular plants with a dominant gametophyte generation (bryophytes)
- Phylum Bryophyta (mosses)
- Phylum Hepatophyta (liverworts)
- Phylum Anthocerophyta (hornworts)

Vascular plants with a dominant sporophyte generation

Seedless plants
- Phylum Lycopodiophyta (club mosses)
- Phylum Pteridophyta (ferns and their allies, the whisk ferns and horsetails)

Seed plants

Plants with naked seeds (gymnosperms)
- Phylum Coniferophyta (conifers)
- Phylum Cycadophyta (cycads)
- Phylum Ginkgophyta (ginkgoes)
- Phylum Gnetophyta (gnetophytes)

Seeds enclosed within a fruit
- Phylum Anthophyta (angiosperms or flowering plants)
  - Class Eudicotyledones (eudicots)
  - Class Monocotyledones (monocots)

Key Point

This cladogram shows hypothetical evolutionary relationships among living plants, based on current evidence. The four major groups of plants are bryophytes, seedless vascular plants, and two groups of seed plants—gymnosperms and angiosperms.

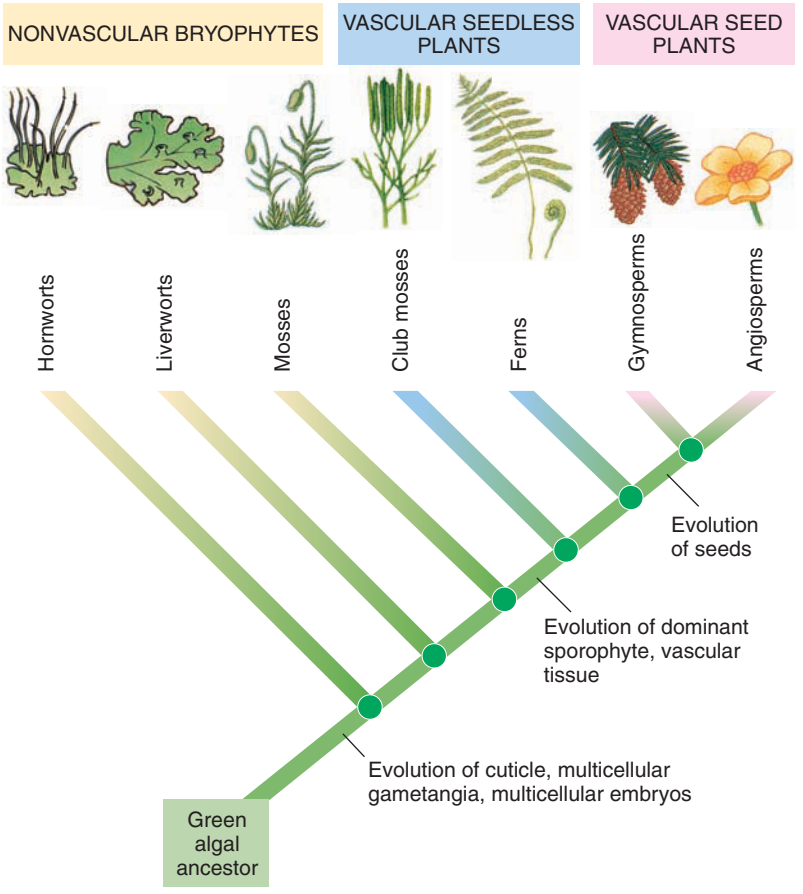


Figure 27-4 ***Animated*** Plant evolution

Cladograms such as this one represent an emerging consensus that is open to change as new discoveries are made. Although the arrangement of nonvascular, seedless vascular, and seed plant groupings is widely recognized, the order in which the hornworts, liverworts, and mosses evolved is not yet resolved.

materials. This reliance means that bryophytes are restricted in size; if they were much larger, some of their cells could not obtain enough necessary materials. Bryophytes do not form seeds, the reproductive structures discussed in Chapter 28. Bryophytes reproduce and disperse primarily via haploid spores. Recent molecular and fossil evidence, discussed later in the chapter, suggests that bryophytes may have been the earliest plants to colonize land.

The other three groups of plants—seedless vascular plants, gymnosperms, and flowering plants—have vascular tissues and are thus known as vascular plants. The two vascular tissues are **xylem,** for conducting water and dissolved minerals, and **phloem,** for conducting dissolved organic molecules such as sugar. A key step in the evolution of vascular plants was the ability to produce **lignin,** a strengthening polymer in the walls of cells that function for support and conduction (see Chapter 32 for a discussion of plant cell wall chemistry, including lignin). The stiffening property of lignin enabled plants to grow tall (which let them maximize light interception). The successful occupation of the land by plants, in turn, made the evolution of terrestrial animals possible by providing them with both habitat and food.

Club mosses and ferns (which include whisk ferns and horsetails) are seedless vascular plants that, like the bryophytes, reproduce and disperse primarily via spores. Seedless vascular plants arose and diversified during the Silurian and Devonian periods of the Paleozoic era, between 444 mya and 359 mya. Club mosses and ferns extend back more than 420 million years and were of considerable importance as Earth's dominant plants in past ages. Fossil evidence indicates that many species of these plants were the size of immense trees. Most living representatives of club mosses and ferns are small.

The gymnosperms are vascular plants that reproduce by forming seeds. Gymnosperms produce seeds borne exposed (unprotected) on a stem or in a cone. Plants with seeds as their primary means of reproduction and dispersal first appeared about 359 mya, at the end of the Devonian period. These early seed plants diversified into many varied species of gymnosperms.

The most recent plant group to appear is the flowering plants, or angiosperms, which arose during the early Cretaceous period of the Mesozoic era, about 130 mya. Like gymnosperms, flowering plants reproduce by forming seeds. Flowering plants, however, produce seeds enclosed within a fruit.

Review

- What are the most important environmental challenges that plants face living on land?
- What adaptations do plants have to meet these environmental challenges?
- From which group of green algae are plants hypothesized to have descended?
- What is alternation of generations in plants?

BRYOPHYTES

Learning Objectives

3 Summarize the features that distinguish bryophytes from other plants.
4 Name and briefly describe the three phyla of bryophytes.
5 Describe the life cycle of mosses, and compare their gametophyte and sporophyte generations.

The **bryophytes** (from the Greek words meaning "moss plant") consist of about 16,000 species of mosses, liverworts, and hornworts; bryophytes are the only living nonvascular plants (Table 27-2). Because they have no means for extensive internal transport of water, sugar, and essential minerals, bryophytes are typically quite small. They generally require a moist environment for

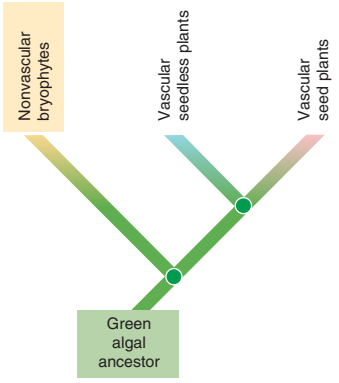
TABLE 27-2

A Comparison of Major Groups of Seedless Plants

Plant Group	Dominant Stage of Life Cycle	Representative Genera
Nonvascular; reproduce by spores (bryophytes)		
Mosses (phylum Bryophyta)	Gametophyte: leafy plant	*Polytrichum, Sphagnum, Physcomitrella*
Liverworts (phylum Hepatophyta)	Gametophyte: thalloid or leafy plant	*Marchantia*
Hornworts (phylum Anthocerophyta)	Gametophyte: thalloid plant	*Anthoceros*
Vascular; reproduce by spores		
Club mosses (phylum Lycopodiophyta)	Sporophyte: roots, rhizomes, erect stems, and leaves (microphylls)	*Lycopodium, Selaginella*
Ferns (phylum Pteridophyta)	Sporophyte: roots, rhizomes, and leaves (megaphylls)	*Pteridium, Polystichum, Azolla, Platycerium*
Whisk ferns (phylum Pteridophyta)	Sporophyte: rhizomes and erect stems; no true roots or leaves	*Psilotum*
Horsetails (phylum Pteridophyta)	Sporophyte: roots, rhizomes, erect stems, and leaves (reduced megaphylls)	*Equisetum*

active growth and reproduction, but some bryophytes tolerate dry areas.

The bryophytes are divided into three distinct phyla: mosses (phylum Bryophyta), liverworts (phylum Hepatophyta), and hornworts (phylum Anthocerophyta) (Fig. 27-5). These three groups differ in many ways and may or may not be closely related. They are usually studied together because they lack vascular tissues and have similar life cycles.



Moss gametophytes are differentiated into "leaves" and "stems"

Mosses (phylum Bryophyta), which include about 9900 species, usually live in dense colonies or beds (see Fig. 27-5a). Each individual plant has tiny, hairlike absorptive structures called *rhizoids* and an upright, stemlike structure that bears leaflike blades, each normally consisting of a single layer of undifferentiated cells except at the midrib. Because mosses lack vascular tissues, they do not have true roots, stems, or leaves; the moss structures are not homologous to roots, stems, or leaves in vascular plants. Some moss species have water-conducting cells and sugar-conducting

Figure 27-5 Bryophytes

cells, although these cells are not lignified and as specialized or as effective as the conducting cells of vascular plants.

Alternation of generations is clear in the life cycle of mosses (Fig. 27-6). As shown in 1, the green moss gametophyte often bears its gametangia at the top of the plant. Many moss species have separate sexes: male plants that bear antheridia and female plants that bear archegonia. Other mosses produce antheridia and archegonia on the same plant.

Fertilization occurs when one of the sperm cells fuses with the egg within the archegonium 2. Sperm cells, which have flagella, are transported from antheridium to archegonium by flowing water, such as splashing rain droplets. A raindrop lands on the top of a male gametophyte, and sperm cells are released into it from the antheridia. Another raindrop landing on the male plant may splash the sperm-laden droplet into the air and onto the top of a nearby female plant. Alternatively, insects may touch the sperm-laden fluid and inadvertently carry it for considerable distances. Once in a film of water on the female moss, a sperm cell swims into the archegonium, which secretes chemicals to attract and guide the sperm cells, and fuses with the egg.

The diploid zygote, formed by fertilization 3, grows by mitosis into a multicellular embryo that develops into a mature moss sporophyte 4. This sporophyte grows out of the top of the female gametophyte and remains attached and nutritionally dependent on the gametophyte throughout its existence (Fig. 27-7). Initially green and photosynthetic, the sporophyte becomes golden brown at maturity. It consists of three main parts: a *foot,* which anchors the sporophyte to the gametophyte and absorbs minerals and nutrients from it; a *seta,* or stalk; and a *capsule,* which contains sporogenous cells (spore mother cells). The capsule of some species is covered by a caplike structure, the *calyptra,* which is derived from the archegonium.

The sporogenous cells undergo meiosis to form haploid spores (see Fig. 27-6 5). When the spores are mature, the capsule opens and releases the spores, which are then transported by wind or rain. If a moss spore lands in a suitable spot, it germinates

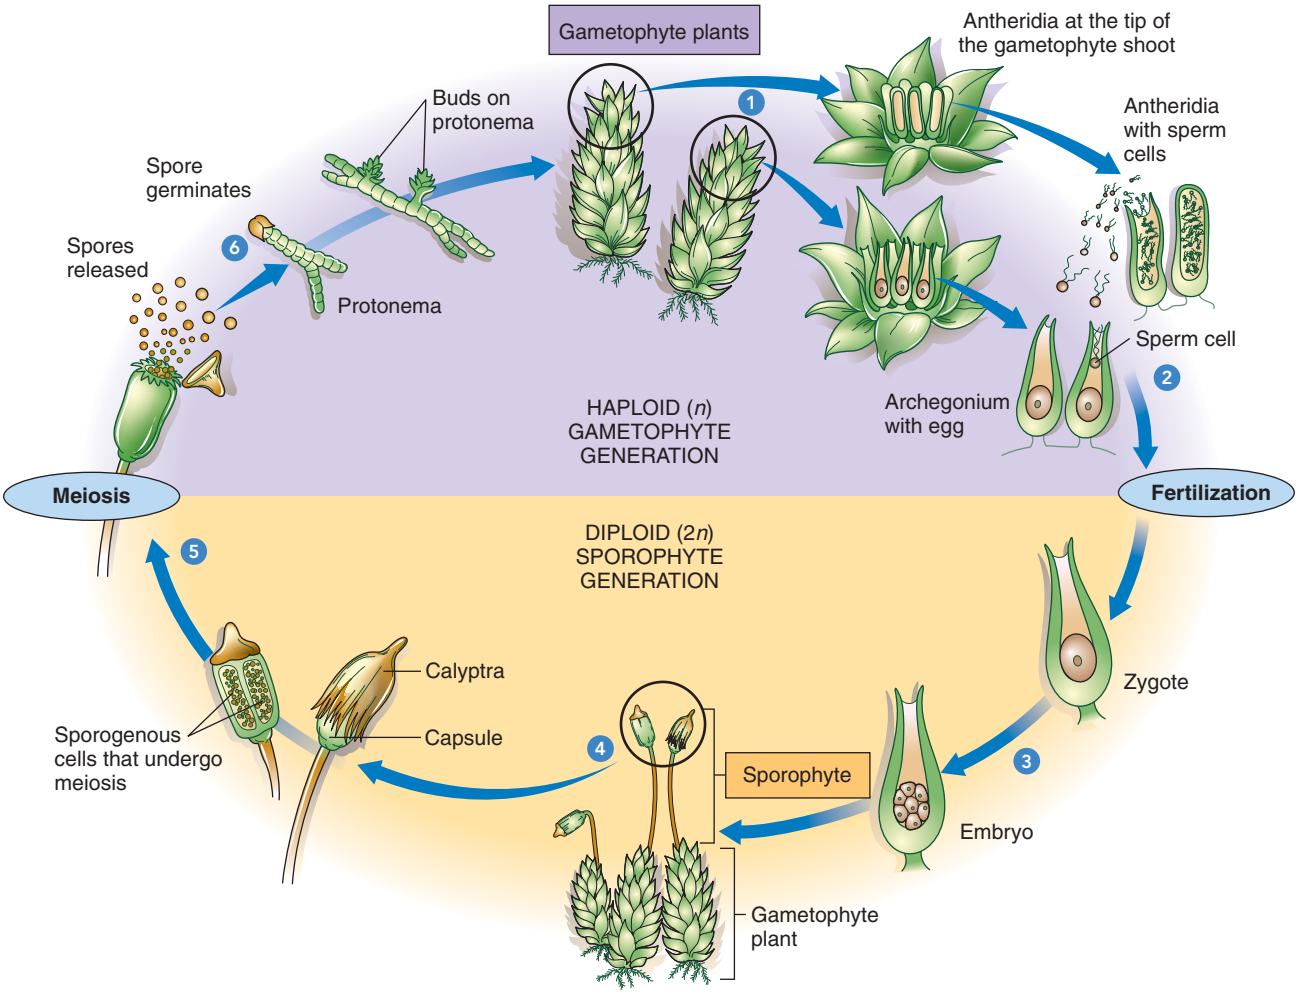

Figure 27-6 ***Animated*** The life cycle of mosses

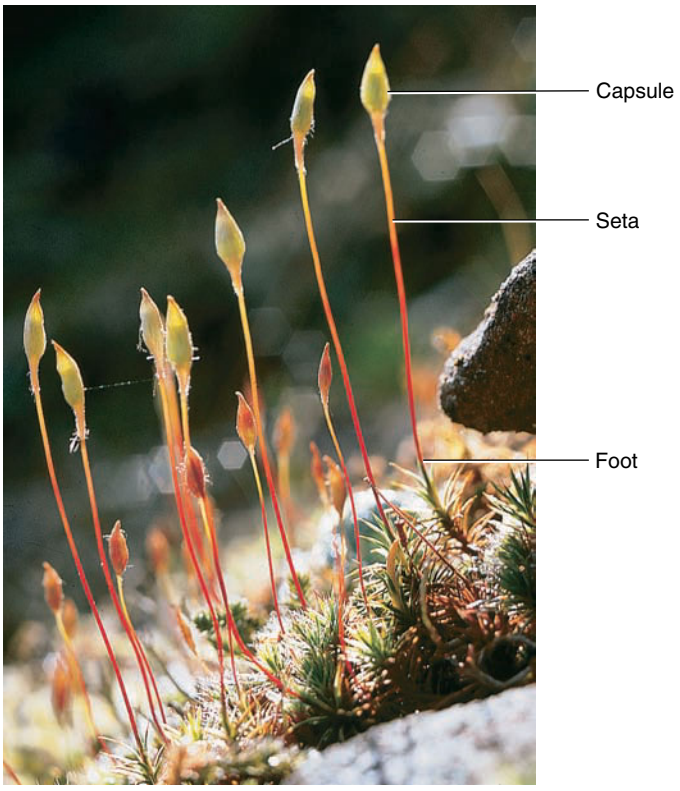
The gametophyte generation is dominant in the moss life cycle. After sexual reproduction, the sporophyte grows out of the gametophyte. See text for a detailed description.



David Cavagnaro

Figure 27-7 Moss sporophytes

and grows into a filament of cells called a **protonema** 6. The protonema, which superficially resembles a filamentous green alga, forms buds, each of which grows into a green gametophyte, and the life cycle continues.

Biologists consider the haploid gametophyte generation the dominant generation in mosses because it lives independently of the diploid sporophyte. In contrast, the moss sporophyte is attached to and nutritionally dependent on the gametophyte.

Mosses make up an inconspicuous but significant part of their environment. They play an important role in forming soil. Because they grow tightly packed in dense colonies, mosses hold soil in place and help prevent erosion.

Commercially, the most important mosses are the peat mosses in the genus *Sphagnum*. One of the distinctive features of *Sphagnum* "leaves" is the presence of many large dead cells that absorb and hold water. This feature makes peat moss particularly beneficial as a soil conditioner. Added to sandy soils, for example, peat moss helps absorb and retain moisture. In some countries, such as Ireland and Scotland, people cut out layers of dead peat moss that have accumulated for hundreds of years in peat bogs, dry them, and burn them for fuel.

The name "moss" is often misused to refer to plants that are not truly mosses. For example, reindeer "moss" is a lichen that is a dominant form of vegetation in the arctic tundra, Spanish "moss" is a flowering plant, and club "moss" (discussed later in the chapter) is a relative of ferns.

Liverwort gametophytes are either thalloid or leafy

Liverworts (phylum Hepatophyta) consist of about 6000 species of nonvascular plants with a dominant gametophyte generation, but the gametophytes of some liverworts are quite different from those of mosses. Their body form is often a flattened, lobed structure called a **thallus** (pl., *thalli*) that is not differentiated into leaves, stems, or roots. The common liverwort, *Marchantia polymorpha,* is thalloid (see Fig. 27-5b). Liverworts are so named because the lobes of their thalli superficially resemble the lobes of the human liver; *wort* is derived from the Old English word *wyrt,* meaning "plant." On the underside of the liverwort thallus are hairlike rhizoids that anchor the plant to the soil. Other liverworts, known as *leafy liverworts,* superficially resemble mosses, with leaflike blades, "stems," and rhizoids rather than a lobed thallus. As in the mosses, leafy liverwort "leaves" consist of a single layer of undifferentiated cells. Like other bryophytes, liverworts are small, generally inconspicuous plants that are largely restricted to damp environments. Unlike mosses, hornworts, and other plants, liverworts lack stomata (although some liverworts have surface pores thought to be analogous to stomata).

Liverworts reproduce both sexually and asexually (Fig. 27-8). As shown in 1, their sexual reproduction involves production of archegonia and antheridia on the haploid gametophyte. In some liverworts, these gametangia are borne on stalked structures called *archegoniophores,* which bear archegonia, and *antheridiophores,* which bear antheridia. Their life cycle is basically the same as that of mosses, although some of the structures look quite different. Splashing raindrops transport sperm cells to the archegonia, where fertilization takes place 2. The resulting zygote develops into a multicellular embryo that becomes a mature sporophyte 3. The liverwort sporophyte, which is usually somewhat spherical, is attached to the gametophyte, as in mosses. As shown in 4, sporogenous cells in the capsule of the sporophyte undergo meiosis, producing haploid spores. Each spore has the potential to develop into a green gametophyte 5, and the cycle continues.

Some liverworts reproduce asexually by forming tiny balls of tissue called **gemmae** (sing., *gemma*), which are borne in a saucer-shaped structure, the gemmae cup, directly on the liverwort thallus. Splashing raindrops and small animals help disperse gemmae. When a gemma lands in a suitable place, it grows into a new liverwort thallus. Liverworts may also reproduce asexually by thallus branching and growth. The individual thallus lobes elongate, and each becomes a separate plant when the older part of the thallus that originally connected the individual lobes dies.

Hornwort gametophytes are inconspicuous thalloid plants

Hornworts (phylum Anthocerophyta) are a small group of about 100 species of bryophytes whose gametophytes superficially resemble those of the thalloid liverworts. Hornworts live in disturbed habitats such as fallow fields and roadsides.

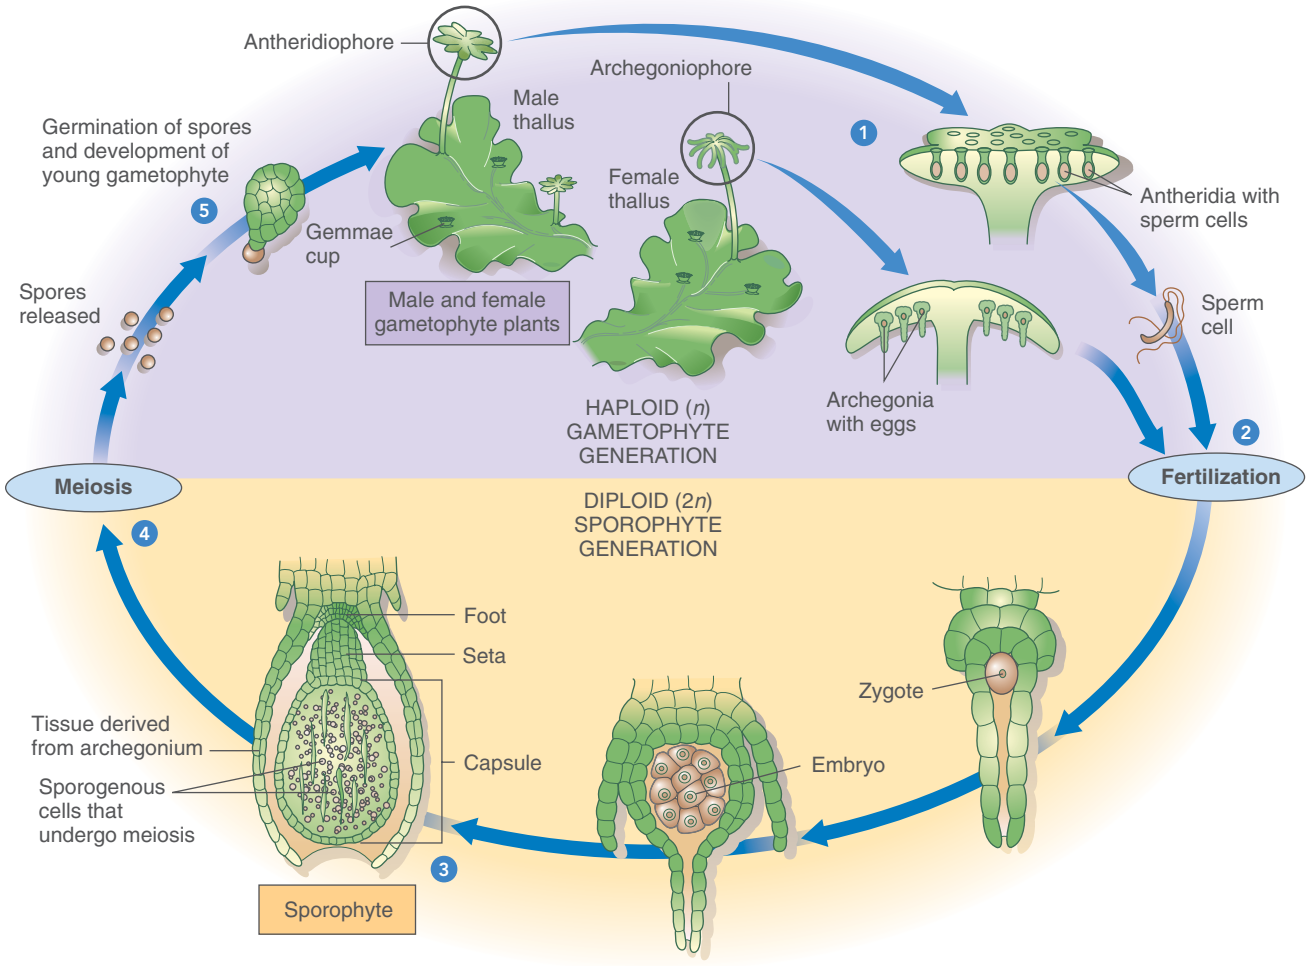

Figure 27-8 ***Animated*** The life cycle of the common liverwort (*Marchantia polymorpha*)

The dominant generation is the gametophyte, represented by separate male and female thalli. The stalked, umbrella-shaped structures are the antheridiophores, with antheridia that produce sperm cells, and the archegoniophores, with archegonia that each bear an egg cell. See text for a detailed description.

Hornworts may or may not be closely related to other bryophytes. For example, their cell structure, particularly the presence of a single large chloroplast in each cell, resembles certain algal cells more than plant cells. In contrast, mosses, liverworts, and other plants have many disc-shaped chloroplasts per cell.

In the common hornwort (*Anthoceros natans*), archegonia and antheridia are embedded in the gametophyte thallus rather than on archegoniophores and antheridiophores. After fertilization and development, the needlelike sporophyte projects out of the gametophyte thallus, forming a spike or "horn"—hence the name *hornwort.* A single gametophyte often produces multiple sporophytes (see Fig. 27-5c). Meiosis occurs, forming spores within each **sporangium** (pl., *sporangia*), or spore case. The sporangium splits open from the top to release the spores; each spore can give rise to a new gametophyte thallus. A unique feature of hornworts is that the sporophytes, unlike those of mosses and liverworts, continue to grow from their bases for the remainder of the gametophyte's life.

Bryophytes are used for experimental studies

Botanists use certain bryophytes as experimental models to study many fundamental aspects of plant biology, including genetics, growth and development, plant ecology, plant hormones, and *photoperiodism,* which is plant responses to varying periods of night and day length. The moss *Physcomitrella patens* is a particularly important research organism for studying plant evolution because its features and genome can be compared to those of flowering plants. In this regard, *Physcomitrella* is the plant equivalent of the fruit fly *Drosophila,* which is an important model organism for studies of animal inheritance, development, and evolution. As

Researchers inoculated this petri dish with offspring from a genetic cross in the moss *Physcomitrella patens.* They will test the cultures for their phenotypes with respect to vitamin requirements. (The culture medium in which the mosses are currently growing is supplemented with all the vitamins required by the parental strains.)

experimental organisms, *Physcomitrella* and other bryophytes are easy to grow on artificial media and do not require much space because they are so small (Fig. 27-9).

Details of bryophyte evolution are based on fossils and on structural and molecular evidence

Plants are a **monophyletic group**—that is, all plants probably evolved from a common ancestral green alga. Fossil evidence indicates that bryophytes are ancient plants, probably the first group of plants to arise from the common plant ancestor. The fossil record of ancient bryophytes is incomplete, consisting mostly of spores and small tissue fragments, and can be interpreted in different ways. As a result, it does not provide a definite answer on bryophyte evolution.

The oldest known recognizable plant fossils are dated at about 425 million years old. These fossils resemble modern liverworts in many respects, but the spores are virtually identical to those in 470-million-year-old rocks. In 2003, scientists reported fossil fragments of tiny liverwort-like plants associated with ancient spores that were discovered in Oman. This evidence suggests that liverwort-like plants may have been the earliest plants to colonize land.

Structural and molecular evidence, however, supports the hypothesis that *hornworts* may be the most ancient group of plants alive today. A 1998 cladistic analysis using structural data was the first to strongly support this hypothesis, which was reinforced in 2000 by DNA evidence. The study of nuclear, chloroplast, and mitochondrial genes from numerous plant species, from bryophytes to flowering plants, suggests that an early plant ancestor gave rise to two lineages, one from which the hornworts descended and the other from which all other plants descended.

Review

- Which of the following are parts of the gametophyte generation in mosses: antheridia, zygote, embryo, capsule, archegonia, sperm cells, egg cell, spores, and protonema?
- How are mosses, liverworts, and hornworts similar? How is each group distinctive?

SEEDLESS VASCULAR PLANTS

Learning Objectives

6 Discuss the features that distinguish seedless vascular plants from algae and bryophytes.
7 Name and briefly describe the two phyla of seedless vascular plants.
8 Describe the life cycle of ferns, and compare their sporophyte and gametophyte generations.
9 Compare the generalized life cycles of homosporous and heterosporous plants.

The most important adaptation found in seedless vascular plants, though absent in algae and bryophytes, is specialized vascular tissues—xylem and phloem—for support and conduction. This system of conduction lets vascular plants grow larger than the bryophytes because water, minerals, and sugar are transported to all parts of the plant. Although seedless vascular plants in temperate environments are relatively small, tree ferns in the tropics may grow to heights of 18 m (60 ft). All seedless vascular plants have true stems with vascular tissues, and most also have true roots and leaves.

Botanists have extensively studied the evolution of the leaf as the main organ of photosynthesis. The two basic types of true leaves—microphylls and megaphylls—evolved independently of one another (Fig. 27-10). The **microphyll,** which is usually small and has a single vascular strand, probably evolved from small, projecting extensions of stem tissue (*enations*). Only one group of living plants, the club mosses, has microphylls. In contrast, **megaphylls** probably evolved from stem branches that gradually filled in with additional tissue (*webbing*) to form most leaves as we know them today. Megaphylls have more than one vascular strand, as we would expect if they evolved from branch systems. Ferns (with the exception of whisk ferns, discussed later in the chapter), gymnosperms, and flowering plants have megaphylls.

Recent evidence suggests megaphylls evolved over a 40-million-year period in the Late Paleozoic era in response to a gradual decline in the level of atmospheric CO_2. As CO_2 declined, plants developed a flattened blade with more stomata for gas exchange. (More stomata allowed cells inside the leaf to get enough CO_2.)

There are two main clades of seedless vascular plants: the club mosses and the ferns. Biologists originally considered horsetails and whisk ferns distinct enough to be classified in separate phyla. However, many kinds of evidence, such as DNA comparisons and similarities in sperm structure, have resulted in their being reclassified as ferns. As shown in Figure 27-4, ferns, including horsetails and whisk ferns, are a monophyletic group and the closest living relatives of seed plants.

focus on

ANCIENT PLANTS AND COAL FORMATION

Industrial society depends on energy from fossil fuels that formed from the remains of ancient organisms. One of the most important fossil fuels is coal, which people burn to produce electricity and to manufacture items of steel and iron. Although mined, coal is not an inorganic mineral like gold or aluminum but an organic material formed from the remains of ancient vascular plants, particularly those of the Carboniferous period, approximately 320 mya. Five main groups of plants contributed to coal formation. Three were seedless vascular plants: the club mosses, horsetails, and ferns. The other two were seed plants: seed ferns (now extinct) and early gymnosperms.

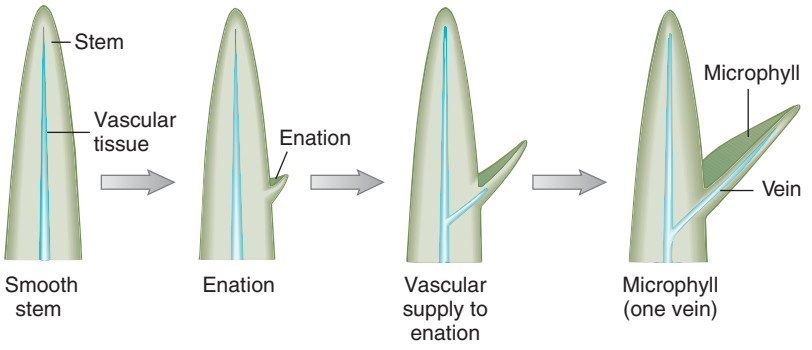
It is hard to imagine that relatives of the small, relatively inconspicuous club mosses, ferns, and horsetails of today were so significant in forming vast beds of coal. However, many members of these groups that existed during the Carboniferous period were giants compared with their modern counterparts and formed immense forests (see Fig. 21-11).

The climate during the Carboniferous period was warm, moist, and mild. Plants in most locations could grow year-round because of the favorable conditions. Forests of these plants often grew in low-lying, swampy areas that periodically flooded when the sea level rose. As the sea level receded, these plants would re-establish.

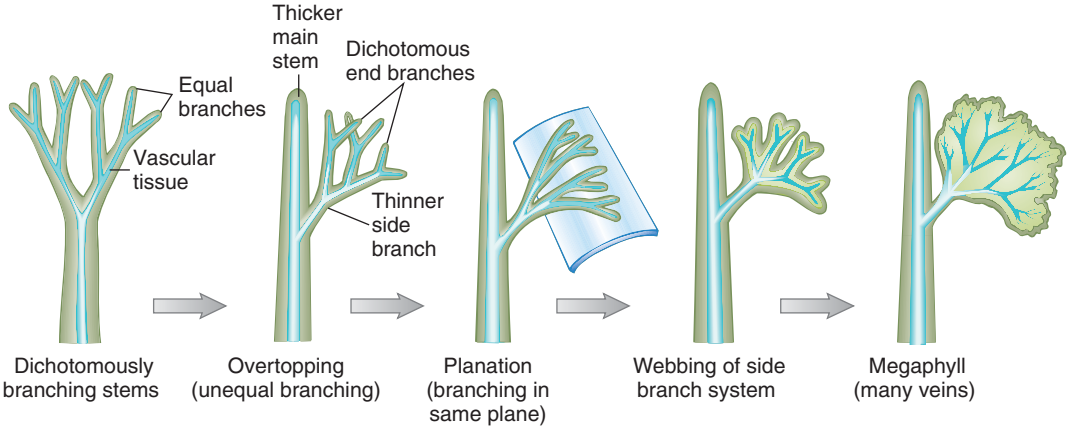
When these large plants died or were blown over in storms, they decomposed incompletely because they were covered by swamp water. (The anaerobic conditions of the water prevented wood-rotting fungi from decomposing the plants, and anaerobic bacteria do not decompose wood rapidly.) Thus, over time the partially decomposed plant material accumulated and consolidated.

Layers of sediment formed over the plant material each time the water level rose and flooded the low-lying swamps. With time, heat and pressure built up in these accumulated layers and converted the plant material to coal and the sediment layers to sedimentary rock. Much later, geologic upheavals raised the layers of coal and sedimentary rock. Coal is usually found in seams, underground layers that vary in thickness from 2.5 cm to more than 30 m (100 ft).

The various grades of coal (lignite, subbituminous, bituminous, and anthracite) formed as a result of the different temperatures and pressures to which the layers were exposed. Coal exposed to high heat and pressure during its formation is drier, is more compact (and therefore harder), and has a higher heating value (that is, a higher energy content).



(a) Microphyll evolution



(b) Megaphyll evolution

Figure 27-10
Evolution of microphylls and megaphylls

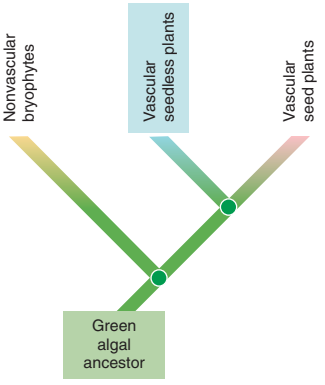
Dichotomous branching (in **b**) is branching into two equal halves. Webbing (in **b**) is the evolutionary process in which the spaces between close branches become filled with chlorophyll-containing cells.

Club mosses are small plants with rhizomes and short, erect branches

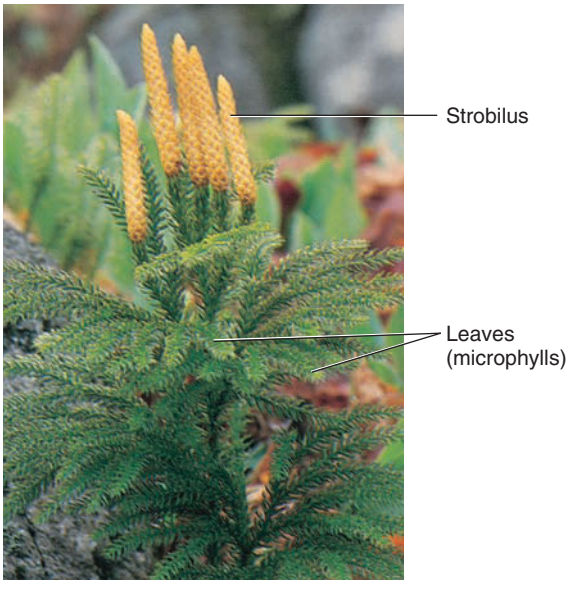
Club mosses (phylum Lycopodiophyta) were important plants millions of years ago, when species that are now extinct often reached great size (Fig. 27-11a). These large, treelike plants were major contributors to our present-day coal deposits (see *Focus On: Ancient Plants and Coal Formation*).

The 1200 or so species of club mosses living today, such as *Lycopodium* (Fig. 27-11b), are small (less than 25 cm, or 10 in, tall), attractive plants common in temperate woodlands. They possess true roots; both rhizomes and erect aerial stems; and small, scalelike leaves (microphylls). Sporangia are borne on reproductive leaves that are either clustered in conelike strobili at the tips of stems or scattered in reproductive areas along the stem. Club mosses are evergreen and often fashioned into Christmas wreaths and other decorations. In some areas they are endangered by overharvesting.

That common names are sometimes misleading in biology is vividly evident in this group of plants. The most common names for the phylum Lycopodiophyta are "club mosses" and "ground pines," yet these plants are neither mosses, which are nonvascular, nor pines, which are seed plants.



(a) Reconstruction of *Lepidodendron*. This ancient club moss was the size of a large tree—to 40 m (about 130 ft). Numerous fossils of *Lepidodendron* were preserved in coal deposits, particularly in Great Britain and the central United States.



Ed Reschke

(b) The sporophyte of *Lycopodium*, a club moss, has small, scalelike leaves (microphylls) that are evergreen. Spores are produced in sporangia on reproductive leaves clustered in a conelike strobilus (*as shown*) or, in other species, scattered along the stem.

Ferns are a diverse group of spore-forming vascular plants

Most of the 11,000 species of **ferns** (phylum Pteridophyta) are terrestrial, although a few have adapted to aquatic habitats (Fig. 27-12a and b). Ferns range from the tropics to the Arctic Circle, with most species living in tropical rain forests, where they perch high in the branches of trees (Fig. 27-12c). In temperate regions, ferns commonly inhabit swamps, marshes, moist woodlands, and stream banks. Some species grow in fields, rocky crevices on cliffs or mountains, or even deserts.

The life cycle of ferns involves a clearly defined alternation of generations. The ferns grown as houseplants (such as Boston fern, maidenhair fern, and staghorn fern) represent the larger, more conspicuous sporophyte generation. As shown in Figure 27-13 (1), the fern sporophyte consists of a horizontal underground stem, or *rhizome,* that bears leaves, called *fronds,* and true roots. As each young frond first emerges from the ground, it is tightly coiled and resembles the top of a violin, hence the name *fiddlehead.* As fiddleheads grow, they unroll and expand to form fronds. Fern fronds are usually compound (the blade is divided into several leaflets), with the leaflets forming beautifully complex leaves. Fronds, roots, and rhizomes all contain vascular tissues.

Spore production usually occurs in certain areas on the fronds, which develop sporangia. Many species bear the sporangia in clusters, called **sori** (sing., *sorus*) (2). Within sporangia, sporogenous cells (spore mother cells) undergo meiosis to form haploid spores. The sporangia burst open and discharge spores that may germinate and grow by mitosis into gametophytes (3).

The mature fern gametophyte, which bears no resemblance to the sporophyte, is a tiny (less than half the size of one of your fingernails), green, often heart-shaped structure that grows flat against the ground (4). Called a **prothallus** (pl., *prothalli*), the fern gametophyte lacks vascular tissues and has tiny, hairlike absorptive rhizoids to anchor it. The prothallus usually produces both archegonia and antheridia on its underside (5). Each archegonium contains a

Figure 27-11 Club mosses

(**a,** Redrawn from M. Hirmer, *Handbuch der Paläobotanik,* R. Olderbourg, Munich, 1927.)

single egg, whereas numerous sperm cells are produced in each antheridium.

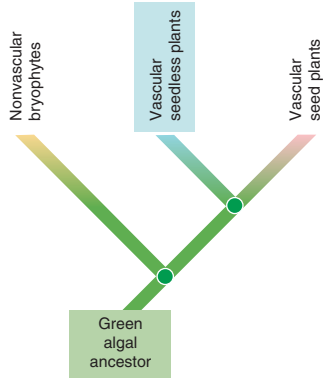
Ferns use water as a transport medium. The flagellate sperm cells swim, usually from a nearby prothallus, to the neck of an archegonium through a thin film of water on the ground underneath the prothallus. As shown in 6, after one of the sperm cells fertilizes the egg, a diploid zygote grows by mitosis into a multicellular embryo (an immature sporophyte). At this stage, the sporophyte embryo is attached to and dependent on the gametophyte; but as the embryo matures, the prothallus withers and dies, and the sporophyte becomes free-living.

The fern life cycle alternates between the dominant, diploid sporophyte with its rhizome, roots, and fronds, and the haploid gametophyte (prothallus). The sporophyte generation is dominant not only because it is larger than the gametophyte but also because it persists for an extended period (most fern sporophytes are perennials), whereas the gametophyte dies soon after reproducing.

Whisk ferns are classified as reduced ferns

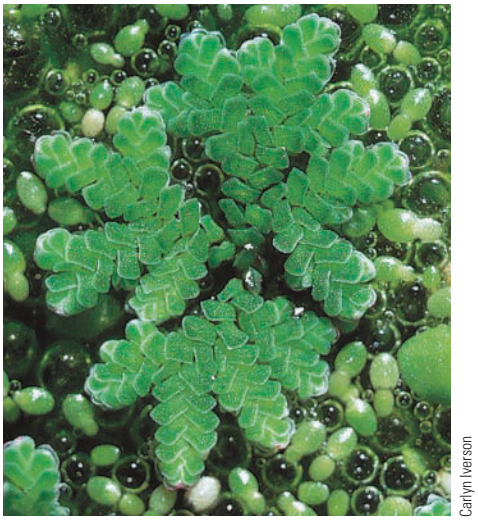
Only about 12 species of **whisk ferns** (phylum Pteridophyta) exist today, and the fossil record contains several extinct species. Whisk ferns, which live mainly in the tropics and subtropics, are relatively simple in structure and lack true roots and leaves but have vascularized stems. *Psilotum nudum,* a representative whisk fern, has both a horizontal underground rhizome and vertical aerial stems (Fig. 27-14).Whenever the stem forks, or branches, it always divides into two equal halves. Botanists call this forking **dichotomous branching**. In contrast, when most plant stems branch, one stem is more vigorous and becomes the main trunk.

The upright stems of *Psilotum* are green and are the main organs of photosynthesis. Tiny, round sporangia, borne directly on the erect, aerial stems, contain sporogenous cells that undergo



Ed Reschke

(a) The Christmas fern (*Polystichum acrostichoides*) is green at Christmas, making it a popular decoration. This fern, photographed in the Great Smoky Mountains in Tennessee, has fronds that grow to 0.6 m (2 ft) in length.



W. Oremrod/Visuals Unlimited

(b) The tiny mosquito fern (*Azolla caroliniana*) is a free-floating aquatic fern that does not resemble "typical" ferns. Although each individual plant grows to only about 1.3 cm (0.5 in) in length, *Azolla* populations sometimes grow so densely across ponds that they reportedly smother mosquito larvae. Photographed in Massachusetts.

Carlyn Iverson

(c) The staghorn fern (*Platycerium bifurcatum*) is native to Australian rain forests and is widely cultivated elsewhere. In nature the staghorn fern is an epiphyte, a plant that grows attached to another organism (in this case, a tree trunk) but derives no nourishment from it. The individual leaves grow to 0.9 m (3 ft) in length.

Figure 27-12 Ferns

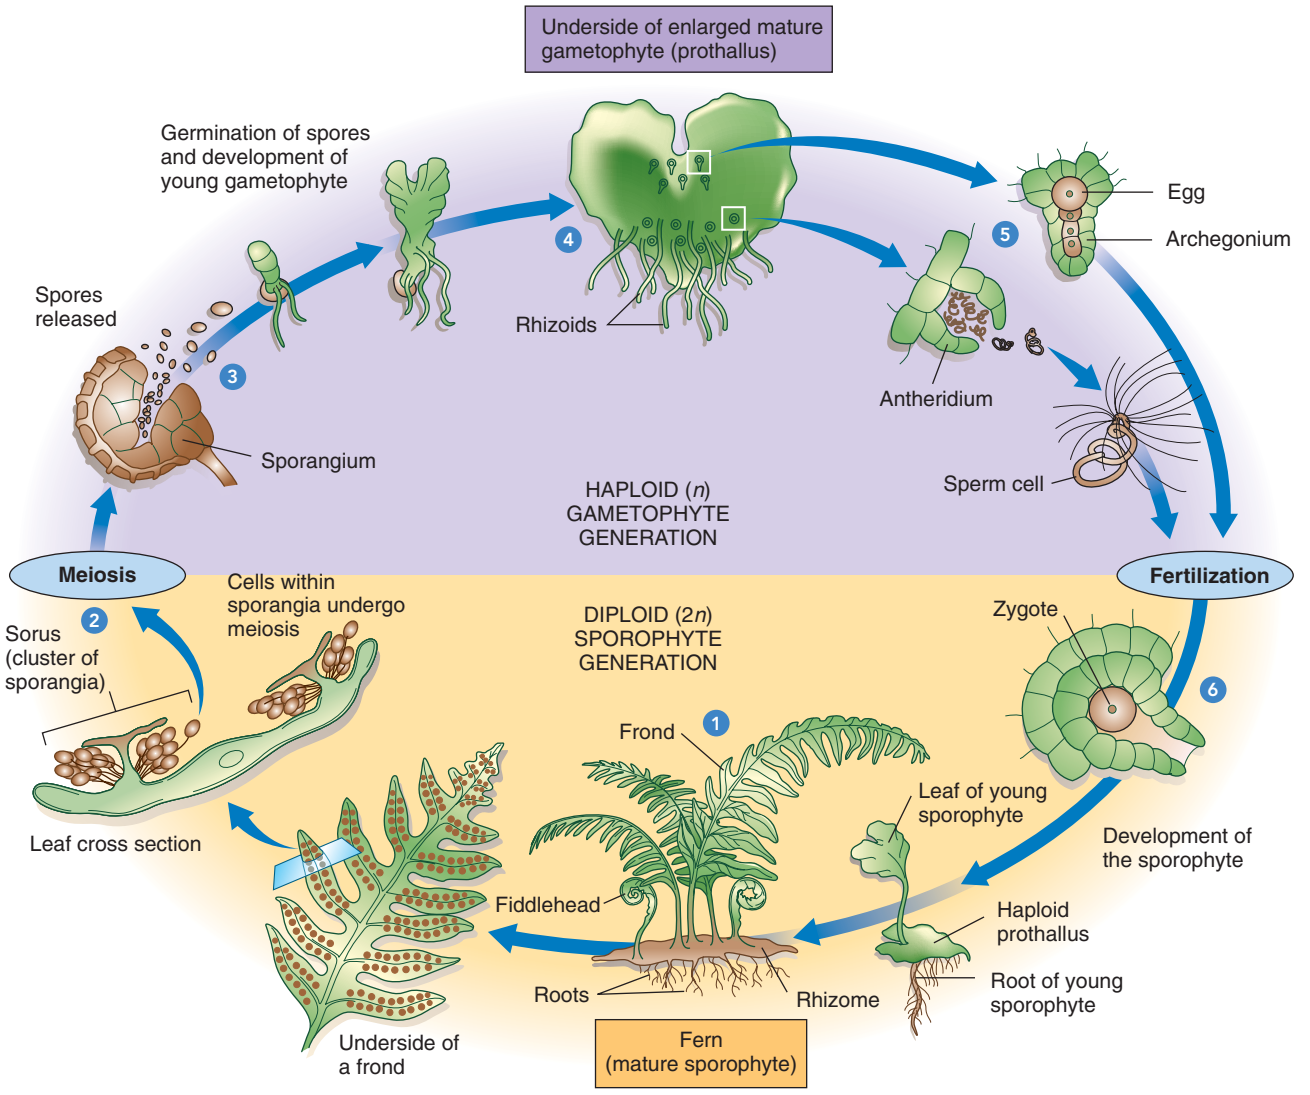


Figure 27-13 ***Animated*** The life cycle of ferns

Note the clearly defined alternation of generations between the gametophyte (prothallus) and sporophyte (leafy plant) generations. See text for a detailed description.

meiosis to form haploid spores. After dispersal, the spores germinate to form haploid prothalli. Because they grow underground, the prothalli of whisk ferns are difficult to study. They are nonphotosynthetic as a result of their subterranean location, and they apparently have a symbiotic relationship with mycorrhizal fungi that provides them with sugar and essential minerals (see Chapter 26).

Botanists have carefully studied whisk ferns in recent years. Molecular data, including comparisons of nucleotide sequences of ribosomal RNA, chloroplast DNA, and mitochondrial DNA in living species, support the hypothesis that the whisk ferns should be classified as reduced ferns rather than as surviving representatives of extinct vascular plants (see discussion of rhyniophytes later in the chapter).

Horsetails are a second evolutionary line of ferns

About 300 mya the **horsetails** (phylum Pteridophyta) were among the dominant plants and grew as large as modern trees (Fig 27-15a). Because they contributed to Earth's vast coal deposits, these ancient horsetails, like ancient club mosses, are still significant today.

The few surviving horsetails, about 15 species in the genus *Equisetum*, grow mostly in wet, marshy habitats and are less than

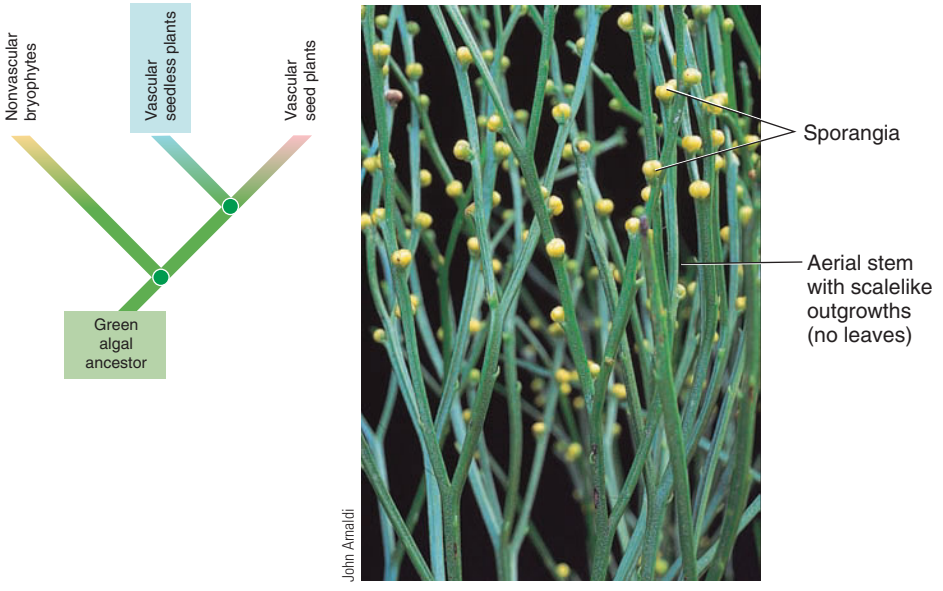

Figure 27-14 ***Animated*** The sporophyte of *Psilotum nudum*, a whisk fern

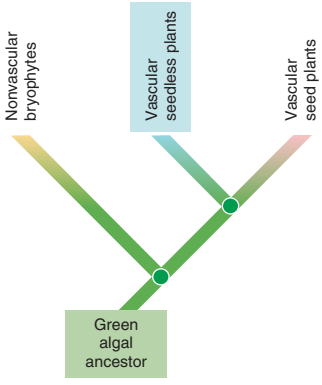
The stem is the main organ of photosynthesis in this rootless, leafless, vascular plant. Sporangia, which are initially green but turn yellow as they mature, are borne on short lateral branches directly on the stems.

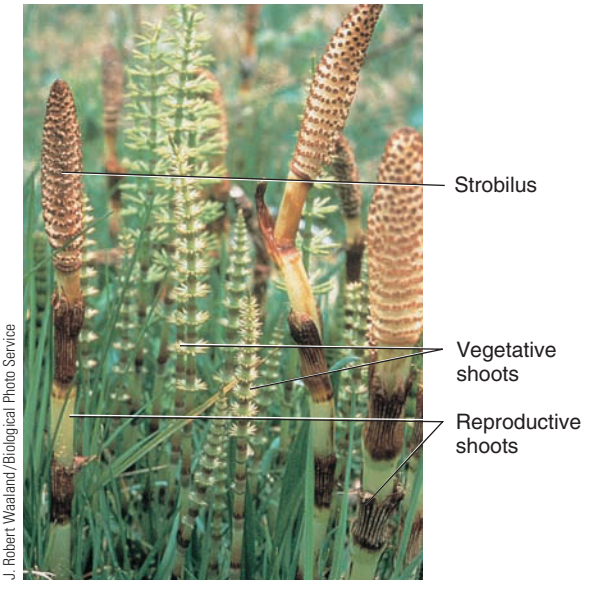
1.3 m (4 ft) tall, but extremely distinctive (▮ Fig. 27-15b). They are widely distributed on every continent except Australia. Traditionally classified in their own phylum, horsetails are now grouped with ferns. This reclassification is based on molecular similarities between horsetails and other ferns.

Horsetails have true roots, stems (both rhizomes and erect aerial stems), and small leaves. The hollow, jointed stems are impregnated with silica, which gives them a gritty texture. Small leaves, interpreted as reduced megaphylls, are fused in whorls at each node (the area on the stem where leaves attach). The green stem is the main organ of photosynthesis. Horsetails are so named because certain vegetative (nonreproductive) stems have whorls of branches that give the appearance of a bushy horse's tail. In the past, horsetails were called "scouring rushes" and were used to scrub pots and pans along stream banks.

Each reproductive branch of a horsetail bears a terminal conelike **strobilus**



(a) Reconstruction of *Calamites*, an ancient horsetail that grew as tall as many modern trees—to 20 m (about 65 ft). *Calamites* had an underground rhizome where roots and aerial shoots originated.



(b) *Equisetum telematia*, a horsetail with a wide distribution in Eurasia, Africa, and North America, has unbranched reproductive shoots bearing conelike strobili and separate, highly branched vegetative (nonreproductive) shoots. In some horsetail species, both reproductive and vegetative shoots are unbranched.

Figure 27-15 ***Animated*** Horsetails

(**a,** Redrawn from L. Emberger, *Les Plantes Fossiles,* Masson et Cie, Paris, 1968.)

(pl., *strobili*). The strobilus consists of several stalked, umbrella-like structures, each of which bears 5 to 10 sporangia in a circle around a common axis.

The horsetail life cycle is similar in many respects to the fern life cycle. In horsetails, as in ferns, the sporophyte is the conspicuous plant, whereas the gametophyte is a minute, lobed thallus ranging in width from the size of a pinhead to about 1 cm across. The sporophyte and gametophyte are both photosynthetic and nutritionally independent at maturity. Like ferns, horsetails require water as a medium for flagellate sperm cells to swim to the egg.

Some ferns and club mosses are heterosporous

In the life cycles examined thus far, plants produce only one type of spore as a result of meiosis. This condition, known as **homospory,** is characteristic of bryophytes, horsetails, whisk ferns, and most ferns and club mosses. However, certain ferns and club mosses exhibit **heterospory,** in which they produce two types of spores: microspores and megaspores. Figure 27-16 illustrates the generalized life cycle of a heterosporous plant.

Spike moss (*Selaginella*), a club moss, is an example of a heterosporous plant (Fig. 27-17). As shown in 1, the sporophyte plant produces sporangia within a conelike strobilus. Each strobilus usually bears two kinds of sporangia: microsporangia and megasporangia. *Microsporangia* are sporangia that produce *microsporocytes* (also called *microspore mother cells*), which undergo meiosis to form microscopic, haploid **microspores** 2. Each microspore develops into a male gametophyte that produces sperm cells within antheridia 3.

As shown in 4, *megasporangia* in the *Selaginella* strobilus produce *megasporocytes* (also called *megaspore mother cells*). When megasporocytes undergo meiosis, they form haploid **megaspores,** each of which develops into a female gametophyte that produces eggs in archegonia 5.

In *Selaginella,* the development of male gametophytes from microspores and of female gametophytes from megaspores occurs within their respective spore walls, using stored food provided by the sporophyte. As a result, the male and female gametophytes are not truly free-living, unlike the gametophytes of other seedless vascular plants. Fertilization is followed by the development of a new sporophyte 6.

Heterospory evolved several times during the history of land plants. It was a significant development in plant evolution because it was the forerunner of the evolution of seeds. Heterospory characterizes the two most successful groups of plants existing today, the gymnosperms and the flowering plants, both of which produce seeds.

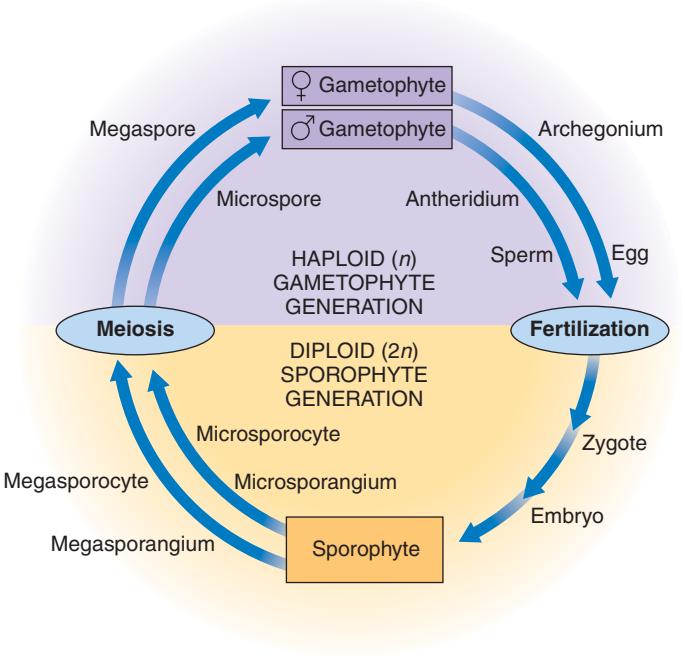


Figure 27-16 The basic life cycle of heterosporous plants

Two types of spores, microspores and megaspores, are produced during the life cycle of heterosporous plants.

Seedless vascular plants are used for experimental studies

Botanists use many seedless vascular plants as experimental models to study certain aspects of plant biology, such as physiology, growth, and development. Ferns and other seedless vascular plants are useful in studying how apical meristems give rise to plant tissues. An **apical meristem** is the area at the tip (apex) of a root or shoot where growth—cell division, elongation, and differentiation—occurs. Ferns and other seedless vascular plants have a single large *apical cell* located at the center tip of the apical meristem. This apical cell is the source, by mitosis, of all the cells that eventually make up the root or shoot. The apical cell divides in an orderly fashion, and the smaller daughter cells produced by the apical cell, in turn, divide and give rise to different parts of the root or shoot. It is possible to trace mature cells in the root or shoot back to their origin from the single apical cell.

Ferns are interesting research plants for studies in genetics because they are **polyploids** and have multiple sets of chromosomes. (Many ferns have hundreds of chromosomes.) However, gene expression in ferns is exactly what one would expect of a *diploid* plant. Apparently, genes in the extra sets of chromosomes are gradually silenced and therefore not expressed.

Seedless vascular plants arose more than 420 mya

Currently, the oldest known megafossils of early vascular plants are from Silurian (420 mya) deposits in Europe. (Plant *megafossils* are fossilized roots, stems, leaves, and reproductive structures.) Megafossils of several kinds of small, seedless vascular

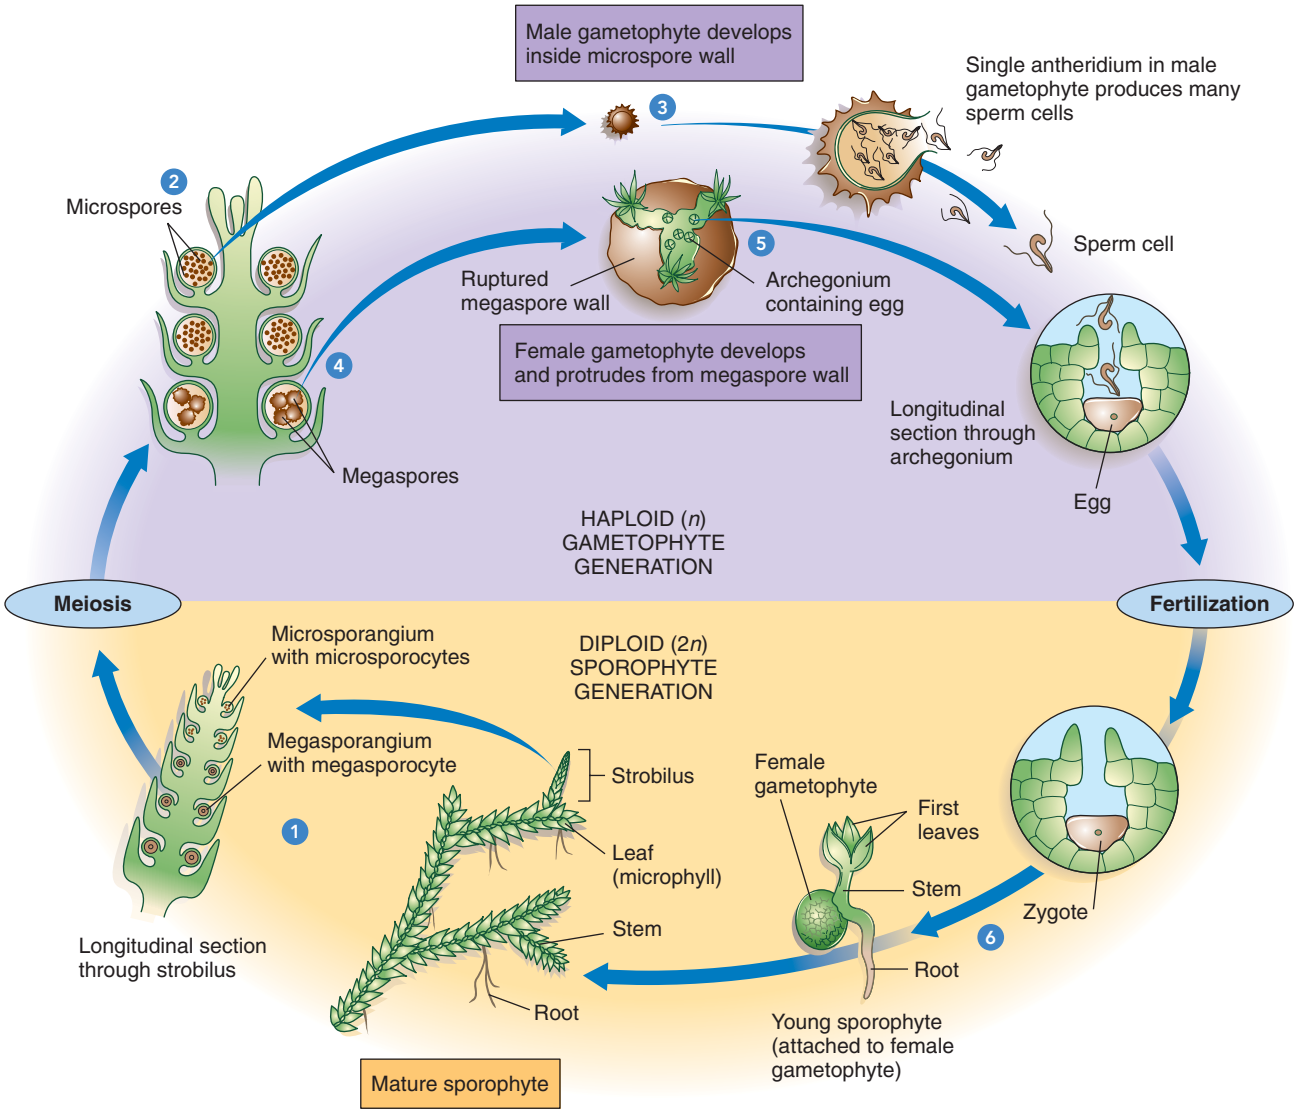

Figure 27-17 The life cycle of spike moss (*Selaginella*)

Spike moss is heterosporous, producing two types of spores in one strobilus. The megaspores develop into female gametophytes, and the microspores become male gametophytes. See text for a detailed description.

plants were also discovered in Silurian deposits in Bolivia, Australia, and northwestern China. Microscopic spores of early vascular plants appear in the fossil record earlier than megafossils, suggesting that even older megafossils of simple vascular plants may be discovered.

Botanists assign the oldest vascular plants to phylum Rhyniophyta, which, according to the fossil record, arose some 420 mya and became extinct about 380 mya. The rhyniophytes are so named because many fossils of these extinct plants were found in fossil beds near Rhynie, Scotland. *Rhynia gwynne-vaughanii* is an example of an early vascular plant that superficially resembled whisk ferns in that it consisted of leafless upright stems that branched dichotomously from an underground rhizome (Fig. 27-18). *Rhynia* lacked roots, although it had absorptive rhizoids. Sporangia formed at the ends of short branches. The internal structure of its rhizome contained a central core of xylem cells for conducting water and minerals.

For many years, botanists considered *Rhynia major,* a plant that grew about 50 cm (20 in) tall and probably lived in marshes, a classic example of a rhyniophyte. Fossils indicate that this plant had rhizoids, dichotomously branching rhizomes, and upright stems that terminated in sporangia. However, recent microscopic studies of fossil rhizomes indicate that the central core of tissue lacked the xylem cells characteristic of vascular plants. For that reason, *R. major* was reclassified into a new genus, *Aglaophyton,* and is no longer considered a rhyniophyte (Fig. 27-19). Science

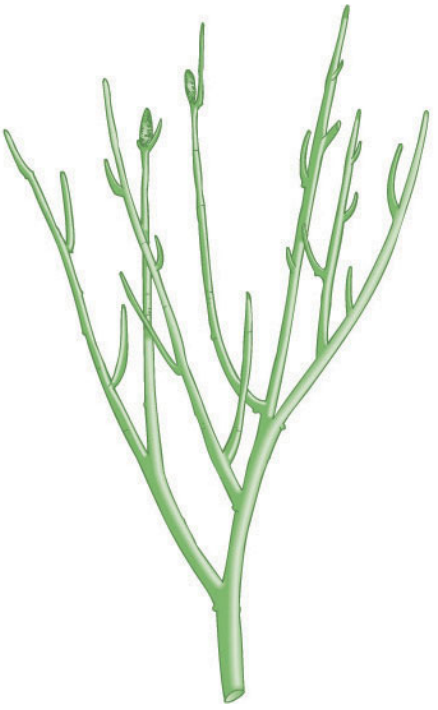

Figure 27-18 Reconstruction of *Rhynia gwynne-vaughanii*
This leafless plant, one of Earth's earliest vascular plants, is now extinct. It grew about 18 cm (7 in) tall. (Redrawn from D. Edwards, "Evidence for the Sporophytic Status of the Lower Devonian Plant *Rhynia gwynne-vaughanii*," *Review of Palaeobotany and Palynology,* Vol. 29, 1980.)

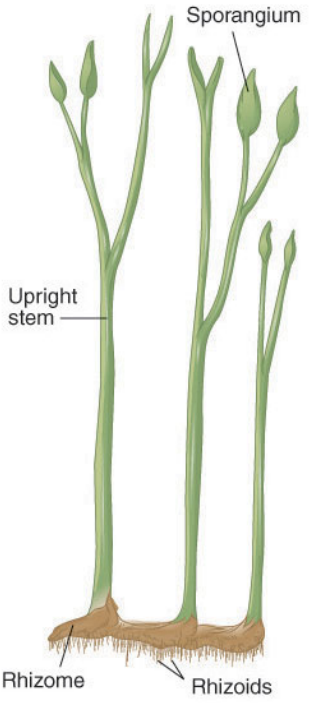

Figure 27-19 Reconstruction of *Aglaophyton major*
Recent evidence indicates that this plant, although superficially similar to other early vascular plants, lacked conducting tissues that are characteristic of vascular plants. For this reason, it has been reclassified into a new genus and is no longer considered a rhyniophyte. (Redrawn from J. D. Mauseth, *Botany: An Introduction to Plant Biology,* 2nd ed., Saunders College Publishing, Philadelphia, 1995.)

is an ongoing enterprise, and over time, existing knowledge is re-evaluated in light of newly discovered evidence. *Aglaophyton major* is an excellent example of the self-correcting nature of science, which is in a perpetually dynamic state and changes in response to newly available techniques and data.

Review

- What adaptations do ferns have that both algae and bryophytes lack?
- How does one distinguish between megaphylls and microphylls?
- Which of the following are parts of the sporophyte generation in ferns: frond, sperm cells, egg cell, roots, sorus, sporangium, spores, prothallus, rhizome, antheridium, archegonium, and zygote?
- Why are whisk ferns and horsetails now classified as ferns?
- How does heterospory modify the life cycle?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Discuss some environmental challenges of living on land, and describe how several plant adaptations meet these challenges (page 582).

- The colonization of land by plants required the evolution of many anatomical, physiological, and reproductive adaptations. Plants have a waxy **cuticle** to protect against water loss and **stomata** for gas exchange needed for photosynthesis.
- Plant life cycles have an **alternation of generations** in which they spend part of their life cycle in a haploid **gametophyte generation** and part in a diploid **sporophyte generation.** The gametophyte plant produces gametes by mitosis. During fertilization these gametes fuse to form a **zygote,** the first stage of the sporophyte generation. The zygote develops into a multicellular **embryo** that the gametophyte protects and nourishes. The mature sporophyte plant develops from the embryo and produces sporogenous cells (spore mother cells). These undergo meiosis to form **spores,** the first stage in the gametophyte generation.

- Most plants have multicellular **gametangia** with a protective jacket of sterile cells surrounding the gametes. **Antheridia** are gametangia that produce sperm cells, and **archegonia** are gametangia that produce eggs.
- Ferns and other vascular plants have **xylem** to conduct water and dissolved minerals and **phloem** to conduct dissolved sugar.

2 Name the green algal group from which plants are hypothesized to have descended, and describe supporting evidence (page 582).
- Plants probably arose from a group of green algae called **charophytes.** This conclusion is based in part on molecular comparisons of DNA and RNA sequences, which show the closest match between charophytes and plants.

ThomsonNOW™ Explore plant evolution by clicking on the figure in ThomsonNOW.

3 Summarize the features that distinguish bryophytes from other plants (page 584).
- Unlike other land plants, bryophytes are nonvascular and lack xylem and phloem. Bryophytes are the only plants with a dominant gametophyte generation. Their sporophytes remain permanently attached and nutritionally dependent on the gametophytes.

4 Name and briefly describe the three phyla of bryophytes (page 584).
- Mosses (phylum Bryophyta) have gametophytes that are green plants that grow from a filamentous **protonema.**
- Many **liverworts** (phylum Hepatophyta) have gametophytes that are flattened, lobelike **thalli;** others are leafy.
- **Hornworts** (phylum Anthocerophyta) have thalloid gametophytes.

5 Describe the life cycle of mosses, and compare their gametophyte and sporophyte generations (page 584).
- The green moss gametophyte bears archegonia and/or antheridia at the top of the plant. During fertilization, a sperm cell fuses with an egg cell in the archegonium. The zygote grows into an embryo that develops into a moss sporophyte, which is attached to the gametophyte. Meiosis occurs within the capsule of the sporophyte to produce spores. When a spore germinates, it grows into a protonema that forms buds that develop into gametophytes.

ThomsonNOW™ Watch the life cycles of the mosses and liverworts by clicking on the figures in ThomsonNOW.

6 Discuss the features that distinguish seedless vascular plants from algae and bryophytes (page 589).
- Seedless vascular plants have several adaptations that algae and bryophytes lack, including vascular tissues and a dominant sporophyte generation. As in bryophytes, reproduction in seedless vascular plants depends on water as a transport medium for motile sperm cells.

7 Name and briefly describe the two phyla of seedless vascular plants (page 589).
- Sporophytes of **club mosses** (phylum Lycopodiophyta) consist of roots, rhizomes, erect branches, and leaves that are **microphylls.**
- **Ferns** (phylum Pteridophyta) are the largest and most diverse group of seedless vascular plants. The fern sporophyte consists of a rhizome that bears fronds and true roots. Phylum Pteridophyta also includes whisk ferns and horsetails. Sporophytes of **whisk ferns** have **dichotomously branching** rhizomes and erect stems; they lack true roots and leaves. **Horsetail** sporophytes have roots, rhizomes, aerial stems that are hollow and jointed, and leaves that are reduced **megaphylls.**

8 Describe the life cycle of ferns, and compare their sporophyte and gametophyte generations (page 589).
- Fern sporophytes have roots, rhizomes, and leaves that are megaphylls. Their leaves, or fronds, bear sporangia in clusters called **sori.** Meiosis in sporangia produces haploid spores. The fern gametophyte, called a **prothallus,** develops from a haploid spore and bears both archegonia and antheridia.

ThomsonNOW™ Watch the life cycle of the ferns by clicking on the figure in ThomsonNOW.

9 Compare the generalized life cycles of homosporous and heterosporous plants (page 589).
- **Homospory,** the production of one kind of spore, is characteristic of bryophytes, most club mosses, and most ferns, including whisk ferns and horsetails. In homospory, spores give rise to gametophyte plants that produce both egg cells and sperm cells.
- **Heterospory,** the production of two kinds of spores (microspores and megaspores), occurs in certain club mosses, certain ferns, and all seed plants. **Microspores** give rise to male gametophytes that produce sperm cells. **Megaspores** give rise to female gametophytes that produce eggs. The evolution of heterospory was an essential step in the evolution of seeds.

TEST YOUR UNDERSTANDING

1. The bryophytes (a) include mosses, liverworts, and hornworts (b) include whisk ferns, horsetails, and club mosses (c) are small plants that lack a vascular system (d) a and c (e) b and c
2. The waxy layer that covers aerial parts of plants is the (a) cuticle (b) archegonium (c) protonema (d) stoma (e) thallus
3. A strengthening compound found in cell walls of vascular plants is (a) xanthophyll (b) lignin (c) cutin (d) cellulose (e) carotenoid
4. Stomata (a) help prevent desiccation of plant tissues (b) transport water and minerals through plant tissues (c) allow gas exchange for photosynthesis (d) strengthen cell walls (e) produce male gametes
5. The female gametangium, or _____, produces an egg; the male gametangium, or _____, produces sperm cells. (a) antheridium; archegonium (b) archegonium; megaphyll (c) megasporangium; antheridium (d) archegonium; antheridium (e) megasporangium; megaphyll
6. Liverworts and hornworts share life-cycle similarities with (a) ferns (b) mosses (c) horsetails (d) club mosses (e) whisk ferns

7. The green, gametangia-bearing moss plant (a) is the haploid gametophyte generation (b) is the diploid sporophyte generation (c) is called a protonema (d) contains cells with single large chloroplasts (e) b and c
8. Seedless vascular plants have _____ to conduct water and minerals and _____ to conduct sugar. (a) cuticle; xylem (b) phloem; stomata (c) phloem; xylem (d) stomata; cuticle (e) xylem; phloem
9. A(an) _____ is a leaf that arose from a branch system. (a) antheridium (b) microphyll (c) megaphyll (d) sorus (e) microspore
10. These plants have vascularized stems but lack true roots and leaves. (a) mosses (b) club mosses (c) horsetails (d) whisk ferns (e) hornworts
11. These plants have hollow, jointed stems that are impregnated with silica. (a) mosses (b) club mosses (c) horsetails (d) whisk ferns (e) hornworts
12. Which of the following statements about ferns is *not* true? (a) ferns have motile sperm cells that swim through water to the egg-containing archegonium (b) ferns are vascular plants (c) ferns are the most economically important group of bryophytes (d) the fern sporophyte consists of a rhizome, roots, and fronds (e) the diversity of ferns is greatest in the tropics
13. Plants probably descended from a group of green algae called (a) rhyniophytes (b) *Calamites* (c) epiphytes (d) charophytes (e) club mosses
14. Which of the following is *not* a characteristic of plants? (a) cuticle (b) unicellular gametangia (c) stomata (d) multicellular embryo (e) alternation of generations
15. In plant life cycles (a) the first products of meiosis are gametes (b) spores are part of the diploid sporophyte generation (c) the embryo gives rise to a zygote (d) the first stage in the diploid sporophyte generation is the zygote (e) the first stage in the haploid gametophyte generation is the prothallus

CRITICAL THINKING

1. Which group probably colonized the land first, plants or animals? Explain.
2. What adaptations do bryophytes have that algae lack?
3. **Evolution Link.** How may the following trends in plant evolution be adaptive to living on land?
   a. dependence on water for fertilization ⟶ no need for water as a transport medium
   b. homospory ⟶ heterospory
4. **Analyzing Data.** According to the cladogram in Figure 27-4, which plants evolved first: nonvascular bryophytes, seedless vascular plants, or seed plants? Which clade would be considered the outgroup: hornworts, liverworts, or mosses?

The Plant Kingdom: Seed Plants

M. F. Merlet/Science Photo Library/Photo Researchers, Inc.

Magnolia fruit with protruding seeds. Magnolia (*Magnolia grandiflora*) is a flowering plant, and its seeds are enclosed within a fruit.

KEY CONCEPTS

Seed plants include gymnosperms and angiosperms.

Gymnosperms produce exposed seeds, usually in cones borne on the sporophytes.

Conifers are the most diverse and numerous of the four living gymnosperm phyla.

Angiosperms produce ovules enclosed within carpels; following fertilization, seeds develop from the ovules, and the ovaries of carpels become fruits.

Angiosperms, which compose a single phylum, dominate the land and exhibit great diversity in both vegetative and reproductive structures.

Gymnosperms and angiosperms evolved from ancestral seedless vascular plants.

Chapter 27 focused on plants that reproduce by means of *spores,* haploid reproductive units that give rise to gametophytes. Although the most successful and widespread plants also produce spores, their primary means of reproduction and dispersal is by **seeds,** which represent an important adaptation for life on land (see photograph). Each seed consists of an embryonic sporophyte, nutritive tissue, and a protective coat. Seeds develop from the fertilized egg cell, the female gametophyte, and its associated tissues. The two groups of seed plants, gymnosperms and angiosperms (flowering plants), exhibit the greatest evolutionary complexity in the plant kingdom and are the dominant plants in most terrestrial environments.

Seeds are reproductively superior to spores for three main reasons. First, a seed contains a multicellular young plant with embryonic root, stem, and one or more leaves already formed, whereas a spore is a single cell. Second, a seed contains an abundant food supply. After germination, food stored in the seed nourishes the plant embryo until it becomes self-sufficient. Because a spore is a single cell, few food reserves exist for the plant that develops from a spore. Third, a seed is protected by a multicellular **seed coat** that is very thick and hard in some plants, as, for example, in lima beans. Like spores, seeds live for extended periods at reduced rates of metabolism and germinate when conditions become favorable.

Seeds and seed plants are intimately connected with the development of human civilization. From prehistoric times, early humans collected and used seeds for food. The food stored in seeds is a concentrated source of proteins, oils, carbohydrates, and vitamins,

which are nourishing for humans as well as for germinating plants. Seeds are easy to store (if kept dry), so humans can collect them during times of plenty to save for times of need. Few other foods are stored as conveniently or for as long. Although flowering plants produce most seeds that humans consume, the seeds of certain gymnosperms—the piñon pine, for example—are edible. ■

AN INTRODUCTION TO SEED PLANTS

Learning Objective

1 Compare the features of gymnosperms and angiosperms.

In Chapter 27, you learned that some seedless vascular plants are heterosporous. However, *all* seed plants are heterosporous and produce two types of spores: microspores and megaspores. In fact, heterospory is a requirement of seed production.

Following fertilization in seed plants, an **ovule,** which is a *megasporangium* and its enclosed structures, develops into a seed. Seed plants also have **integuments,** layers of sporophyte tissue that surround and enclose the megasporangium. After fertilization takes place, the seed coat develops from the integuments.

Botanists divide seed plants into two groups based on whether or not an ovary wall surrounds their ovules (an *ovary* is a structure that contains one or more ovules). The two groups of seed plants are the **gymnosperms** and the **angiosperms** (▮ Table 28-1). The word *gymnosperm* is derived from the Greek for "naked seed." Gymnosperms produce seeds that are totally exposed or borne on the scales of cones. In other words, an ovary wall does not surround the ovules of gymnosperms. Pine, spruce, fir,

that means "seed enclosed in a vessel or case." Angiosperms are flowering plants that produce their seeds within a *fruit* (a mature ovary). Thus, the ovules of angiosperms are protected. Flowering plants, which are extremely diverse, include corn, oaks, water lilies, cacti, apples, grasses, palms, and buttercups.

Both gymnosperms and flowering plants have vascular tissues: **xylem,** for conducting water and dissolved minerals (inorganic nutrients); and **phloem,** for conducting dissolved sugar. Both have life cycles with an **alternation of generations,** that is, they spend part of their lives in the multicellular diploid sporophyte stage and part in the multicellular haploid gametophyte stage. The sporophyte generation is the dominant stage in each group, and the gametophyte generation is significantly reduced in size and entirely dependent on the sporophyte generation. Unlike the plants we have considered so far (bryophytes and ferns; see Chapter 27), gymnosperms and flowering plants do not have free-living gametophytes. Instead, the female gametophyte is attached to and nutritionally dependent on the sporophyte generation.

Review

- What is an ovule?
- How do gymnosperm and angiosperm seeds differ?

GYMNOSPERMS

Learning Objectives

2 Trace the steps in the life cycle of a pine, and compare its sporophyte and gametophyte generations.

3 Summarize the features that distinguish gymnosperms from bryophytes and ferns.

4 Name and briefly describe the four phyla of gymnosperms.

The gymnosperms include some of the most interesting members of the plant kingdom. For example, a giant sequoia (*Sequoiadendron giganteum*) known as the General Sherman Tree, in Sequoia National Park in California, is one of the world's most massive organisms. It is 82 m (267 ft) tall and has a girth of 23.7 m (77 ft) measured 1.5 m (5 ft) above ground level. Another gymnosperm, a coast redwood (*Sequoia sempervirens*) known as the Mendocino

TABLE 28-1

A Comparison of Gymnosperms and Angiosperms

Characteristic	Gymnosperms	Angiosperms
Growth habit	Woody trees and shrubs	Woody or herbaceous
Conducting cells in xylem	Tracheids	Vessel elements and tracheids
Reproductive structures	Cones (usually)	Flowers
Pollen grain transfer	Wind (usually)	Animals or wind
Fertilization	Egg and sperm ⟶ zygote; double fertilization in gnetophytes	Double fertilization: egg and sperm ⟶ zygote; two polar nuclei and sperm ⟶ endosperm
Seeds	Exposed or borne on scales of cones	Enclosed within fruit derived from ovary
Number of species	About 840	More than 300,000
Geographic distribution	Worldwide	Worldwide

Keith Kent/Science Photo Library/Photo Researchers, Inc.

Figure 28-1 Bristlecone pine at sunrise

Bristlecone pines (*Pinus aristata*), found in mountainous parts of California, Nevada, and Utah, are the world's longest-lived trees.

tree, is among the world's tallest trees, measuring 112 m (364 ft) in the year 2000. Botanists using tree-ring analysis determined that one of the oldest living trees, a bristlecone pine (*Pinus aristata*) in the White Mountains of California, is 4900 years old (Fig. 28-1).

Gymnosperms are usually classified into four phyla, which represent four different evolutionary lines (Fig. 28-2). Numbering 630 species, the largest phylum of gymnosperms is Coniferophyta, commonly called *conifers.* Two phyla of gymnosperms, Ginkgophyta (the ginkgoes) and Cycadophyta (the cycads), are evolutionary remnants of groups that were more significant in the past. The fourth phylum, Gnetophyta (gnetophytes), is a collection of some unusual plants that share certain traits not found in other gymnosperms.

Conifers are woody plants that produce seeds in cones

The **conifers** (phylum Coniferophyta), which include pines, spruces, hemlocks, and firs, are the most familiar group of gymnosperms (Fig. 28-3a). These woody trees or shrubs produce annual additions of secondary tissues (wood and bark; see Chapter 34); there are no herbaceous (nonwoody) conifers. The wood (*secondary xylem*) consists of **tracheids,** which are long, tapering cells with pits through which water and dissolved minerals move from one cell to another.

Many conifers produce **resin,** a viscous, clear or translucent substance consisting of several organic compounds that may protect the plant from attack by fungi or insects. The resin collects in resin ducts, tubelike cavities that extend throughout the roots, stems, and leaves. Cells lining the resin ducts produce and secrete resin.

Most conifers have leaves called **needles** that are commonly long and narrow, tough, and leathery (Fig. 28-3b). Pines bear clusters of two to five needles, depending on the species. In a few conifers, such as American arborvitae, the leaves are scalelike and

Key Point

Seed plants include four gymnosperm phyla and one phylum of flowering plants (angiosperms).

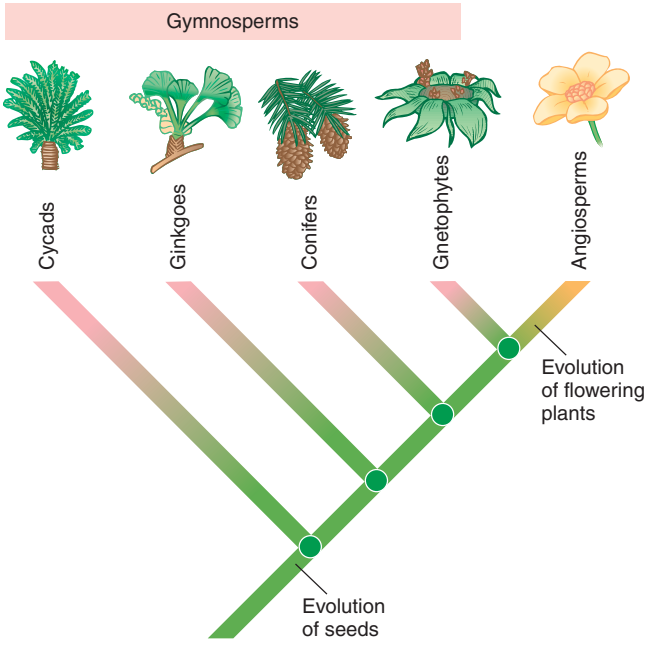

Figure 28-2 Gymnosperm and angiosperm evolution

This cladogram shows one hypothesis of phylogenetic relationships among living seed plants, based on structural evidence and molecular comparisons. The arrangement of the phyla shown here may change as future analyses help clarify relationships.

cover the stem (Fig. 28-3c). Most conifers are evergreen and bear their leaves throughout the year. Only a few, such as the dawn redwood, larch, and bald cypress, are deciduous and shed their needles at the end of each growing season.

Most conifers are **monoecious:** they have separate male and female reproductive parts in different locations on the same plant. These reproductive parts are generally borne in *strobili* (commonly called *cones*), hence the name *conifer,* which means "cone-bearing."

Conifers occupy extensive areas, ranging from the Arctic to the tropics, and are the dominant vegetation in the forested regions of Alaska, Canada, northern Europe, and Siberia. In addition, they are important in the Southern Hemisphere, particularly in wet, mountainous areas of temperate and tropical regions in South America, Australia, New Zealand, and Malaysia. Southwestern China, with more than 60 species of conifers, has the greatest regional diversity of conifer species in the world. California, New Caledonia (an island east of Australia), southeastern China, and Japan also have considerable diversity of conifer species.

Ecologically, conifers contribute food and shelter to animals and other organisms, and their roots hold the soil in place and help prevent soil erosion. Humans use conifers for their wood (for building materials as well as paper products), medicinal

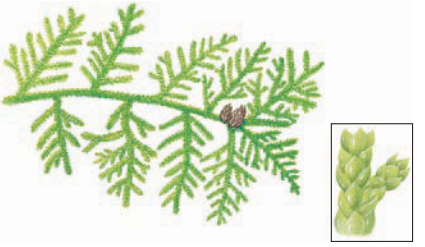
(a)

(b)



(c)

Figure 28-3 Conifers

(a) Colorado blue spruce (*Picea pungens*) is a coniferous evergreen tree native to Colorado, Wyoming, Utah, and New Mexico. Spruces are important ornamental plants, as shown in this New Jersey garden. **(b, c)** Leaf variation in conifers. **(b)** Needles of white pine (*Pinus strobus*). **(c)** Small, scalelike leaves of American arborvitae (*Thuja occidentalis*).

value (such as the anticancer drug Taxol from the Pacific yew), turpentine, and resins. Because of their attractive appearance, conifers such as firs, spruces, pines, and cedars are grown for landscape design and decorative holiday trees and wreaths.

Pines represent a typical conifer life cycle

The genus *Pinus,* by far the largest genus in the conifers, consists of about 100 species. As shown in Figure 28-4 (1), a pine tree is a mature sporophyte. Pine is heterosporous and therefore produces microspores and megaspores in separate cones.[1] Male cones, usually 1 cm or less in length, are smaller than female cones and are generally produced on the lower branches each spring (Fig. 28-5). The more familiar, woody female cones, which are on the tree year-round, are usually found on the upper branches of the tree and bear seeds after reproduction. Female cones vary considerably in size. The sugar pine (*P. lambertiana*) that grows in California produces the world's longest female cones, which reach lengths of 60 cm (2 ft).

Each male cone, also called a *pollen cone,* consists of **sporophylls,** leaflike scales that bear sporangia on the underside. At the base of each sporophyll are two **microsporangia,** which contain numerous **microsporocytes,** also called *microspore mother cells.*

[1]It may be helpful to review alternation of generations in Chapter 27, including Figure 27-16, which depicts a heterosporous life cycle, before studying the pine life cycle.

In Figure 28-4 (2), each microsporocyte undergoes meiosis to form four haploid microspores. **Microspores** then develop into extremely reduced male gametophytes. Each immature male gametophyte, also called a **pollen grain,** consists of four cells, two of which—a *generative cell* and a *tube cell*—are involved in reproduction. The other two cells soon degenerate. Two large air sacs on each pollen grain provide buoyancy for wind dissemination. In (3), male cones shed pollen grains in great numbers, and wind currents carry some to the immature female cones.

Many botanists think that the female cones (also called *seed cones*) are modified branch systems. As shown in (4), each cone scale bears two ovules, or **megasporangia,** on its upper surface. Within each megasporangium, meiosis of a **megasporocyte,** or *megaspore mother cell,* produces four haploid **megaspores.** One of these divides mitotically, developing into the female gametophyte, which produces an egg within each of several archegonia. The other three megaspores are nonfunctional and soon degenerate.

When the ovule is ready to receive pollen, it produces a sticky droplet at the opening where the pollen grains land. **Pollination,** the transfer of pollen to the female cones, occurs in the spring for a week or 10 days, after which the pollen cones wither and drop off the tree. One of the many pollen grains that adhere to the sticky female cone grows a **pollen tube,** an outgrowth that digests its way through the megasporangium to the egg within the archegonium. The germinated pollen grain with its pollen tube is the mature male gametophyte. The tube cell, which is involved

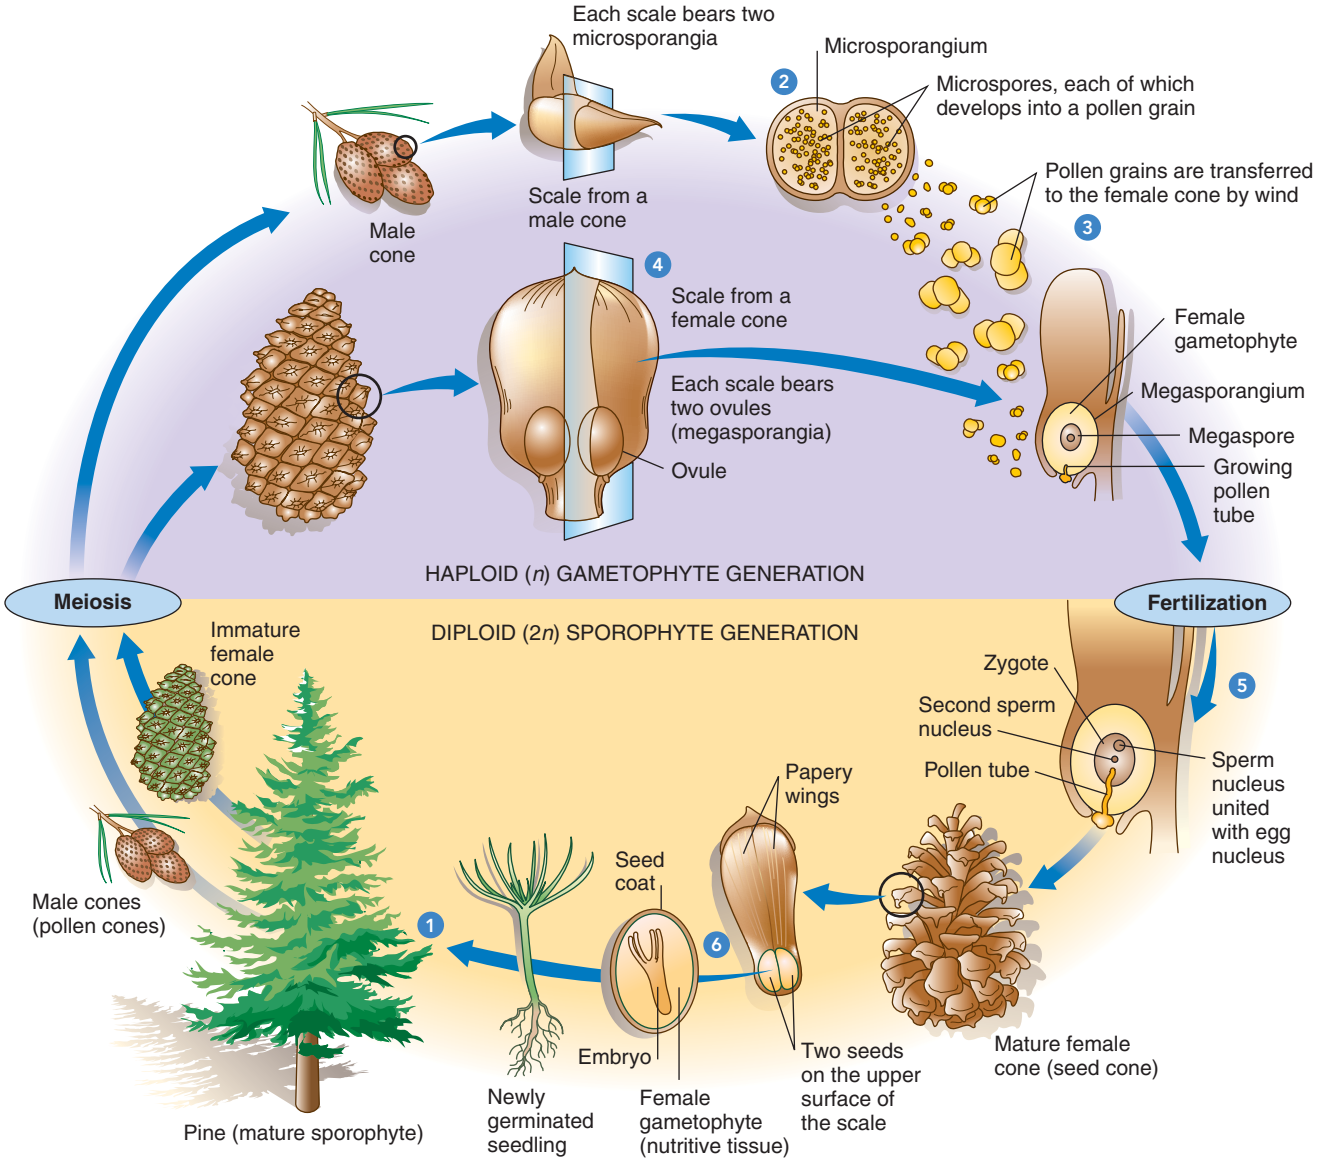


Figure 28-4 ***Animated*** Life cycle of pine

One major advantage of gymnosperms over the seedless vascular plants is the production of wind-borne pollen grains. See text for a detailed description.

in the growth of the pollen tube, and the generative cell enter the pollen tube.

The generative cell divides and forms a *stalk cell* and a *body cell;* the body cell later divides and forms two nonmotile (nonflagellate) sperm cells. When it reaches the female gametophyte, the pollen tube discharges the two sperm cells near the egg. In 5, one of these sperm cells fuses with the egg, in the process of **fertilization,** to form a zygote, or fertilized egg, which subsequently grows into a young pine embryo in the seed. The other sperm cell degenerates.

In 6, the developing embryo, which consists of an embryonic root and an embryonic shoot with several cotyledons (embryonic leaves), is embedded in haploid female gametophyte tissue that becomes the nutritive tissue in the mature pine seed. A tough, protective seed coat derived from the integuments surrounds the embryo and nutritive tissue. The seed coat forms a thin, papery wing at one end that enables dispersal by air currents.

A long time elapses between the appearance of female cones on a tree and the maturation of seeds in those cones. When pollination occurs during the first spring, the female cone is still immature, and meiosis of the megasporocytes (megaspore mother cells) has not yet occurred. After the megaspore has formed, it takes more than a year for eggs to form within archegonia. Meanwhile, the pollen tube grows slowly through the megasporangium to the archegonia. About 15 months after pollination, fertilization occurs and the embryo begins to develop. Seed maturation takes several additional months, although some seeds remain within the female cones for several years before being shed.

In the pine life cycle, the sporophyte generation is dominant, and the gametophyte generation is restricted in size to micro-

Walt Anderson/Visuals Unlimited

Figure 28-5 ***Animated*** Male and female cones in lodgepole pine (*Pinus contorta*)

(*Top*) Mature female cones have opened to shed their seeds. (*Bottom*) Clusters of male cones produce copious amounts of pollen grains in the spring.

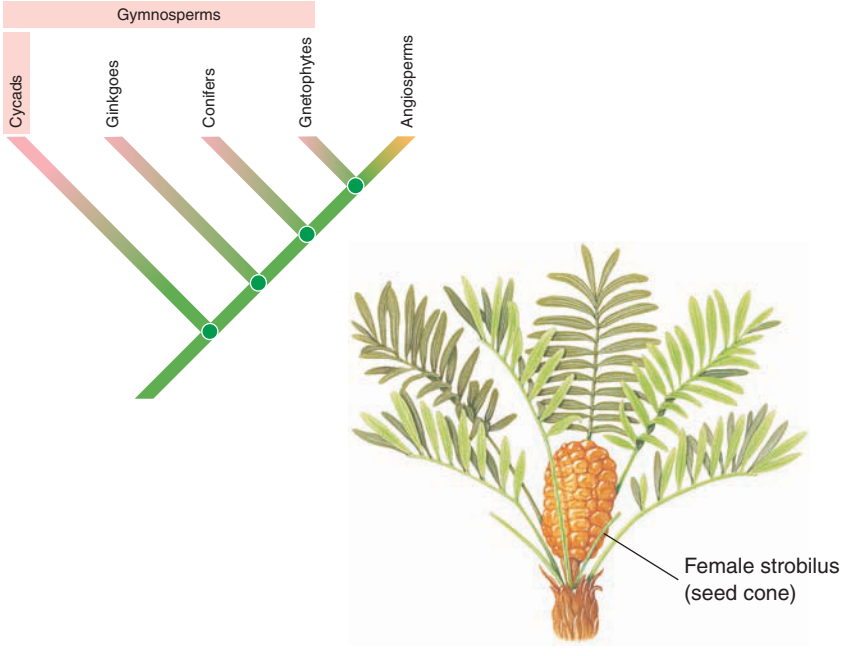
scopic structures in the cones. Although the female gametophyte produces archegonia, the male gametophyte is so reduced that it does not produce antheridia. The gametophyte generation in pines, as in all seed plants, depends totally on the sporophyte generation for nourishment.

A major adaptation in the pine life cycle is elimination of the need for external water as a sperm transport medium. Instead, air currents carry pine pollen grains to female cones, and non-flagellate sperm cells accomplish fertilization by moving through a pollen tube to the egg. Pine and other conifers are plants whose reproduction is totally adapted for life on land.

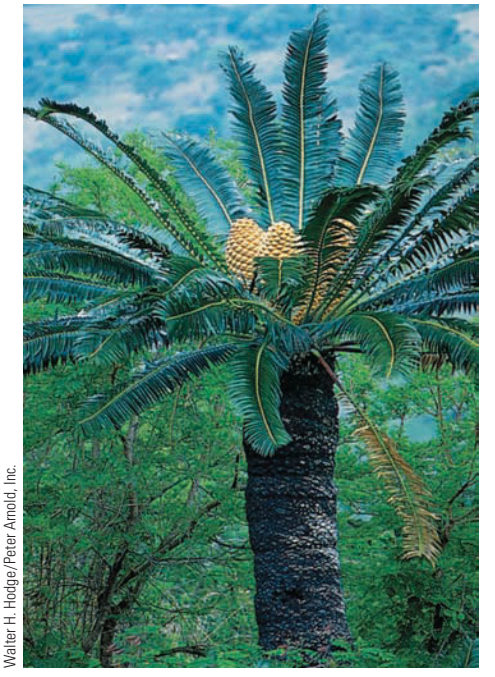
Cycads have seed cones and compound leaves

Cycads (phylum Cycadophyta) were very important during the Triassic period, which began about 251 million years ago (mya) and is sometimes referred to as the "Age of Cycads." Most species are now extinct, and the few surviving cycads, about 140 species, are tropical and subtropical plants with stout, trunklike stems and compound leaves that resemble those of palms or tree ferns (Fig. 28-6). Many cycads are endangered, primarily because they are popular as ornamentals and are gathered from the wild and sold to collectors.

Cycad reproduction is similar to that in pines except that cycads are **dioecious** and therefore have seed cones on female plants and pollen cones on male plants. Their seed structure is most like that of the earliest seeds found in the fossil record. Cycads have also retained motile sperm cells, each of which has many hair-like flagella. Motile sperm cells are a vestige retained from the ancestors of cycads, in which sperm cells swam from antheridia to archegonia. In cycads, air or insects carry pollen grains to the female plants and their cones; there the pollen grain germinates and grows a pollen tube. The sperm cells are released at the top of this tube and swim to the egg.



(a) A female Florida arrowroot (*Zamia integrifolia*) produces seed cones. This plant is the only cycad native to the United States. Like *Zamia*, most cycads are short plants, less than 2 m (6.5 ft) tall.



Walter H. Hodge/Peter Arnold, Inc.

(b) This female cycad (*Encephalartos transvenosus*) in South Africa has a trunk that reaches a height of about 9 m (30 ft) and resembles a palm. Note its immense seed cones, to 0.8 m (30 in) in length.

Figure 28-6 Cycads

Ginkgo biloba is the only living species in its phylum

Ginkgo (phylum Ginkgophyta) is represented by a single living species, the maidenhair tree, *Ginkgo biloba* (Fig. 28-7). This native of eastern China grew in the wild in only two locations, although people had cultivated it for its edible seeds in China and Japan for centuries. *Ginkgo* is the oldest genus (and species) of living trees. Fossil ginkgoes 200 million years old have been discovered that are similar to the modern ginkgo.

People often plant ginkgo in North America and Europe today, particularly in parks and along city streets, because it is hardy and somewhat resistant to air pollution. Its leaves are deciduous and turn a beautiful yellow before being shed in the fall.

Like cycads, ginkgo is dioecious, with separate male and female trees. It has flagellate sperm cells—an evolutionary vestige that is not required, because ginkgo produces airborne pollen grains. Ginkgo seeds are completely exposed rather than contained within cones. Male trees are usually planted, because the female trees bear seeds whose fleshy outer coverings give off a foul odor that smells like rancid butter. In China and Japan, where people eat the seeds, the female trees are more common.

Ginkgo has been an important medicinal plant for centuries. Extracts from the leaves may enhance neurological functioning by increasing blood flow to the brain. Several studies are underway to determine if ginkgo improves memory in elderly people.

Gnetophytes include three unusual genera

The **gnetophytes** (phylum Gnetophyta) consist of about 70 species in three diverse genera (*Gnetum, Ephedra,* and *Welwitschia*). Gnetophytes share certain features that make them unique among the gymnosperms. For example, gnetophytes have more efficient water-conducting cells, called *vessel elements,* in their xylem (see Chapter 32). Flowering plants also have vessel elements in their xylem, but of the gymnosperms, only the gnetophytes do. In addition, the cone clusters that some gnetophytes produce resemble flower clusters, and certain details in their life cycles resemble those of flowering plants.

The genus *Gnetum* contains tropical vines, shrubs, and trees with broad leaves that resemble those of flowering plants (Fig. 28-8a). Species in the genus *Ephedra* include many shrubs and vines that grow in deserts and other dry temperate and tropical regions. Some *Ephedra* species resemble horsetails in that they have jointed green stems with tiny leaves (Fig. 28-8b). Commonly called *joint fir, Ephedra* has been used medicinally for centuries. An Asiatic *Ephedra* is the source of ephedrine, which stimulates the heart and raises blood pressure. Ephedrine is sold

over the counter in weight-control medications and herbal energy boosters; several deaths have been reported from chronic use or overdose of products containing ephedrine.

The third gnetophyte genus, *Welwitschia,* contains a single species found in deserts of southwestern Africa (Fig. 28-8c). Most of *Welwitschia*'s body—a long taproot—grows underground. Its short, wide stem forms a shallow disc, up to 0.9 m (3 ft) in diameter, from which two ribbonlike leaves extend. These two leaves continue to grow from the stem throughout the plant's life, but their ends are usually broken and torn by the wind, giving the appearance of numerous leaves. Each leaf grows to about 2 m (6.5 ft) in length. When *Welwitschia* reproduces, cones form around the edge of its disclike stem.

Review

- What is the dominant generation in the pine life cycle? How does pollination occur in gymnosperms?
- What features distinguish gymnosperms from other plants?
- What are the four groups of gymnosperms?
- What features distinguish cycads from ginkgo? From gnetophytes?

FLOWERING PLANTS

Learning Objectives

5 Summarize the features that distinguish flowering plants from other plants.
6 Briefly explain the life cycle of a flowering plant, and describe double fertilization.
7 Contrast eudicots and monocots, the two largest classes of flowering plants.
8 Discuss the evolutionary adaptations of flowering plants.

Flowering plants, or angiosperms (phylum Anthophyta), are the most successful plants today, surpassing even the gymnosperms in importance. They have adapted to almost every habitat and, with at least 300,000 species, are Earth's dominant plants. Flowering plants come in a wide variety of sizes and forms, from herbaceous violets to massive eucalyptus trees. Some flowering plants—tulips and roses, for example—have large, conspicuous flowers; others, such as grasses and oaks, produce small, inconspicuous flowers.

Flowering plants are vascular plants that reproduce sexually by forming flowers and, after a unique double fertilization process (discussed later), seeds within fruits. The fruit protects the developing seeds and often aids in their dispersal (see Chapter 36). Flowering plants have efficient water-conducting cells called **ves-**

sel elements in their xylem, and efficient sugar-conducting cells called **sieve tube elements** in their phloem (see Chapter 32).

Flowering plants are extremely important to humans because our survival as a species literally depends on them. All our major food crops are flowering plants, including cereal crops such as rice, wheat, corn, and barley. Woody flowering plants such as oak, cherry, and walnut provide valuable lumber. Flowering plants give us fibers such as cotton and linen and medicines such as digitalis and codeine. Products as diverse as rubber, tobacco, coffee, chocolate, and aromatic oils for perfumes come from flowering plants. **Economic botany** is the subdiscipline of botany that deals with plants of economic importance.

Monocots and eudicots are the two largest classes of flowering plants

Phylum Anthophyta is divided into several classes with only a few members each and two very large classes: the monocots (class Monocotyledones) and the eudicots (class Eudicotyledones) (Fig. 28-9). The smaller classes will be discussed later in the chapter in the context of their evolutionary significance; for now, we restrict our discussion of flowering plants to the monocots and eudicots, which collectively represent about 97% of all flowering plant species. Eudicots are more diverse and include many more species (at least 200,000) than the monocots (at least 90,000). Table 28-2 provides a comparison of some of the general features of the two classes.

Monocots include palms, grasses, orchids, irises, onions, and lilies. Monocots are mostly herbaceous plants with long, narrow leaves that have parallel veins (the main leaf veins run parallel to one another). The parts of monocot flowers usually occur in threes. For example, a flower may have three sepals, three petals, six stamens, and a compound pistil consisting of three fused carpels (these flower parts are discussed shortly). Monocot seeds have a single **cotyledon,** or embryonic seed leaf; **endosperm,** a nutritive tissue, is usually present in the mature seed.

Eudicots include oaks, roses, mustards, cacti, blueberries, and sunflowers. Eudicots are either herbaceous (such as a tomato plant) or woody (such as a hickory tree). Their leaves vary in shape but usually are broader than monocot leaves, with netted veins (branched veins resembling a net). Flower parts usually occur in fours or fives or multiples thereof. Two cotyledons are present in eudicot seeds, and endosperm is usually absent in the mature seed, having been absorbed by the two cotyledons during seed development.

Flowers are involved in sexual reproduction

Flowers are reproductive shoots usually composed of four parts—sepals, petals, stamens, and carpels—arranged in whorls (circles) on the end of a flower stalk, or **peduncle** (Fig. 28-10). The peduncle may terminate in a single flower or a cluster of flowers known as an **inflorescence.** The tip of the flower stalk that bears the flower parts is known as the **receptacle.**

All four floral parts are important in the reproductive process, but only the stamens (the "male" organs) and carpels (the "female" organs) produce gametes. A flower that has all four parts is **complete,** whereas an **incomplete** flower lacks one or more of these four parts. A flower with both stamens and carpels is **perfect,** whereas an **imperfect** flower has stamens or carpels, but not both.

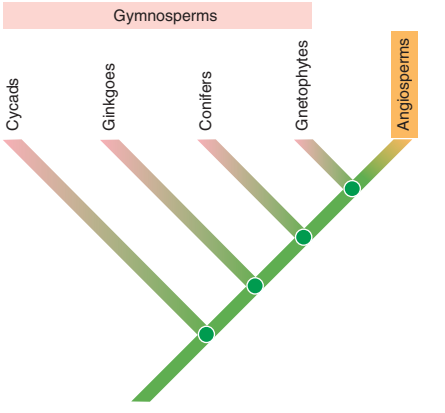

Figure 28-9 Flowering plants

(b) A twinleaf (*Jeffersonia diphylla*) flower has eight yellow stamens. Note the simple pistil with its green ovary in the center of the flower.

Figure 28-11 Parts of a flower

Sepals, which make up the lowermost and outermost whorl on a floral shoot, are leaflike in appearance and often green (Fig. 28-11a). Sepals cover and protect the other flower parts when the flower is a bud. As the blossom opens, the sepals fold back to reveal the more conspicuous petals. The collective term for all the sepals of a flower is the **calyx.**

The whorl just above the sepals consists of **petals,** which are broad, flat, and thin (like sepals and leaves) but vary in shape and are frequently brightly colored. Petals play an important role in attracting animal pollinators to the flower (see Chapter 36). Sometimes petals are fused to form a tube (as in trumpet honeysuckle flowers) or other floral shape (as in snapdragons, whose petals form two lips). The petals of a flower are referred to collectively as the **corolla.**

Just inside the petals is a whorl of **stamens** (Fig. 28-11b). Each stamen is composed of a thin stalk, called a **filament,** and a saclike **anther,** where meiosis occurs to form microspores that develop into pollen grains. Each pollen grain produces two cells surrounded by a tough outer wall. One cell eventually divides to form two male gametes, or sperm cells, and the other produces a pollen tube through which the sperm cells travel to reach the ovule.

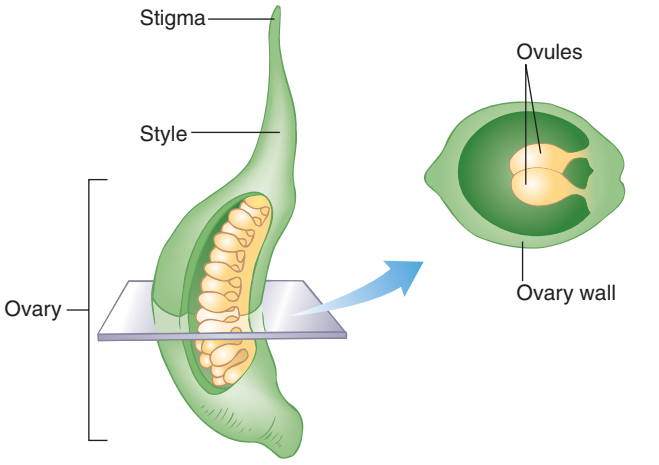
In the center of most flowers is one or more closed **carpels,** the "female" reproductive organs. Carpels bear ovules, which, as you may recall, are structures with the potential to develop into seeds. The carpels of a flower are separate or fused into a single structure. The female part of the flower is also called a **pistil** (see Fig. 28-11b). A pistil may consist of a single carpel (a simple pistil) or a group of fused carpels (a compound pistil) (Fig. 28-12). Each pistil generally has three sections: a **stigma,** on which the pollen grain lands; a **style,** a necklike structure through which the pollen tube grows; and an **ovary,** an enlarged structure that contains one or more ovules. Each young ovule contains a female gametophyte that forms one female gamete (an egg), two *polar nuclei,* and several other haploid cells. After fertilization, the ovule develops into a seed; and the ovary, into a fruit.

The life cycle of flowering plants includes double fertilization

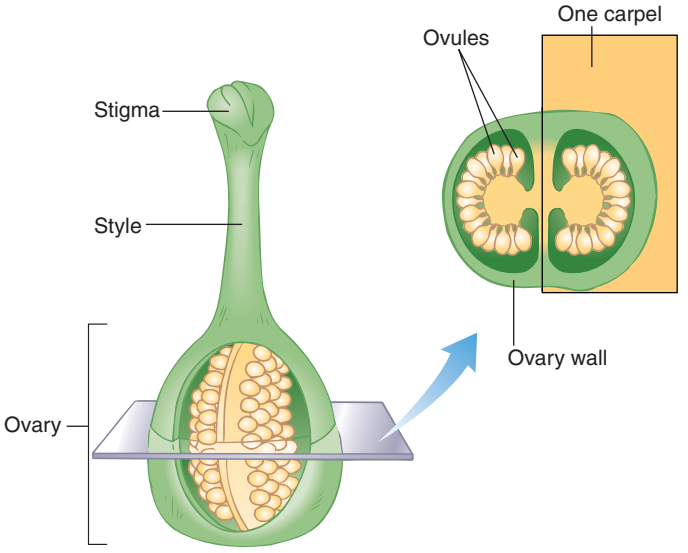
Flowering plants undergo alternation of generations in which the sporophyte generation is larger and nutritionally independent. The gametophyte generation in flowering plants is microscopic and nutritionally dependent on the sporophyte. Flowering plants, like gymnosperms and certain other vascular plants, are heterosporous and produce two kinds of spores: microspores and megaspores. As shown in Figure 28-13 1, sexual reproduction occurs in the flower.

In 2, each young ovule within an ovary contains a megasporocyte (megaspore mother cell) that undergoes meiosis to produce four haploid megaspores. Three of these usually disintegrate, and one divides mitotically and 3 develops into a mature female gametophyte, also called an **embryo sac.** The most widely studied type of embryo sac contains seven cells with eight haploid nuclei. Six of these cells, including the egg cell, contain a single nucleus each, and a central cell has two nuclei, called **polar nuclei.** The egg and the central cell with two polar nuclei are directly involved in fertilization; the other five cells in the embryo sac apparently have no direct role in the fertilization process and disintegrate. As the *synergids* (the two cells closely associated with the egg) disintegrate, however, they release chemicals that may affect the direction of pollen tube growth.

Each pollen sac, or microsporangium, of the anther contains numerous microsporocytes (microspore mother cells) 4, each of which undergoes meiosis to form four haploid microspores. Every microspore develops into 5 an immature male gameto-



(a) Simple pistil. This simple pistil consists of a single carpel.



(b) Compound pistil. This compound pistil has two united carpels. In most flowers with single pistils, the pistils are compound, consisting of two or more fused carpels.

Figure 28-12 Simple and compound pistils

phyte, also called a *pollen grain.* Pollen grains are extremely small; each consists of two cells: the *tube cell* and the *generative cell.*

The anthers split open and begin to shed pollen. A variety of agents, including wind, water, insects, and other animal pollinators (see Chapter 36), transfer pollen grains to the stigma. As shown in 6, if compatible with the stigma, the pollen grain germinates; that is, the tube cell forms a pollen tube that grows down the style and into the ovary. The germinated pollen grain with its pollen tube is the mature male gametophyte. Next, the generative cell divides to form two nonflagellate sperm cells. The sperm cells move down the pollen tube and are discharged into the embryo sac. Both sperm cells are involved in fertilization.

Something happens during sexual reproduction in flowering plants that does not occur anywhere else in the living world. As shown in 7, when the two sperm cells enter the embryo sac, *both* participate in fertilization. One sperm cell fuses with the egg, forming a zygote that grows by mitosis and develops into a multicellular embryo in the seed. The second sperm cell fuses with the two haploid polar nuclei of the central cell to form a triploid ($3n$) cell that grows by mitosis and develops into **endosperm,** a nutrient tissue rich in lipids, proteins, and carbohydrates that nourishes the growing embryo. This fertilization process, which involves two separate nuclear fusions, is called **double fertilization** and is, with two exceptions, unique to flowering plants. (Double fertilization has been reported in the gymnosperms *Ephedra nevadensis* and *Gnetum gnemon.* This process differs from double fertilization in flowering plants in that an additional zygote, rather than endosperm, is produced. The second zygote later disintegrates.)

Seeds and fruits develop after fertilization

As a result of double fertilization and subsequent growth and development, each seed contains a young plant embryo and nutritive tissue (the endosperm), both of which are surrounded by a protective seed coat. In monocots the endosperm persists and is the main source of food in the mature seed. In most eudicots the endosperm nourishes the developing embryo, which subsequently stores food in its cotyledons.

As a seed develops from an ovule following fertilization (Fig. 28-13 8), the ovary wall surrounding it enlarges dramatically and develops into a **fruit.** In some instances, other tissues associated with the ovary also enlarge to form the fruit. Fruits serve two purposes: to protect the developing seeds from desiccation as they grow and mature and to aid in the dispersal of seeds (see Chapter 36). For example, dandelion fruits have feathery plumes that are lifted and carried by air currents. Animals often assist in dispersing seeds found in edible fruits (Fig. 28-14). Once a seed lands in a suitable place, it may germinate and develop into a mature sporophyte that produces flowers, and the life cycle continues as described.

Flowering plants have many adaptations that account for their success

The evolutionary adaptations of flowering plants account for their success in terms of their ecological dominance and their great number of species. Seed production as the primary means of reproduction and dispersal, an adaptation shared with the gymnosperms, is clearly significant and provides a definite advantage over seedless vascular plants. Closed carpels, which give rise to fruits surrounding the seeds, and the process of double fertilization increase the likelihood of reproductive success. The evolution of a variety of interdependencies with many types of insects, birds, and bats, which disperse pollen from one flower to another of the same species, is another reason for angiosperm success. Pollen transfer results in cross-fertilization, which mixes the genetic material and promotes genetic variation among the offspring.

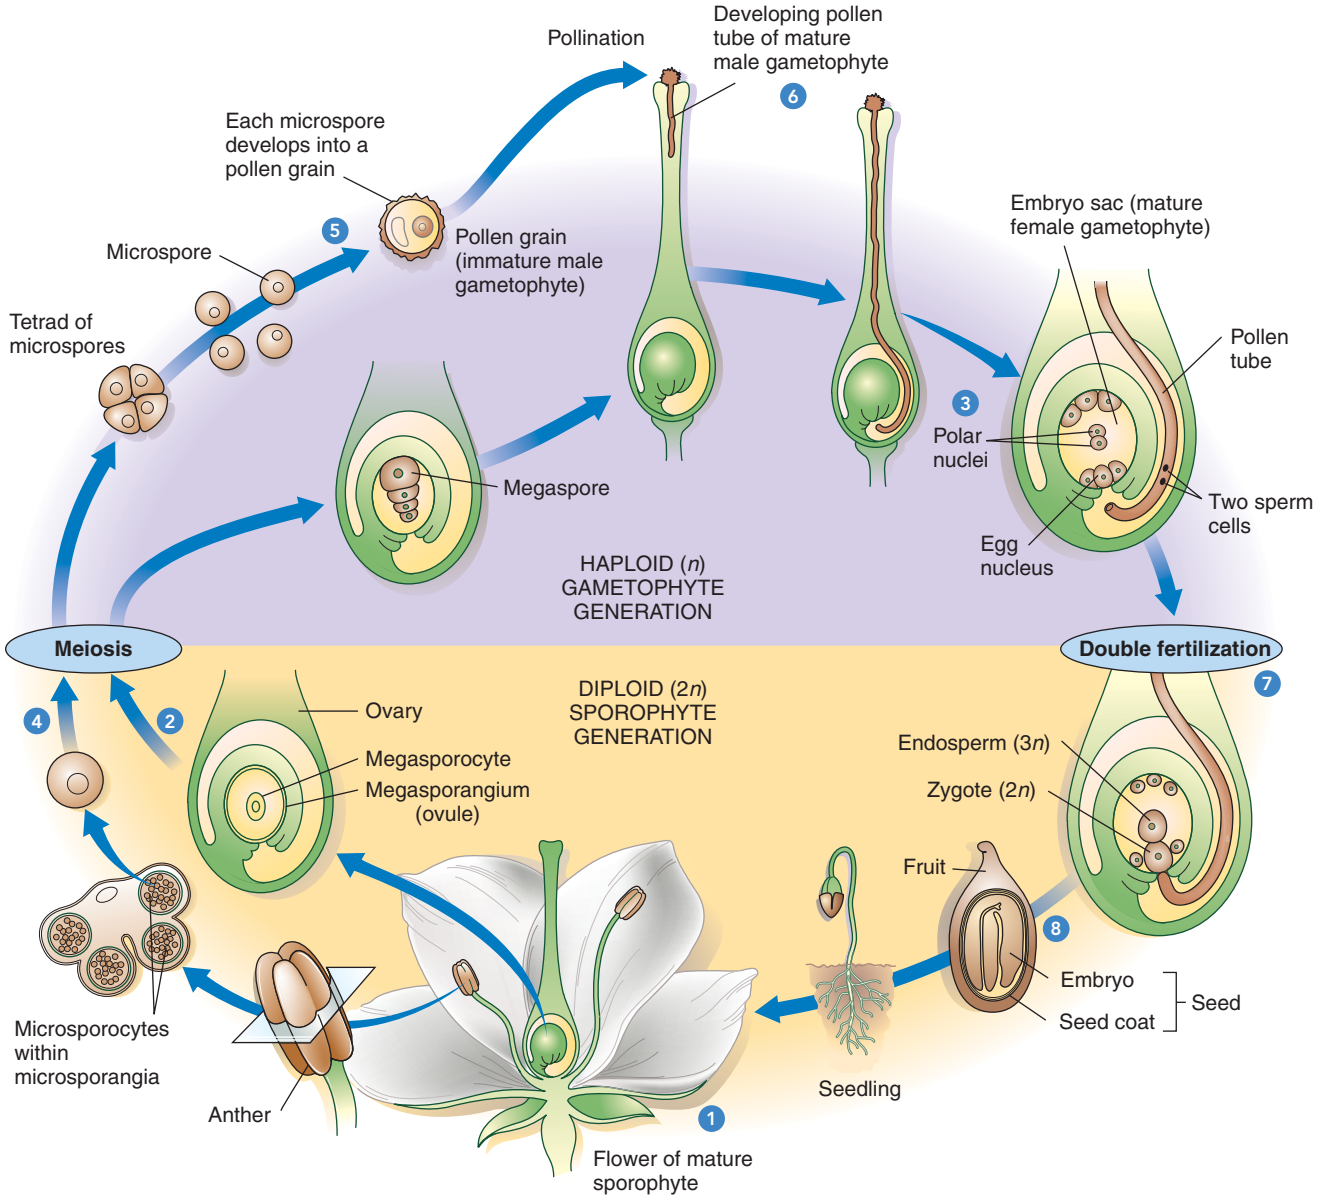


Figure 28-13 ***Animated*** Life cycle of flowering plants

A significant feature of the flowering plant life cycle is double fertilization, in which one sperm cell unites with the egg, forming a zygote, and the other sperm cell unites with the two polar nuclei, forming a triploid cell that gives rise to endosperm. See text for a detailed description.

Several distinctive features have contributed to the success of flowering plants in addition to their highly successful reproduction involving flowers, fruits, and seeds. Recall that most flowering plants have very efficient water-conducting vessel elements in their xylem, as well as tracheids. In contrast, the xylem of almost all seedless vascular plants and gymnosperms consists exclusively of tracheids. Most flowering plants also have efficient carbohydrate-conducting sieve tube elements in their phloem. Vascular plants other than flowering plants and gnetophytes lack vessel elements and sieve tube elements.

The leaves of flowering plants, with their broad, expanded blades, are very efficient at absorbing light for photosynthesis. Abscission (shedding) of these leaves during cold or dry periods reduces water loss and has enabled some flowering plants to expand into habitats that would otherwise be too harsh for survival. The stems and roots of flowering plants are often modified for food or water storage, another feature that helps flowering plants survive in severe environments.

Probably most crucial to the evolutionary success of flowering plants, however, is the overall adaptability of the sporophyte generation. As a group, flowering plants readily adapt to new habitats and changing environments. This adaptability is evident in the great diversity exhibited by the various species of flowering plants. For example, the cactus is remarkably well adapted to des-

Holt Studies Intl./Silvestra Silva/Photo Researchers, Inc.

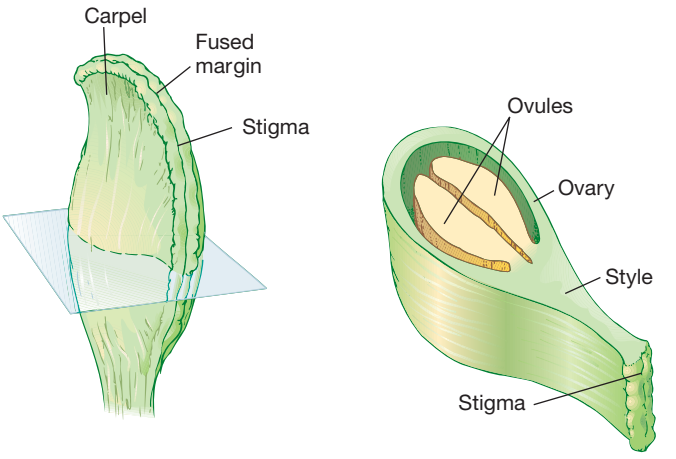
Figure 28-14 Guava fruit and seeds

Animals eat fleshy fruits such as guava. The seeds are frequently swallowed whole and pass unharmed through the animals' digestive tracts.

ert environments. Its stem stores water; its leaves (spines) have a reduced surface area available for transpiration (loss of water vapor; see Chapter 33) and may also protect against thirsty herbivorous animals; and its thick, waxy cuticle reduces water loss. In contrast, the water lily is well adapted for wet environments, in part because it has air channels that provide adequate oxygen to stems and roots living in oxygen-deficient water and mud.

Studying how flowers evolved provides insights into the evolutionary process

In evolution, new structures or organs often originate by modification of previously existing structures or organs (see Chapter 20). Much evidence supports the classical interpretation that the four organs of a flower—sepals, petals, stamens, and carpels—arose from highly modified leaves. This evidence includes comparisons of the arrangement of vascular tissues in both flowers and leafy stems and of the developmental stages of floral parts and leaves.



(a) The carpel resembles a folded leaf in which the ovules borne on its upper surface are enclosed.

(b) A cross section of the carpel, cut along the dashed line in **(a)**.

Figure 28-15 Carpel of *Drimys piperita*

Sepals are the most leaflike of the four floral organs, and botanists generally agree that sepals are specialized leaves. Although petals of many flowering plant species are leaflike in appearance, botanists generally view petals as modified stamens that later became sterile and leaflike. Cultivated roses and camellias provide evidence supporting this hypothesis; in some varieties the stamens have been transformed into petals, forming showy flowers with large numbers of petals.

The remarkably leaflike stamens and carpels of certain tropical trees and other species support the origin of stamens and carpels from leaves or leaflike organs. Consider, for example, the carpel of *Drimys,* a genus of flowering trees and shrubs native to Southeast Asia, Australia, and South America. This carpel resembles a leaf that is folded inward along the midrib, thereby enclosing the ovules, and joined along the entire length of the leaf's margin (▮ Fig. 28-15).

The fundamental question is whether these leaflike stamens and carpels are early organs that were conserved (retained) during the course of evolution or are highly specialized organs that do not resemble early stamens and carpels. Many botanists who have studied this question have concluded that stamens and carpels are probably derived from leaves. Not all botanists accept the origin of stamens and carpels from highly modified leaves, however. As we noted in Chapter 1, uncertainty and debate are part of the scientific process, and scientists can never claim to know a final answer.

During the course of more than 130 million years of angiosperm evolution, flower structure diversified as floral organs fused or became reduced in size or number. These changes led to greater complexity in floral structure in some species and to greater simplicity in other species. Interpreting the floral structures of so many different angiosperm species is sometimes difficult, but it is important because correct interpretations are essential to devising a phylogenetic classification scheme.

(a) Progymnosperm. *Archaeopteris,* which existed about 370 mya, had some features in common with modern seed plants but did not produce seeds.

(b) Seed fern. *Emplectopteris* produced seeds on fernlike leaves. Seed ferns existed from about 360 mya to 250 mya.

Figure 28-16 Evolution of seed plants

(**a,** Redrawn from C. B. Beck, "Reconstructions of *Archaeopteris* and Further Consideration of Its Phylogenetic Position," *American Journal of Botany,* Vol. 49, 1962. **b,** Redrawn from H. N. Andrews, *Ancient Plants and the World They Lived In,* Comstock, New York, 1947.)

gymnosperms, however, reproduced by spores, not seeds. *Archaeopteris,* a progymnosperm that lived about 370 mya, is the earliest known tree with "modern" woody tissue (Fig. 28-16a).

Fossils of several progymnosperms with reproductive structures intermediate between those of spore plants and seed plants have been discovered. For example, the evolution of microspores into pollen grains and of megasporangia into ovules (seed-producing structures) can be traced in fossil progymnosperms. Plants producing seeds appeared during the late Devonian period, more than 359 mya. The fossil record indicates that different groups of seed plants apparently arose independently several times.

As mentioned previously, fossilized remains of ginkgo are found in 200-million-year-old rocks, and other groups of gymnosperms were well established by 160 mya to 100 mya. Although the gymnosperms are an ancient group, some questions persist about the exact pathways of gymnosperm evolution. The fossil record indicates that progymnosperms probably gave rise to conifers and to another group of extinct plants called **seed ferns,** which were seed-bearing woody plants with fernlike leaves (Fig. 28-16b). The seed ferns, in turn, probably gave rise to cycads and possibly ginkgo, as well as to several gymnosperm groups now extinct. The origin of gnetophytes remains unclear, although molecular data indicate that they are closely related to conifers.

Review

- How do nonreproductive adaptations of flowering plants differ from those of gymnosperms?
- How does the flowering plant life cycle differ from that of the gymnosperms?
- What are the two classes of flowering plants, and how can one distinguish between them?
- How does pollination occur in flowering plants?
- How does fertilization differ in gymnosperms and flowering plants?

THE EVOLUTION OF SEED PLANTS

Learning Objective

9 Summarize the evolution of gymnosperms from seedless vascular plants, and trace the evolution of flowering plants from gymnosperms.

One group that descended from ancestral seedless vascular plants was the **progymnosperms,** all of which are now extinct. Progymnosperms had two derived features absent in their immediate ancestors: leaves with branching veins (*megaphylls*) and woody tissue (*secondary xylem*) similar to that of modern gymnosperms. Pro-

Our understanding of the evolution of flowering plants has made great progress in recent years

Flowering plants are the most recent group of plants to evolve. The fossil record, although incomplete, suggests that flowering plants descended from gymnosperms. By the middle of the Jurassic period, about 180 mya, several gymnosperm lines existed with some features resembling those of flowering plants. Among other traits, these derived gymnosperms possessed leaves with broad, expanded blades and the first modified seed-bearing leaves, which nearly enclose the ovules. Beetles were evidently visiting these plants, and biologists have suggested that perhaps this relationship was the beginning of **coevolution,** a mutual adaptation between plants and their animal pollinators (see Chapter 36).

One important task facing paleobotanists (biologists who study fossil plants) is determining which of the ancient gymnosperms are in the direct line of evolution leading to the flowering plants. Given the structural data, most botanists hypothesize that flowering plants arose only once—that is, there is only one line of evolution from the gymnosperms to the flowering plants. The gnetophytes are the gymnosperm group considered by some

Figure 28-18 Fossil flower

The fossilized flower of the extinct plant *Archaeanthus linnenbergeri,* which lived about 100 mya. The scars on the reproductive axis (receptacle) may show where stamens, petals, and sepals were originally attached but abscised (fell off). Many spirally arranged pistils were still attached at the time this flower was fossilized.

botanists to be the closest living relatives of flowering plants; both structural similarities and certain comparative molecular data support this conclusion. Like angiosperms, gnetophytes have vessels, lack archegonia, have flowerlike compound strobili, and undergo double fertilization. However, some molecular data refute a close link between the gnetophytes and flowering plants. It is hoped additional studies will clarify the relationships among the various gymnosperm phyla and the flowering plants.

The oldest definitive trace of flowering plants in the fossil record consists of ovules enclosed in tiny podlike fruits interpreted as carpels in Jurassic and Lower Cretaceous rocks some 125 million to 145 million years old (Fig. 28-17). The oldest fossilized flowers are about 118 million to 120 million years old. Based on the fossil record as well as structural and molecular data of living angiosperms, the first flowering plants were probably small, weedy shrubs or herbaceous plants adapted to disturbed habitats. They may have been fragile plants that were not easily preserved. If so, the reason there are few fossils of early angiosperms may be that the environment in which they evolved was repeatedly disturbed and not favorable for their preservation as fossils.

Botanists hypothesize that the rapid diversification of angiosperms did not occur until early flowering plants had invaded lowland regions. By 90 mya, during the Cretaceous period, flowering plants had diversified and had begun to replace gymnosperms as Earth's dominant plants. Fossils of flowering plant leaves, stems, flowers, fruits, and seeds are numerous and diverse. They outnumber fossils of gymnosperms and ferns in Late Cretaceous deposits, indicating the rapid success of flowering plants once they appeared (Fig. 28-18). Many angiosperm species apparently arose from changes in chromosome number (see discussion of allopolyploidy and sympatric evolution in Chapter 20).

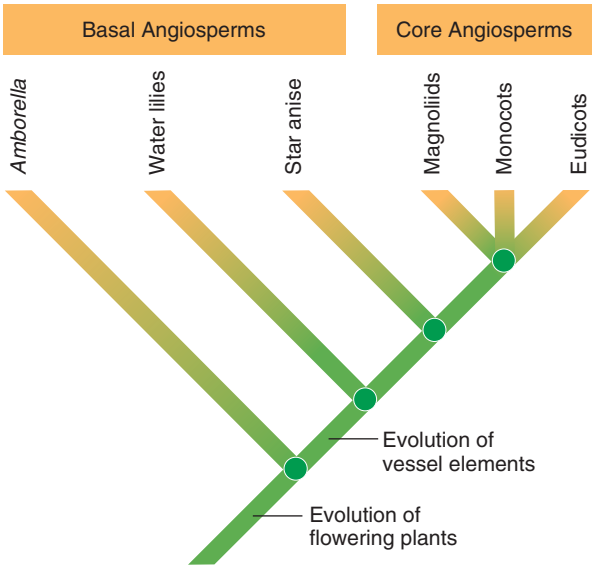
The basal angiosperms comprise three clades

Recent cladistic analyses of structural features and molecular comparisons have helped clarify relationships among the angiosperm classes. The evidence indicates that three clades of basal angiosperms evolved before the divergence of core angiosperms (Fig. 28-19a). **Basal angiosperms** consist of about 170 species thought to be ancestral to all other flowering plants.

The oldest surviving clade of basal angiosperms is represented by a single living species, *Amborella trichopoda* (Fig. 28-19b). A shrub native to New Caledonia, an island in the South Pacific, *Amborella* may be the nearest living relative to the ancestor of all flowering plants. The water lilies and related families compose the second clade of basal angiosperms (Fig. 28-19c). This clade, which contains about 70 species of aquatic or wetland herbs, may be the second-oldest surviving lineage. Star anise and relatives—the third clade of basal angiosperms—consist of about 100 species of vines, trees, and shrubs found mostly in warmer climates. Star anise is important economically because it is a source of spice and anise oil (Fig. 28-19d). Star anise is also used to make Tamiflu, one of the treatments for influenza.

Key Point

There are six clades of angiosperms, three of basal angiosperms and three of core angiosperms. The monocot and eudicot clades have the greatest number of species.



(a) One hypothesis of relationships among the flowering plants, based on fossil and molecular evidence. *Amborella*, water lilies, and star anise are living plants whose ancestors apparently branched off the angiosperm family tree early. These early clades were followed by the magnoliids, the monocot branch, and the eudicots.

(d) Star anise (*Illicium verum*), a basal angiosperm.

Sinclair Stammers/Photo Researchers, Inc.

(e) *Magnolia grandiflora*, a core angiosperm.

Figure 28-19 Evolution of flowering plants

The core angiosperms comprise magnoliids, monocots, and eudicots

Most angiosperm species belong to a clade of **core angiosperms,** which is divided into three subclades: magnoliids, monocots, and eudicots. **Magnoliids** include species in the magnolia, laurel, and black pepper families, as well as several related families (Fig. 28-19e). Although magnoliids have been traditionally classified with the eudicots as "dicots," molecular evidence such as DNA sequence comparisons indicates that the magnoliids are neither eudicots nor monocots. Native to tropical or warm temperate regions, magnoliids include several economically important plants, such as avocado, black pepper, nutmeg, and bay laurel.

Note in Figure 28-19a that the magnoliids, monocots, and eudicots are all depicted as arising from a single branch point. Exact relationships among these three subclades, each of which is probably monophyletic, remain to be clarified. In other words, at this time we cannot say with certainty which of the three groups was the first to branch off from the other two.

Review

- What features distinguish progymnosperms from seed ferns?
- Describe the significant features of the oldest known fossil angiosperm.
- Are monocots considered basal or core angiosperms? Explain your answer.

SUMMARY WITH KEY TERMS

Learning Objectives

1 Compare the features of gymnosperms and angiosperms (page 601).

- The two groups of seed plants are the **gymnosperms** and the **angiosperms.** Gymnosperms produce seeds that are totally exposed or borne on the scales of cones; an ovary wall does not surround the ovules of gymnosperms. Angiosperms are flowering plants that produce their seeds within a fruit (a mature ovary).

2 Trace the steps in the life cycle of a pine, and compare its sporophyte and gametophyte generations (page 601).

- A pine tree is a mature sporophyte; pine gametophytes are extremely small and nutritionally dependent on the sporophyte generation. Pine is heterosporous and produces microspores and megaspores in separate cones.
- Male cones produce **microspores** that develop into **pollen grains** (immature male gametophytes) that are carried by air currents to female cones.
- Female cones produce **megaspores.** One of each four megaspores produced by meiosis develops into a female gametophyte within an **ovule (megasporangium).**
- After **pollination,** the transfer of pollen to the female cones, a **pollen tube** grows through the megasporangium to the egg within the archegonium. After **fertilization,** the zygote develops into an embryo encased inside a seed adapted for wind dispersal.

3 Summarize the features that distinguish gymnosperms from bryophytes and ferns (page 601).

- Unlike bryophytes, **gymnosperms** are vascular plants. Unlike bryophytes and ferns, gymnosperms produce seeds. Gymnosperms also produce wind-borne pollen grains, a feature that ferns and other seedless vascular plants lack.

4 Name and briefly describe the four phyla of gymnosperms (page 601).

- **Conifers** (phylum Coniferophyta), the largest phylum of gymnosperms, are woody plants that bear **needles** (leaves that are usually evergreen) and produce seeds in cones. Most conifers are **monoecious** and have male and female reproductive parts in separate cones on the same plant.
- **Cycads** (phylum Cycadophyta) are palmlike or fernlike in appearance. They are **dioecious**—they have male and female reproductive structures on separate plants—but reproduce with pollen and seeds in conelike structures.
- *Ginkgo biloba,* the only surviving species in phylum Ginkgophyta, is a deciduous, dioecious tree. The female **ginkgo** produces fleshy seeds directly on branches.
- **Gnetophytes** (phylum Gnetophyta) share a number of traits with angiosperms.

5 Summarize the features that distinguish flowering plants from other plants (page 607).

- **Flowering plants,** or angiosperms (phylum Anthophyta), constitute the phylum of vascular plants that produce flowers and seeds enclosed within a **fruit.** They are the most diverse and most successful group of plants.
- The flower, which may contain **sepals, petals, stamens,** and **carpels,** functions in sexual reproduction. Unlike those of gymnosperms, the ovules of flowering plants are enclosed within an **ovary.** After fertilization, the ovules become seeds, and the ovary develops into a fruit.

6 Briefly explain the life cycle of a flowering plant, and describe double fertilization (page 607).

- The sporophyte generation is dominant in flowering plants; gametophytes are extremely reduced in size and nutritionally dependent on the sporophyte generation. Flowering plants are heterosporous and produce microspores and megaspores within the flower.
- Each microspore develops into a pollen grain (immature male gametophyte). One of each four megaspores produced by meiosis develops into an **embryo sac** (female gametophyte). The embryo sac contains seven cells with eight nuclei; the egg cell and the central cell with two **polar nuclei** participate in fertilization.
- **Double fertilization,** which results in the formation of a diploid zygote and triploid **endosperm,** is characteristic of flowering plants.

ThomsonNOW™ Explore plant life cycles by clicking on the figures in ThomsonNOW.

7 Contrast eudicots and monocots, the two largest classes of flowering plants (page 607).

- Most **monocots** (class Monocotyledones) have floral parts in threes, and their seeds each contain one **cotyledon.** The nutritive tissue in their mature seeds is endosperm.
- **Eudicots** (class Eudicotyledones) usually have floral parts in fours or fives or multiples thereof, and their seeds each contain two cotyledons. The nutritive organs in their mature seeds are usually the cotyledons, which have absorbed the nutrients in the endosperm.

8 Discuss the evolutionary adaptations of flowering plants (page 607).

- Flowering plants reproduce sexually by forming flowers. After double fertilization, seeds form within fruits. Flowering plants have efficient water-conducting **vessel elements** in their xylem and efficient carbohydrate-conducting **sieve tube elements** in their phloem. Wind, water, insects, or other animals transfer pollen grains in various flowering plants.

ThomsonNOW™ Learn more about flower structure by clicking on the figure in ThomsonNOW.

9 Summarize the evolution of gymnosperms from seedless vascular plants, and trace the evolution of flowering plants from gymnosperms (page 614).

- Seed plants arose from seedless vascular plants. **Progymnosperms** were seedless vascular plants that had megaphylls and "modern" woody tissue. Progymnosperms probably gave rise to conifers as well as to **seed ferns,** which in turn likely gave rise to cycads and possibly ginkgo.
- The evolution of the gnetophytes, particularly their relationship to flowering plants, is unclear.
- Flowering plants probably descended from ancient gymnosperms that had specialized features, such as leaves with broad, expanded blades and closed carpels. Flowering plants likely arose only once.

TEST YOUR UNDERSTANDING

1. Seed plants *lack* which of the following structure(s)? (a) ovules surrounded by integuments (b) microspores and megaspores (c) vascular tissues (d) a large, nutritionally independent sporophyte (e) a large, nutritionally independent gametophyte
2. Conifers, cycads, ginkgo, and gnetophytes are collectively called (a) club mosses (b) gymnosperms (c) angiosperms (d) eudicots (e) seedless vascular plants
3. Most conifers are _____, having male and female reproductive parts at different locations on the same plant. (a) incomplete (b) imperfect (c) monoecious (d) dioecious (e) perfect
4. The immature male gametophytes of pine are called (a) ovules (b) stamens (c) seed cones (d) pollen grains (e) polar nuclei
5. The transfer of pollen grains from the male to the female reproductive structure is known as (a) pollination (b) fertilization (c) embryo sac development (d) seed development (e) fruit development
6. Motile sperm cells are found as vestiges in these two gymnosperm groups: (a) monocots, eudicots (b) gnetophytes, conifers (c) gnetophytes, flowering plants (d) cycads, conifers (e) cycads, ginkgo
7. There are at least _____ species of flowering plants. (a) 235 (b) 3000 (c) 30,000 (d) 300,000 (e) 3,000,000
8. This class of flowering plants includes the palms, grasses, and orchids. (a) eudicots (b) gnetophytes (c) cycads (d) monocots (e) conifers
9. The pistil has three sections: (a) stigma, style, and anther (b) anther, filament, and ovule (c) stigma, style, and ovary (d) ovary, ovule, and sepal (e) corolla, stamen, and sepal
10. A simple pistil consists of a single (a) calyx (b) carpel (c) ovule (d) filament (e) petal
11. A flower that lacks stamens is both _____ and _____. (a) complete; imperfect (b) incomplete; perfect (c) complete; perfect (d) incomplete; imperfect
12. After fertilization, the _____ develop(s) into a fruit and the _____ develop(s) into a seed. (a) ovary; ovule (b) polar nuclei; ovule (c) ovary; endosperm (d) ovule; ovary (e) ovule; polar nuclei
13. The female gametophyte in flowering plants is also called the (a) polar nuclei (b) anther (c) embryo sac (d) endosperm (e) sporophyll
14. This flowering plant may be the nearest living relative to the ancestor of all flowering plants. (a) *Amborella* (b) *Archaeopteris* (c) *Gnetum* (d) water lily (e) *Archaeanthus*
15. This cross section through an ovary reveals that the pistil is (a) simple, with one carpel (b) compound, with two fused carpels (c) compound, with three fused carpels (d) compound, with six separate carpels (e) compound, with six fused carpels

CRITICAL THINKING

1. How are cones and flowers alike? How are they different? (*Hint:* Your answer should consider microspores/megaspores and seeds.)
2. How do the life cycles of seedless plants (see Chapter 27) and seed plants differ? In what fundamental way are they alike?
3. **Evolution Link.** Most flowers contain both male and female reproductive structures, in contrast to the cones of gymnosperms, which are either male or female. Explain how bisexual flowers might be an advantageous evolutionary adaptation to the flowering plants that possess them.
4. **Evolution Link.** Contrast the algae, mosses, ferns, gymnosperms, and angiosperms with respect to their dependence on water as a transport medium for reproductive cells. Suggest a hypothesis to explain how the differences might be adaptive to living on land.
5. **Analyzing Data.** According to the cladogram in Figure 28-19, which plant(s) is/are the outgroup? Which feature does the outgroup lack that all other angiosperms possess?

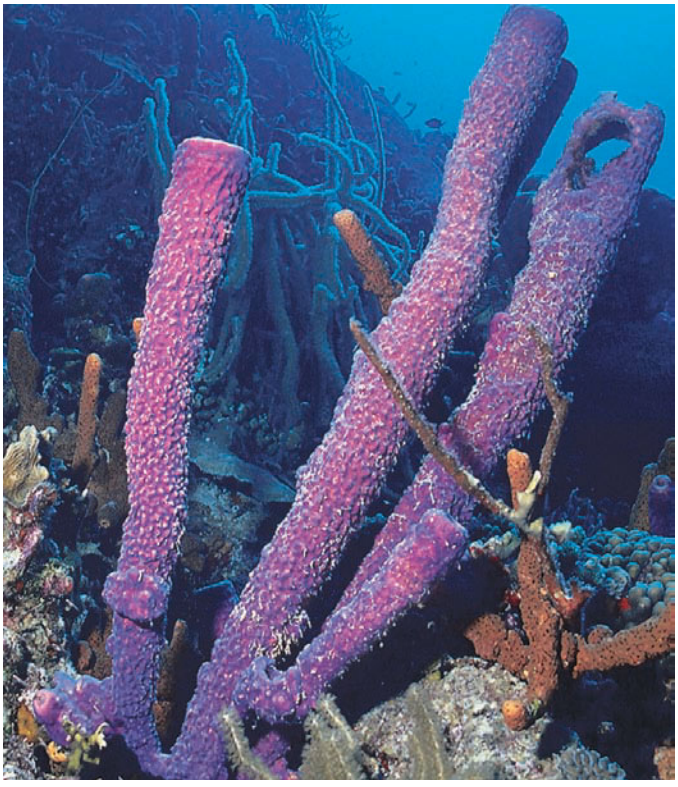
The Animal Kingdom: An Introduction to Animal Diversity



Charles V. Angelo/Photo Researchers, Inc.

The tube sponge (*Callyspongia vaginalis*). This animal, which ranges in color from purple to blue to gray, is common on coral reefs in the Caribbean, from Florida to Mexico.

KEY CONCEPTS

Animals are multicellular, eukaryotic heterotrophs.

Biologists classify animals based on their body plan and features of their early development.

Molecular data indicate that bilateral animals split into three major clades: two protostome groups—Lophotrochozoa (such as flatworms, mollusks, and annelids) and Ecdysozoa (such as nematodes and arthropods)—and deuterostomes (echinoderms and chordates).

Sponges (phylum Porifera) are characterized by collar cells and by loosely associated cells that do not form true tissues.

Members of phylum Cnidaria (hydras, jellyfish, sea anemones) are characterized by radial symmetry, two tissue layers, and cnidocytes, cells that contain stinging organelles.

Members of phylum Ctenophora (comb jellies) have biradial symmetry, two tissue layers, eight rows of cilia, and tentacles with adhesive glue cells.

Animal phylogeny has become an exciting and rapidly changing field of study. Biologists have described and named more than 1.5 million species of animals, and 15,000 to 20,000 new species are named each year. Millions more probably remain to be discovered and classified. Interestingly, an estimated 99% of all animal species that ever inhabited our planet are extinct. Biologists have assigned the extant (living) members of **kingdom Animalia** to about 35 phyla, but the relative positions of phyla and classes are a work in progress. As they consider new data, systematists redraw the tree of animal life.

Although most animal species are readily recognizable as animals, the identity of some others is less obvious. Early naturalists thought sponges were plants, because they did not move from place to place. Some people still mistake certain marine animals, such as sponges and corals, for plants (see photograph). Locomotion is not a requirement for being classified as an animal.

In this chapter we discuss some of the criteria biologists use to determine evolutionary relationships and to classify animals. Then we describe three phyla that diverged early in the evolutionary history of this kingdom. In Chapters 30 and 31, we discuss two major clades of animals: the protostomes and the deuterostomes. Many hypotheses are presented in these chapters, and it is important to remember that biologists continually respond to new data by redrawing branches of the animal phylogenetic tree. ■

ANIMAL CHARACTERS

Learning Objective

1 Describe several characters common to most animals.

Animals are so diverse that for almost any definition, we can find exceptions. However, the following characters describe most animals:

1. Animals are multicellular eukaryotes.
2. Animals are **heterotrophs.** As consumers, they depend on producers for their raw materials and energy. In contrast to the fungi, most animals ingest their food first and then digest it inside the body, usually within a digestive system.
3. Cells that make up the animal body are specialized to perform specific functions. In all but the simplest animals, cells are organized to form tissues, and tissues are organized to form organs. In small animals with simple body plans, life processes such as gas exchange, circulation of materials, and waste disposal can take place by diffusion of gases and other substances directly to and from the environment. In large, complex animals, specialized organ systems have evolved that perform these life processes.
4. Animals have diverse body plans. The term **body plan** refers to the basic structure and functional design of the body. An animal's body plan and lifestyle are adapted to its methods of obtaining food and reproducing.
5. Most animals are capable of locomotion at some time during their life cycle. Some animals (such as sponges and corals) move about as larvae (immature forms) but are **sessile** (firmly attached to the ground or some other surface) as adults (see chapter opening photograph).
6. Most animals have nervous systems and muscle systems that enable them to respond rapidly to stimuli in their environment.
7. Most animals are diploid organisms that reproduce sexually, with large, nonmotile eggs and small, flagellate sperm. A haploid sperm unites with a haploid egg, forming a **zygote** (fertilized egg).
8. Animals go through a period of embryonic development. The zygote undergoes **cleavage,** a series of mitotic cell divisions. During cleavage the zygote develops into a hollow ball of cells called a **blastula.** Cells of the blastula undergo **gastrulation,** a process of forming and segregating specific layers of tissue, called *germ layers.* Although some animals develop directly into adults, the majority first develop into a **larva,** a sexually immature form that may look very different from the adult (Fig. 29-1). The larva differs from the adult in many ways, including where it lives (its habitat), how it moves, and what it eats. Larvae typically go through **metamorphosis,** a developmental process that converts the immature animal into a juvenile form that can then grow into an adult.

Figure 29-1 Larva

Spiny lobster larva (*Panulirus* sp.) hitching a ride on a jellyfish. Photographed in open ocean at night, Hawaii.

Review

- For centuries, scientists classified sponges as plants, but now they are classified as animals. What criteria do biologists use to classify them as animals? (*Hint:* What is their mode of nutrition? Also, consider their larval stage.)

ADAPTATIONS TO HABITATS

Learning Objective

2 Compare the advantages and disadvantages of life in the ocean, in fresh water, and on land.

Fossil evidence suggests that animals evolved in shallow, marine environments during the Proterozoic eon, at least 600 million years ago (mya; see Chapter 21). Although animals are now distributed in virtually every environment, members of most animal phyla still inhabit marine environments.

Marine habitats offer many advantages

The buoyancy of sea water provides support, and the large volume keeps the water temperature relatively stable. The body fluids of most invertebrates have about the same osmotic concentration as sea water, so fluid and salt balance are more easily maintained than in fresh water. **Plankton,** which consists of the mainly microscopic animals and protists that are suspended in water and float with its movement, provides a ready source of food for many aquatic animals.

Life in the ocean also presents some challenges. Although the continuous motion of water brings nutrients to animals and washes their wastes away, the animals must be able to cope with the water's movements and the currents that could sweep them away. Squids, fishes, and marine mammals have evolved as strong swimmers, usually able to direct their movements and maintain their location. However, most invertebrates and young verte-

brates cannot swim strongly, and they have adapted in various ways to the tides and currents. Some sessile animals attach permanently to a stable structure such as a rock. Others burrow in the sand and silt that cover the sea bottom. Many invertebrates have adapted by maintaining a small body size and becoming part of the plankton. As they are tossed about, their food supply continues to surround them.

Some animals are adapted to freshwater habitats

Far fewer kinds of animals make their homes in fresh water than in the ocean, because living in this habitat is more difficult. Fresh water is hypotonic to the tissue fluids of animals, so water tends to move into the animal by osmosis. To survive in this habitat, freshwater species must have mechanisms for removing excess water while retaining salts. This *osmoregulation* requires an expenditure of energy.

Fresh water offers a much less constant environment than sea water. Animals that inhabit fresh water must have adaptations for surviving variations in oxygen content, temperature, turbidity (because of sediments suspended in the water), and even water volume. In addition, fresh water generally contains less food than the sea.

Terrestrial living requires major adaptations

Living on land is even more difficult than living in fresh water, and the evolution of terrestrial animals involved major adaptations. Analyzing the fossil record, many biologists hypothesize that the first air-breathing terrestrial animals were scorpion-like arthropods that came ashore in the Silurian period about 444 mya. The first vertebrates to inhabit terrestrial environments, the amphibians, did not appear until the Devonian period, about 30 million years later.

The chief problem facing all terrestrial organisms is desiccation (drying out). Water is constantly lost by evaporation and is often difficult to replace. A body covering adapted to minimize fluid loss helps solve this problem in many terrestrial animals (Fig. 29-2). Location of the respiratory surface deep within the animal also helps prevent fluid loss. Thus, the gills of aquatic animals are typically located externally, but lungs and tracheal tubes of terrestrial animals are internal.

Reproduction on land also poses challenges to protect gametes and the developing offspring from desiccation. Aquatic animals typically shed their gametes in the water, where fertilization occurs. The surrounding water also serves as an effective shock absorber that protects the delicate embryos as they develop. Some land animals, including most amphibians, return to the water for reproduction, and their larval forms develop in the water.

The evolution of internal fertilization has permitted many terrestrial animals, including earthworms, land snails, insects, reptiles, birds, and mammals, to meet the desiccation challenge. Because these terrestrial animals transfer sperm from the body of the male directly into the body of the female by copulation, a watery medium continuously surrounds the sperm. Another important adaptation to reproduction on land is the tough, protective shell that surrounds the eggs of many species. Secreted by the female, this shell protects the developing embryo from drying out. An alternative adaptation for terrestrial reproduction is development of the embryo within the moist body of the mother.

The temperature extremes of terrestrial habitats also present challenges. In later chapters we discuss behavioral and physiological adaptations for maintaining body temperature.

E. R. Degginger/Photo Researchers, Inc.

Figure 29-2 Adaptations to terrestrial life

The tough, horny skin of the green iguana (*Iguana iguana*) has scales and is water resistant. Leathery eggs protect the embryos from drying out.

Review

- What are some advantages of marine environments over freshwater and terrestrial habitats?
- What are some animal adaptations to the terrestrial environment?

ANIMAL ORIGINS

Learning Objective

3 Use current hypotheses to trace the early evolution of animals.

Biologists generally agree that animals share a common ancestor with a group of protists known as *choanoflagellates* (see Fig. 25-25). The cells of these colonial flagellates became specialized to perform a specific function, such as movement, feeding, or reproduction. As this division of labor evolved, a colony of flagellates reached the level of cooperation and coordination that qualified it to be considered a single organism—the first animal. The choanoflagellates, fungi, and animals are a monophyletic group known as **opisthokonts.** (Recall from Chapter 25 that opisthokonts are characterized by a posterior flagellum on motile cells.)

Historically, biologists depended on fossils, on similarities in body plan, and on patterns of development to determine evolutionary relationships among various groups of animals. Now, molecular methods are providing additional data that help an-

swer questions about phylogeny. **Molecular systematics,** the science that focuses on molecular structure to clarify evolutionary relationships, is contributing greatly to the process of reconstructing animal phylogeny.

Molecular analysis indicates that the structure of genes that control development, RNA molecules, and many other molecules are very similar among all animal groups that have been studied. According to the *principle of parsimony* (see Chapter 23), such complex molecules are unlikely to have evolved multiple times. Thus, these data support the hypothesis that animals evolved only once. They are a monophyletic group.

Molecular systematics helps biologists interpret the fossil record

The evolutionary history of animals has been vigorously debated, because early animals were soft-bodied forms that left few fossils. The scarcity of fossils has made it difficult to determine the age, rate of divergence, and number of branches of animal groups. The earliest known animal fossils are **Ediacaran fossils** from the Ediacaran period (600 mya to 542 mya). These fossils of small, simple animals suggest that sponges, jellyfish, and comb jellies were present at that time (see Fig. 21-8).

Paleontologists have discovered many large, complex animal fossils in Chengjiang, an Early Cambrian (525 mya to 520 mya) fossil site in China, and in the Burgess Shale in British Columbia, a Middle Cambrian fossil site (520 mya to 515 mya). Fossils of most extant phyla (and also many extinct animals) have been found at these sites. The rapid appearance of an amazing variety of body plans during this time is known as the **Cambrian Radiation,** or less formally, **Cambrian explosion** (see Fig. 21-9). According to the Cambrian explosion hypothesis, which is based on the fossil record, the many major modifications in body plan that occurred during this time account for many branches in the animal tree.

Studies of large molecular data sets suggest that most animal clades actually diverged over a very long period during the Proterozoic eon (2.5 bya to 542 mya). Thus, the animal phyla that first left fossils during the Cambrian Radiation may have evolved several hundred million years *before* they appear in the fossil record. Biologists estimate that certain groups are about twice as old as the oldest fossils found to date. According to this view, the Cambrian Radiation was a rapid evolution of new animal body plans among clades that already existed. Perhaps fossils of these early animals remain to be discovered in Proterozoic rocks.

Biologists develop hypotheses about the evolution of development

Changes in animal body plan are linked to changes in patterns of embryonic development. Biologists have long used similarities and differences in embryonic development to hypothesize how animal groups are related. Traditionally, biologists depended mainly on structural changes to compare the process of development in various groups.

During the past 20 years, researchers have begun to study the molecular basis of developmental processes. They have identified the genes that direct the early development of the body plan and have discovered that many of these genes have been conserved during animal evolution. The same basic set of genes controls early development in all animal groups. Furthermore, the same genes are used in similar fashion to regulate development.

Evolutionary developmental biology, sometimes referred to as **Evo Devo,** has become an important approach to studying animal relationships. Biologists compare molecular events, such as gene regulation during development, in various animal groups. Similarities in molecular development among different animal groups suggest that similarities existed in the common ancestor of these groups.

Recall from Chapter 17 that *Hox* genes are a group of regulatory genes that help control early development. All major animal groups, except sponges, have *Hox* genes. Investigators suggest that all the *Hox* gene groups had evolved by the beginning of the Cambrian period. Mutations in *Hox* genes could have resulted in rapid changes in animal body plans. For example, regulation by *Hox* gene groups has been linked with the development of wings or legs.

Review

- What was the Cambrian explosion?
- According to the current hypothesis, when did most major groups of animals evolve?

RECONSTRUCTING ANIMAL PHYLOGENY

Learning Objectives

4 Describe how biologists use structural characters (including variations in body symmetry, number of tissue layers, and type of body cavity) and patterns of early development to infer relationships among animal phyla.

5 Describe three major contributions to animal phylogeny made by molecular systematists. Include the identification of three major clades of bilateral animals.

The basic animal body plan has been highly conserved throughout our evolutionary history. Biologists use similarities and differences in structure and early development to infer evolutionary relationships among animal groups. Variations in major characters of the body plan provide clues to animal relationships. Biologists compare variations in body symmetry, number of tissue layers, type of body cavity, and pattern of development. In addition, biologists now have molecular tools to enhance our understanding of animal phylogeny.

Animals exhibit two main types of body symmetry

Symmetry refers to the arrangement of body structures in relation to the body axis. Most sponges are not symmetrical, so when a sponge is cut in half, the two halves are not similar to each

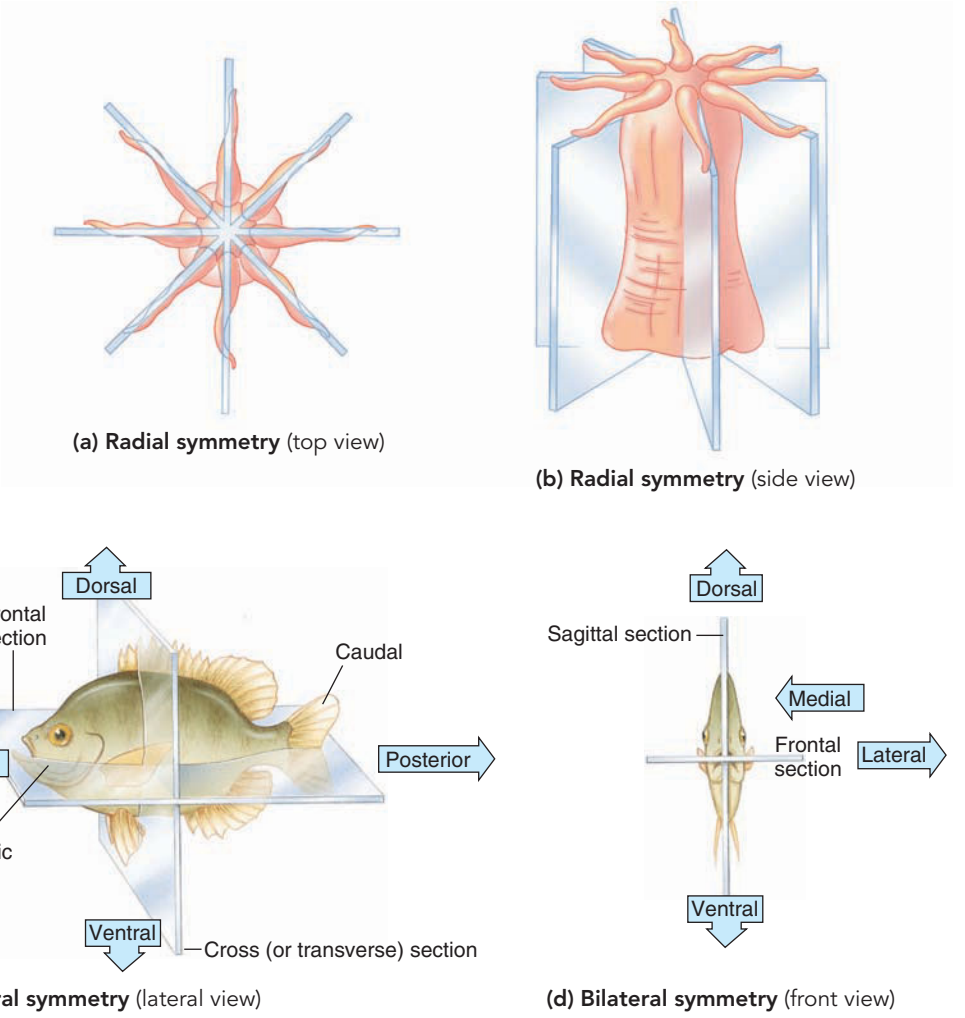

Figure 29-3 ***Animated*** Radial and bilateral symmetry

(a, b) In radial symmetry, multiple planes can be drawn through the central axis; each divides the animal into two mirror images. **(c, d)** In bilateral symmetry, the head end of the animal is its anterior end, and the opposite end is its posterior end. The back of the animal is its dorsal surface, and the belly is its ventral surface. The diagrams also illustrate various ways the body can be sectioned (cut) to study its internal structure. A sagittal section (lengthwise vertical cut) divides the animal into right and left parts. A frontal, or longitudinal, cut (lengthwise horizontal) divides the body into dorsal and ventral parts. Sections are used in illustrations throughout this book to show the structure and arrangement of tissues and organs.

other. Most other animals exhibit either radial or bilateral body symmetry.

Cnidarians (jellyfish, sea anemones, and their relatives), ctenophores (comb jellies), and adult echinoderms (sea stars and their relatives) have **radial symmetry.** In radial symmetry, the body has the general form of a wheel or cylinder, and similar structures are regularly arranged as spokes from a central axis (Fig. 29-3a and b). Multiple planes can be drawn through the central axis, each dividing the organism into two mirror images. An animal with radial symmetry receives stimuli equally from all directions in the environment.

Many radially symmetrical animals have modified radial symmetry. For example, sea anemones and ctenophores (comb jellies) actually have **biradial symmetry,** in which parts of the body have become specialized so that only two planes can divide the body into similar halves.

Most animals exhibit **bilateral symmetry,** at least in their larval stages. A bilaterally symmetrical animal can be divided through only one plane (which passes through the midline of the body) to produce roughly equivalent right and left halves that are mirror images (Fig. 29-3c and d).

As bilateral symmetry evolved, a corresponding evolutionary trend led toward **cephalization,** the development of a head where sensory structures are concentrated. In many animal groups, concentrations of nerve cells in the head form a brain, and a nerve cord extends from the brain toward the rear end of the animal. Biologists consider bilateral symmetry and cephalization as adaptations to locomotion. The head end of the animal meets its environment first and is best equipped to capture food or respond to danger.

Some definitions of basic terms and directions will help in locating body structures in bilaterally symmetrical animals. The

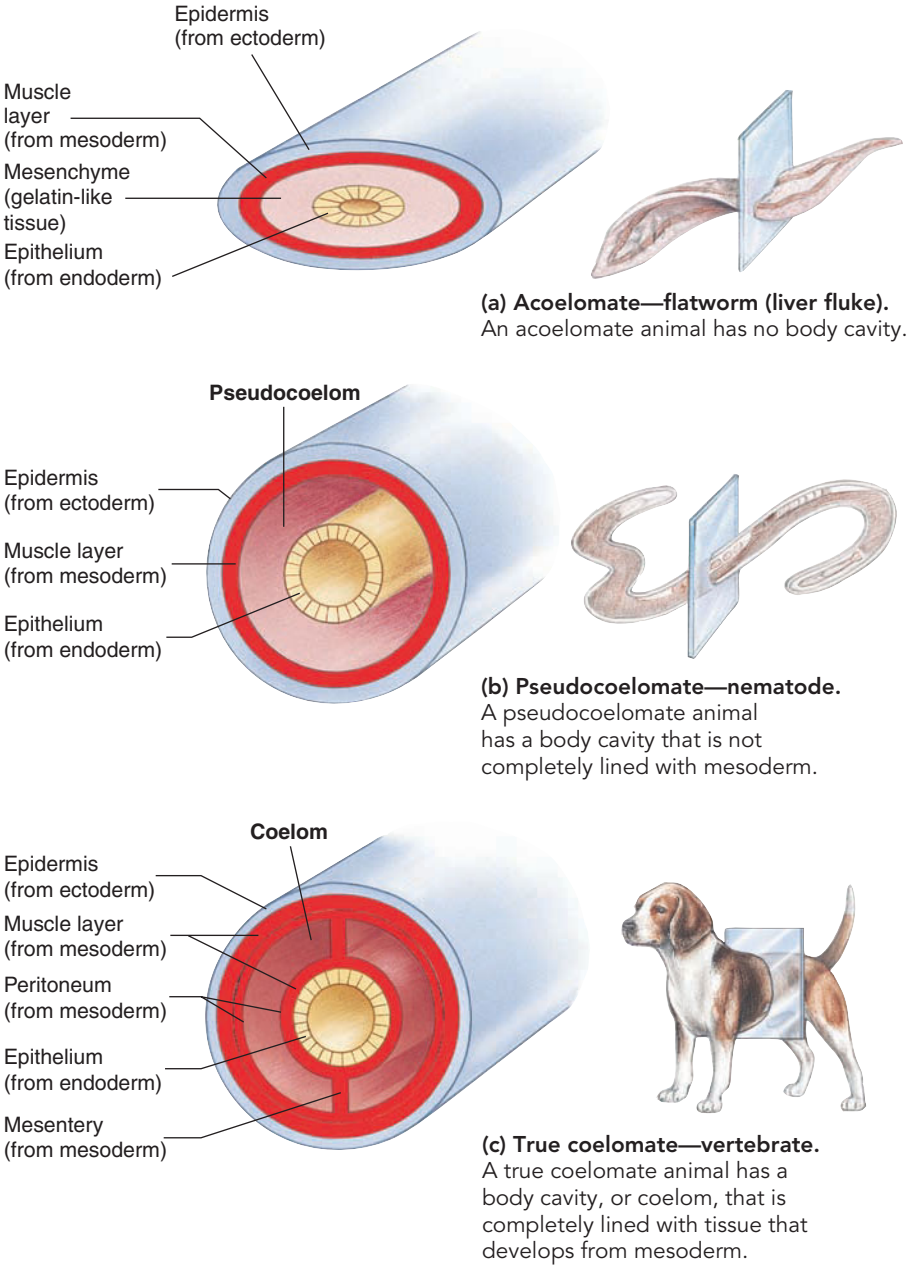

Figure 29-4 ***Animated*** Three basic body plans in triploblastic animals

The germ layer from which each tissue was derived is indicated in parentheses. Ectoderm is shown in blue, mesoderm in red, and endoderm in yellow.

back surface of an animal is its **dorsal** surface; the underside (belly) is its **ventral** surface. **Anterior** (or **cephalic**) means toward the head end of the animal; **posterior,** or **caudal,** means toward the tail end. A structure is said to be **medial** if it is located toward the midline of the body and **lateral** if it is toward one side of the body; for example, the human ear is lateral to the nose. In human anatomy, the term **superior** refers to a structure located above some point of reference, or toward the head end of the body. The term **inferior** is used in human anatomy to mean located below some point of reference, or toward the feet.

A bilaterally symmetrical animal has three axes, each at right angles to the other two: an anterior-posterior axis extending from head to tail, a dorsal-ventral axis extending from back to belly, and a left-right axis extending from side to side. We can distinguish three planes or sections that divide the body into specific parts. A **sagittal plane** divides the body into right and left parts. A sagittal plane passes from anterior to posterior and from dorsal to ventral. A **frontal plane** divides a bilateral body into dorsal and ventral parts. A **transverse section,** or **cross section,** cuts at right angles to the body axis and separates anterior and posterior parts.

Animal body plans are linked to the level of tissue development

Sponges have several types of cells, but they are not organized into **tissues,** groups of closely associated, similar cells that work together to carry out specific functions. In the early development of all animals except sponges, cells form layers, called **germ layers.** The outer germ layer, or **ectoderm,** gives rise to the tissues that form the outer covering of the body and to nervous tissue. The inner layer, or **endoderm,** forms the lining of the digestive tube and other digestive structures. These layers develop into specific types of tissues.

Biologists describe cnidarians and ctenophores as **diploblastic** because they have two tissue layers. Other animals are **triploblastic.** They have a third germ layer, the **mesoderm,** that gives rise to most other body structures, including muscles, skeletal structures, and circulatory system (when present).

Biologists group animals according to type of body cavity

Biologists can classify triploblastic animals based on the presence and type of body cavity, or **coelom** (pronounced "see′-lum"), a fluid-filled space between the body wall and the digestive tube (Fig. 29-4). The flatworms and ribbon worms are triploblastic but have a solid body; that is, they have no body cavity. They are called **acoelomates** (*a-*, "without"; and *coelom,* "cavity").

In most animals, the body cavity is completely lined with mesoderm. Such a body cavity is a *true coelom.* Animals with true coeloms are **coelomates.** The coelom is a space that separates the body wall from the digestive tube, or gut, producing a **tube-**

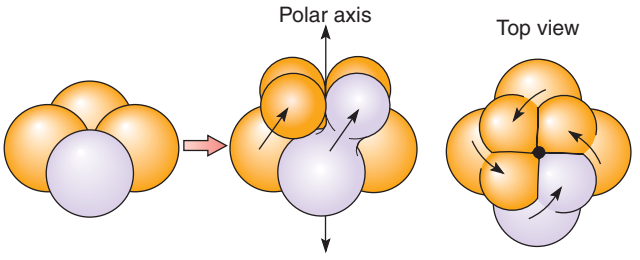
within-a-tube body plan. The body wall, which forms the outer tube, is covered with tissue that develops from ectoderm. Tissue derived from endoderm lines the inner digestive tube, which has an opening at each end: the mouth and the anus.

In some (typically, small) animals, the body cavity is not completely lined with mesoderm; this type of body cavity is called a **pseudocoelom** ("false coelom"). Animals with a pseudocoelom, such as nematodes (roundworms) and rotifers, are **pseudocoelomates,** and biologists formerly classified them as a separate group. Recent evidence indicates that pseudocoelomates are not a monophyletic group and probably evolved through a process of simplification from more than one group of animals with a true coelom.

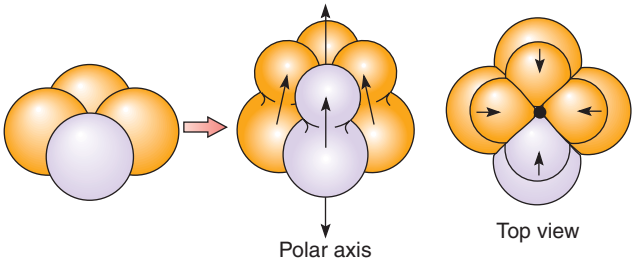
Bilateral animals form two main groups based on differences in development

Basic differences in their pattern of early development distinguish two main evolutionary lines of bilateral animals: Protostomia and Deuterostomia. **Protostomia** includes flatworms, mollusks, annelids, arthropods, and several other phyla. **Deuterostomia** includes the echinoderms (such as sea stars and sea urchins) and chordates (members of the phylum that includes the vertebrates).

One important difference in the development of protostomes and deuterostomes is the pattern of cleavage, the first several cell divisions of the embryo. In many protostomes, the early cell divisions are diagonal to the polar axis (the long axis of the egg), resulting in a somewhat spiral arrangement of cells; any one cell lies between the two cells above or below it (Fig. 29-5a). This pattern of division is known as **spiral cleavage.** In **radial cleavage,** characteristic of the deuterostomes, the early divisions are either parallel or at right angles to the polar axis. The resulting cells lie directly above or below one another (Fig. 29-5b).



(a) Spiral cleavage is characteristic of protostomes. Note the spiral arrangement, with the upper cells centered between the lower cells.



(b) Radial cleavage is characteristic of deuterostomes. The early divisions are either parallel to the polar axis or at right angles to it. The cells are stacked, with the upper cells centered directly above the lower cells.

Figure 29-5 Spiral and radial cleavage

The pattern of cleavage can be appreciated by comparing the positions of the purple cells in **(a)** and **(b).**

In the protostomes, the developmental fate of each embryonic cell is typically fixed very early. For example, if the first four cells of an annelid embryo are separated, each cell develops into only a fixed quarter of the larva; this pattern of cleavage is called **determinate cleavage.** In contrast, deuterostomes typically undergo **indeterminate cleavage.** For example, if the first four cells of a sea star embryo are separated, each cell can form a complete, though small, larva. If a few cells are removed from a blastula undergoing indeterminate cleavage, other cells compensate, and the embryo develops normally. In contrast, if a few cells are removed from the blastula of an embryo undergoing determinate cleavage, some structure, such as a limb, does not develop.

During gastrulation a group of cells moves inward, forming a sac that becomes the embryonic gut. The opening to the outside is called the **blastopore.** In most protostomes, the blastopore develops into the mouth. The word *protostome* comes from Greek words meaning "first" and "the mouth." In deuterostomes the blastopore does not give rise to the mouth but generally develops into the anus. A second opening that forms later in development gives rise to the mouth. The word *deuterostome* derives from words meaning "second" and "the mouth."

Another, though less reliable, difference between protostome and deuterostome development is the manner in which the coelom forms. In most protostomes, the mesoderm splits, and the split widens into a cavity that becomes the coelom (Fig. 29-6). This method of coelom formation is known as **schizocoely.** In deuterostomes, the mesoderm forms as "outpocketings" of the developing gut, a process called **enterocoely.** These outpocketings eventually pinch off and form pouches; the cavity within the pouches becomes the coelom.

Biologists have identified major animal groups based on structure

Biologists have inferred evolutionary relationships among animals, based on the structural variations and pattern of development we have just discussed. Their hypotheses are illustrated in Figure 29-7. Biologists assign sponges to a basal group, **Parazoa** (*para,* "alongside"; and *zoa,* "animals"), based on their asymmetry and their simple body plan. The cells of sponges are loosely associated and do not form true tissues. Other animals have true tissues and are classified as **Eumetazoa** (*eu,* "true"; *meta,* "later"; and *zoa,* "animals"). Thus, biologists divide the animal kingdom into two major animal clades: Parazoa and Eumetazoa. Parazoa is considered a sister group of the Eumetazoa.

The eumetazoan branch of the animal tree splits into the **Radiata,** animals with radial symmetry, and the **Bilateria,** animals with bilateral symmetry. Bilateral animals are characterized by

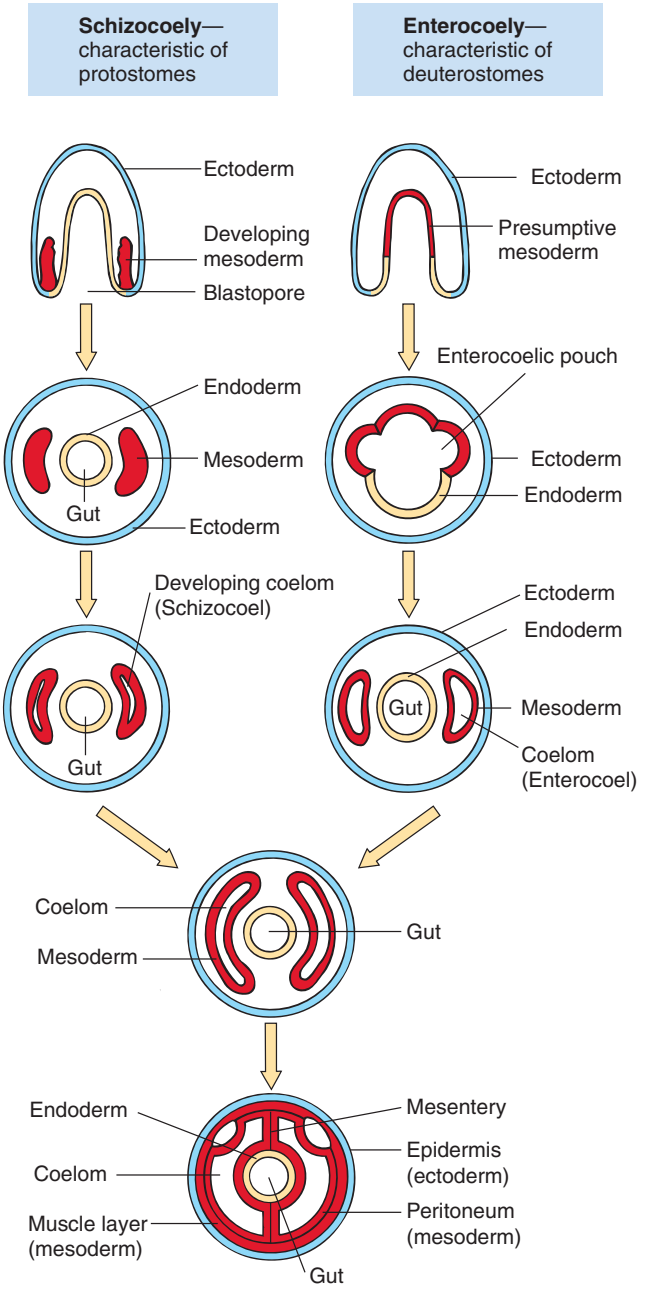


Figure 29-6 Two types of coelom formation

The coelom originates in the embryo from blocks of mesoderm that split off from each side of the embryonic gut. In protostomes, the coelom typically forms by the process of schizocoely, in which the mesoderm (*red*) splits. The split widens, forming a cavity that becomes the coelom. In enterocoely, characteristic of deuterostomes, the mesoderm outpockets from the gut, forming pouches. The cavity within these pouches becomes the coelom. Ectoderm is shown in blue, endoderm in yellow. The diagrams in the top row are longitudinal sections of developing embryos; other diagrams are cross sections.

three distinct tissue layers: ectoderm, endoderm, and mesoderm. Historically, biologists considered acoelomates to be the simplest bilateral animals and hypothesized that the pseudocoelomates evolved next, and finally the coelomates. The coelomate animals split into two groups: protostomes and deuterostomes. As we will discuss, some of these hypotheses have been challenged by molecular data.

Molecular data contribute to our understanding of animal relationships

Molecular systematists are using molecular tools to clarify the evolutionary relationships among animal groups. So far, these systematists have validated much of the phylogeny that biologists have determined based on structure and development. However, molecular data do challenge some traditional conclusions. For example, *when* various animal phyla diverged has been the topic of much debate.

Molecular systematics has confirmed that animal body plans usually evolved from simple to complex. However, there are important exceptions. For example, biologists have traditionally viewed flatworms and ribbon worms as simple groups that appeared early in animal evolution, based on their lack of a body cavity. However, because analysis of molecular data suggests that these worms evolved from more complex animals and then became structurally simpler over time, systematists have repositioned these groups.

As explained in the last section, biologists classify bilateral animals into protostome and deuterostome groups. Molecular data show that the protostomes split into two major clades: **Lophotrochozoa** (pronounced "loh-foh-troh-koh-zoh′-ah") and **Ecdysozoa** (pronounced "ek-die-so-zoh′-ah") (Fig. 29-8 and Table 29-1). The name *Lophotrochozoa* is derived from the names of two major animal groups assigned to this clade: the lophophorate phyla and the Trochozoa. The lophophorate phyla are characterized by a lophophore, a ciliated ring of tentacles surrounding the mouth. The *trochozoa* part of the name refers to the trochophore larva, a type of larva characteristic of two major Lophotrochozoa phyla—the mollusks and annelids. The name *Ecdysozoa* is based on one of the characteristics of this group: the animals in this group molt (a process called *ecdysis*).

The Lophotrochozoa include the flatworms, ribbon worms, mollusks, annelids, the lophophorate phyla, and rotifers. The Ecdysozoa include the nematodes and arthropods. Note that this phylogeny assigns bilateral animals to three major clades: Lophotrochozoa, Ecdysozoa, and Deuterostomia.

Over millions of years, evolutionary forces acting on the basic animal body plan have produced changes resulting in a remarkable diversity of body forms. One very important innovation has been **segmentation,** a body plan in which certain structures are repeated, producing a series of body compartments. Each compartment can be regulated somewhat independently of the others, which means that various parts of the body can become specialized to perform various functions. Perhaps the most obvious example of segmentation can be found in the earthworm. However, as will be discussed in the following chapters, arthropods and vertebrates also have segmented body plans. Thus, segmented animals are found within each of the three major clades of bilateral animals. Molecular data suggest that segmentation evolved independently three times. This view is reflected in the cladogram in Figure 29-8 in which annelids and arthropods are

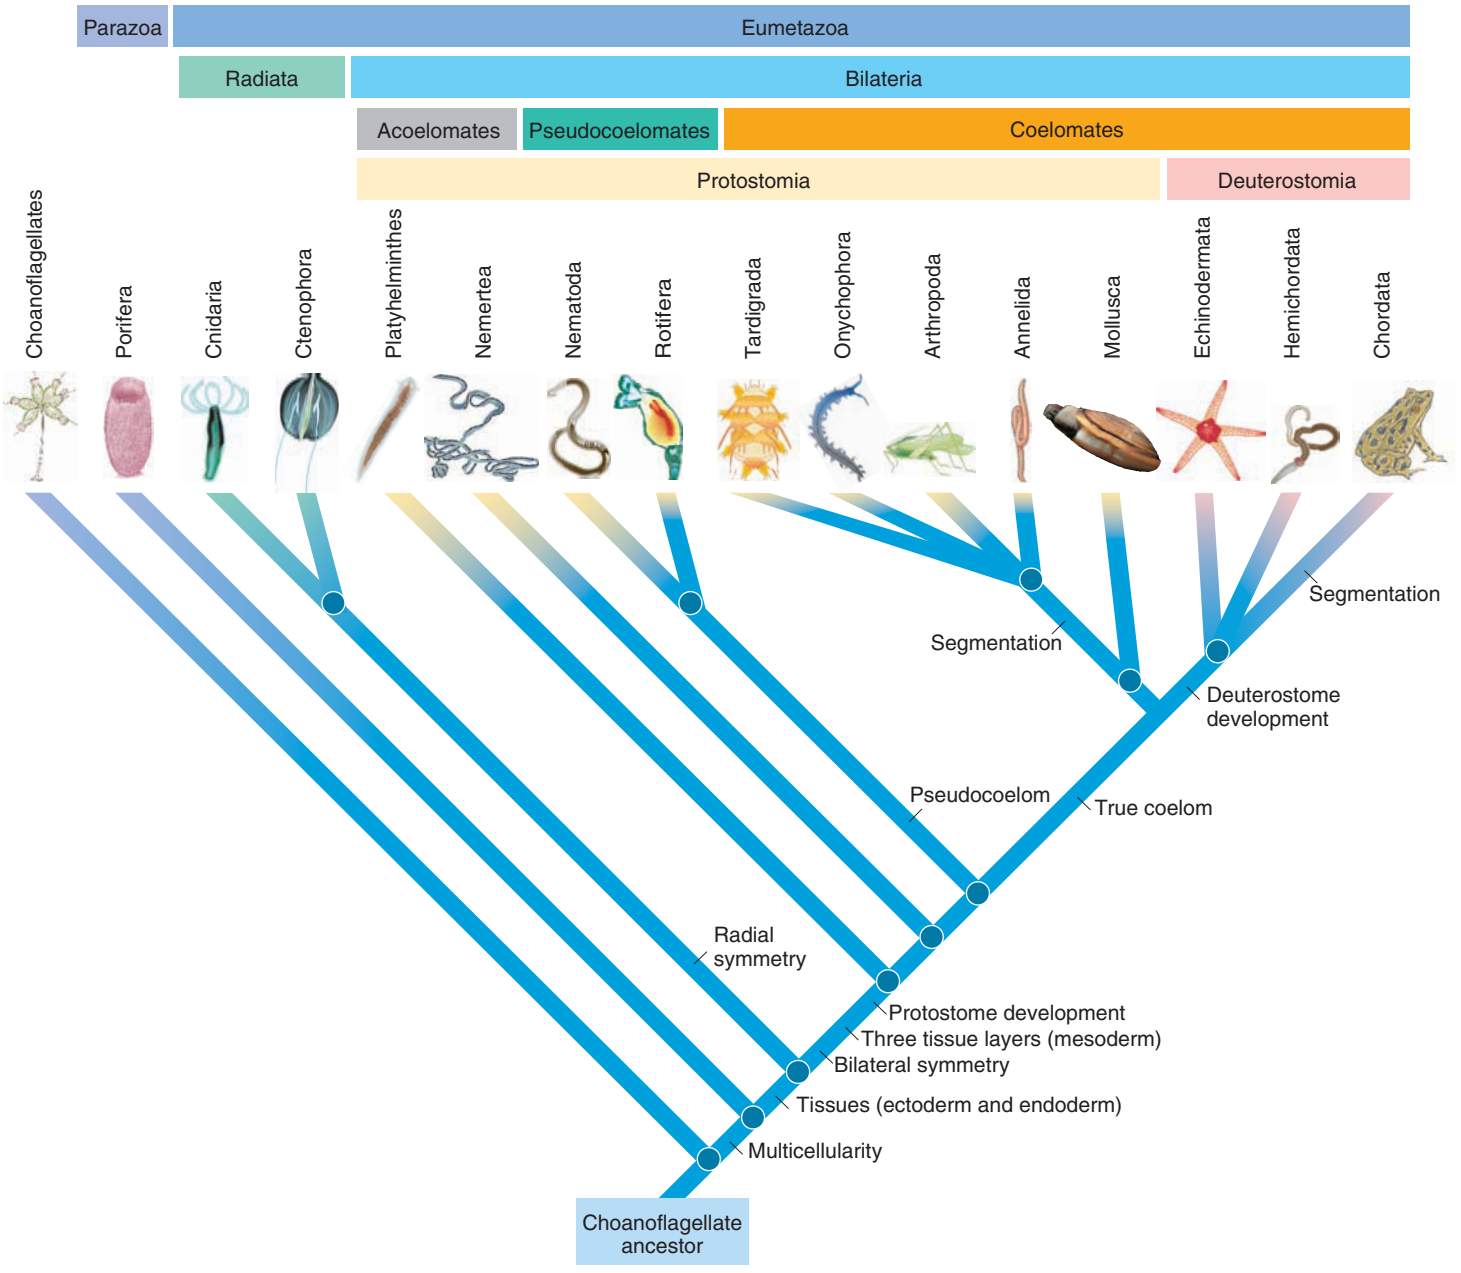

Figure 29-7 Evolutionary relationships of major animal phyla, based on structure

Note that bilateral animals are grouped by several criteria, including type of body cavity: acoelomate, pseudocoelomate, or coelomate. Using the criteria indicated by the colored bars above the cladogram, identify which animal phyla belong in each group. Labels indicate when certain key traits originated.

shown in different clades. Contrast this view with the traditional approach depicted in Figure 29-7. Annelids and arthropods are shown as closely related; segmentation evolved twice. In each independent origin of segmentation, apparently natural selection acted on many of the same genes (for example, *Hox* genes; see Fig. 17-13).

Now that we have briefly discussed animal body plans and some of the criteria for determining phylogenetic relationships, we survey representative animal phyla. In the remainder of this chapter, we discuss two groups that appeared early in animal evolution: the Parazoa and the Radiata. The cladogram shown in Figure 29-8 depicts one current view of the relationships among the major phyla of animals.

Review

- How are animals classified based on type of symmetry?
- What are some differences between protostomes and deuterostomes?
- What are the three main clades of bilateral animals, and how do they differ from one another?

TABLE 29 -1

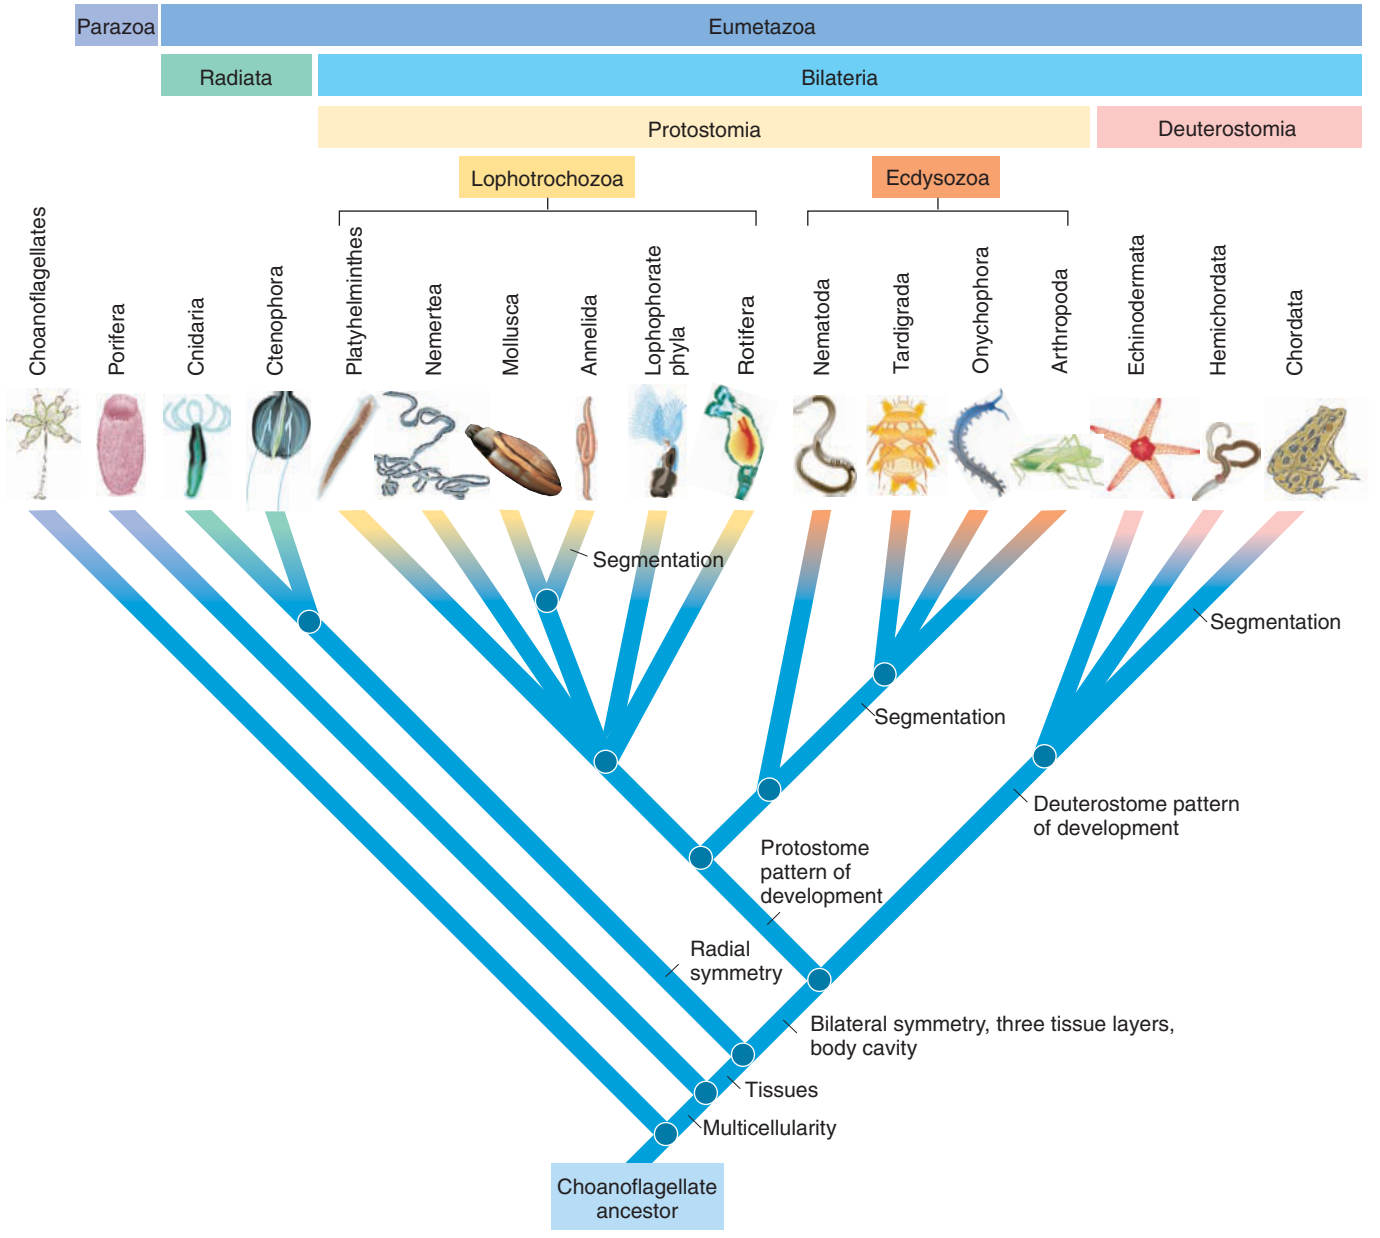
Overview of the Animal Kingdom

Major Groups and Phyla	Body Plan	Key Characteristics
Parazoa		
Porifera (sponges)	Asymmetrical; cells loosely arranged; body is sac with pores, central cavity, and osculum	Choanocytes (collar cells); aquatic, mainly marine
Radiata		
Cnidaria (hydras, jellyfish, corals)	Radial symmetry; diploblastic; gastrovascular cavity with one opening	Tentacles with cnidocytes (stinging cells) that discharge nematocysts; two body forms: polyp and medusa; some form colonies; mainly marine
Ctenophora (comb jellies)	Biradial symmetry; diploblastic; gastrovascular cavity with mouth and anal pores	Eight rows of cilia that resemble combs; tentacles with adhesive glue cells; marine predators
Protostomes: Lophotrochozoan Branch		
Platyhelminthes (flatworms: planarians, tapeworms, flukes)	Bilateral symmetry; triploblastic; simple organ systems; gastrovascular cavity with one opening	No body cavity; some cephalization; some are free-living carnivores; many are parasites
Nemertea (proboscis worms; also known as ribbon worms)	Bilateral symmetry; triploblastic; organ systems; complete digestive tube*	Proboscis (long, muscular tube that can be everted to capture prey); only coelomate space is rhynchocoel surrounding proboscis; mainly marine carnivores
Mollusca (clams, snails, squids)	Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Soft body usually covered by dorsal shell; flat, muscular foot; mantle covers visceral mass; most have a radula (belt of teeth)
Annelida (some marine worms, earthworms, leeches)	Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Segmented body; most have setae, bristles that provide traction during crawling
Lophophorates (brachiopods, phoronids, bryozoans)	Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Lophophore (ciliated ring of tentacles) surrounds mouth, captures suspended particles in water; mainly sessile, marine animals
Rotifera (wheel animals)	Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Crown of cilia at anterior end; cell number constant; microscopic, aquatic animals
Protostomes: Ecdysozoan Branch		
Nematoda (roundworms, e.g., *Ascaris*, hookworms, trichina worms)	Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Cylindrical, threadlike body; pseudocoelom; widely distributed in soil and aquatic sediments; important as decomposers; many are predators; some are parasites
Arthropoda (centipedes, spiders, crabs, lobsters, insects)	Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Segmented body; exoskeleton; paired, jointed appendages; insects and many crustaceans have compound eyes; insects have tracheal tubes for air exchange
Deuterostomes		
Echinodermata (sea stars, sea urchins; sand dollars)	Larva bilateral, ciliated; adult pentaradial; triploblastic; organ systems; complete digestive tube	Endoskeleton with spines; water vascular system functions in locomotion, feeding, and gas exchange; tube feet; marine
Hemichordata (acorn worms)	Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Ring of cilia surrounds mouth; three-part body: proboscis, collar, and trunk; wormlike marine animals
Chordata (tunicates, lancelets, vertebrates)	Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Notochord; dorsal, tubular nerve cord; pharyngeal slits during some time in life cycle; postanal tail; segmented body

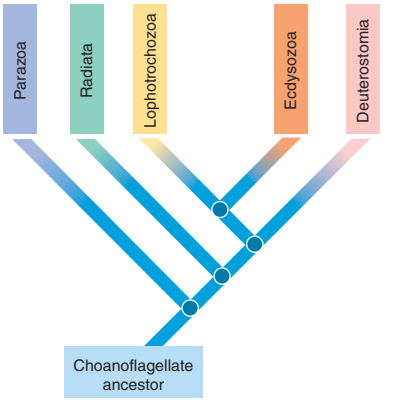
*A complete digestive tube has a mouth for food intake and an opening (anus) for elimination of wastes.

Key Point

Based on molecular data, three major clades of bilateral animals are shown: Lophotrochozoa, Ecdysozoa, and Deuterostomia.



(a) Using the criteria indicated by the colored bars above the cladogram, identify which animal phyla belong in each group.



(b) The five main animal clades based on molecular data.

Figure 29-8 Evolutionary relationships of major animal phyla based on molecular data

This cladogram is based on comparisons of DNA sequences of several genes. Any cladogram of animal relationships is a work in progress. As new data are considered, our understanding of relationships among animal groups changes. Labels indicate when certain key traits originated. Note that the simplified cladogram shown in **(b)** is modified and used as an icon for many figures in Chapters 29 and 30.

THE PARAZOA: SPONGES

Learning Objective

6 Identify distinguishing characteristics of phylum Porifera.

Sponges, the only members of the Parazoa, diverged early from the lineage leading to other animals. The earliest known animal fossils are sponges found in China that are about 600 million years old. Because they have been evolving independently for so long, they are very different from other animals.

Collar cells characterize sponges

Biologists have identified about 10,000 species of sponges and assigned them to phylum **Porifera.** The name *Porifera,* meaning "to have pores," aptly describes the sponges, whose bodies are perforated by tiny holes. Sponges are aquatic, mainly marine animals that are most abundant in warm waters. They range in size from 1 to 200 cm (0.4 to 79 in) in height. Many sponges are asymmetrical, but they vary in shape from flat, encrusting growths to balls, cups, fans, or vases. Living sponges may be brightly colored—green, orange, red, yellow, blue, or purple—or they may be white or drab (Fig. 29-9). Some species are inhabited by symbiotic bacteria or algae that give them color.

Although they are multicellular and can be large, sponges function much like choanoflagellates—colonial, unicellular protists. Recall that according to a current hypothesis, animals (including sponges) and choanoflagellates share a common choanoflagellate ancestor. Choanoflagellates are characterized by a single flagellum surrounded by a collar of microvilli (see Fig. 25-25).

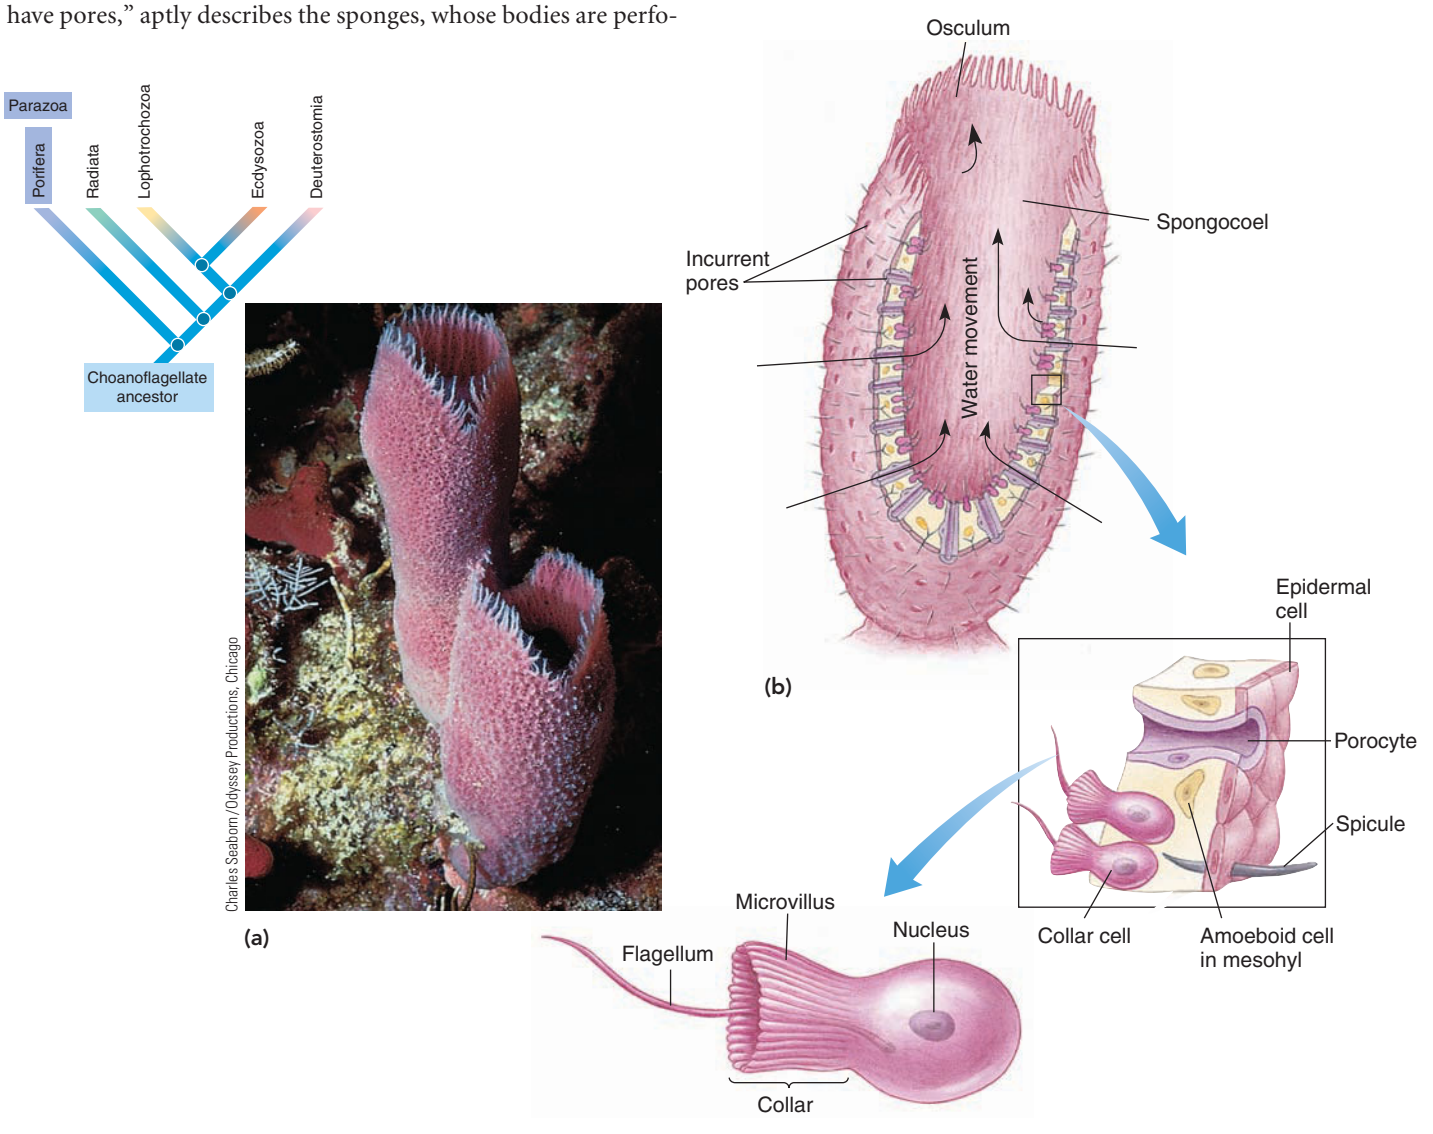


Figure 29-9 ***Animated*** Sponge structure

(a) Tube sponges (*Spinosella plicifera*) from the Caribbean, attached to the coral reef substrate. **(b)** Diagram of a simple sponge cut to expose its organization. Collar cells (choanocytes) beat their flagella, producing a current of water that enters through the pores. The water passes through the spongocoel and exits through the osculum. Food particles in the stream of water are trapped by the collars.

Sponges have **collar cells,** or **choanocytes,** flagellate cells that are strikingly similar to the choanoflagellates.

Sponge larvae have flagella and can swim about. Adult sponges attach to some solid object and have long been described as sessile. However, biologists have observed adults of several species moving slowly (about 4 mm per day), perhaps by the cumulative movement of cells along the sponge's lower surface.

In a simple sponge, water enters through hundreds of tiny pores (*ostia*); passes into the central cavity, or **spongocoel** (not a digestive cavity); and flows out through the sponge's open end, the **osculum.** In most types of sponges, the body wall is extensively folded, and complex systems of canals provide increased surface area for food capture. Although sponges are multicellular, their cells are loosely associated and do not form true tissues. However, a division of labor exists among the several types of cells that make up the sponge, with certain cells specializing in nutrition, support, contraction, or reproduction. Epidermal cells form the outer layer of the sponge and line the canals. Specialized tubelike cells, called *porocytes,* form the pores of a simple sponge. These cells regulate the diameter of the pores by contracting. Many sponge cells are extremely versatile and can change form and function.

Collar cells make up the inner layer of certain sponges. Each cell is equipped with a tiny collar surrounding the base of the flagellum. The collar is an extension of the plasma membrane and consists of microvilli. Collar cells create the water current that brings food and oxygen to the cells and carries away carbon dioxide and other wastes. Collar cells also trap and phagocytose food particles. Together, the collar cells of some sponges can pump a volume of water equal to the volume of the sponge each minute!

Between the outer and inner cell layers of the sponge body is a gelatin-like layer, the *mesohyl,* supported by slender skeletal spikes, or **spicules.** Amoeboid cells, which wander about in the mesohyl, secrete the spicules, which consist of calcium carbonate, silica, or a fibrous protein material known as *spongin.* Other amoeboid cells in the mesohyl are important in digestion and food transport.

Sponges are *suspension feeders,* adapted for trapping and eating whatever food the water brings to them. As water circulates through the body, food is trapped along the sticky collars of the choanocytes. Food particles are either digested within the collar cell or transferred to an amoeboid cell for digestion. The amoeboid cell transports nutrients to epidermal cells. Undigested food passes out through the osculum and is simply eliminated into the water.

Gas exchange and excretion of wastes depend on diffusion into and out of individual cells. Although cells of the sponge can react to stimuli, sponges do not have specialized nerve cells and so cannot react as a whole. Behavior appears limited to basic metabolic necessities such as capturing food and regulating the flow of water through the body.

Sponges reproduce both asexually and sexually. In asexual reproduction, a small fragment or bud may break free from the parent sponge and give rise to a new sponge. Such fragments may attach to the parent sponge and thus form a colony. Most sponges are **hermaphrodites,** meaning the same individual can produce both eggs and sperm. Some of the amoeboid cells develop into sperm cells; others, into egg cells. However, hermaphroditic sponges usually produce eggs and sperm at different times, and they cross-fertilize with other sponges. They release mature sperm into the water, which are taken in by other sponges of the same species.

Fertilization and early development take place within the jellylike mesohyl. Zygotes develop into flagellate larvae that leave the parent along with the stream of outflowing water. After swimming for a while, a larva finds a solid object, attaches to it, and settles down to a sessile life.

Sponges have a remarkable ability to repair themselves when injured and to regenerate lost parts. When the cells of a sponge are separated experimentally, they recognize one another and their place in the whole and aggregate to re-form a complete sponge.

Review

- Why are choanocytes significant? What is their function in sponges?
- In what ways do the cells of sponges specialize?

THE RADIATA: ANIMALS WITH RADIAL SYMMETRY AND TWO CELL LAYERS

Learning Objectives

7 Identify distinguishing characteristics of phylum Cnidaria, describe four classes of this phylum, and give examples of animals that belong to each class.

8 Identify distinguishing characteristics of phylum Ctenophora.

Recall that all animals except the sponges are classified as Eumetazoa. The Radiata, animals with radial symmetry and two tissue layers, may have been the first eumetazoans to evolve. Biologists currently classify two phyla as Radiata: Cnidaria and Ctenophora. However, the relationships of these groups to each other, and the relationship of the Radiata to other animals, is still a matter of debate.

Cnidarians have unique stinging cells

Most of the 10,000 or so species of phylum **Cnidaria** (pronounced "ni-dah′-ree-ah") are marine. The radially symmetrical cnidarian body is organized as a hollow sac with the mouth and surrounding tentacles located at one end. We consider four classes (▮ Table 29-2). Class **Hydrozoa** includes hydras and *hydroids,* such as *Obelia* and the Portuguese man-of-war; class **Scyphozoa** is made up of jellyfish; class **Cubozoa** includes the "box jellyfish"; and class **Anthozoa** includes sea anemones and corals. Some cnidarians live a solitary existence, whereas many others, such as corals, form colonies.

TABLE 29-2

Major Classes of Phylum Cnidaria

Class and Representative Animals	Characteristics
Hydrozoa *Hydra, Obelia,* Portuguese man-of-war	Mainly marine, but some freshwater species; alternation of polyp and medusa stages in most species (polyp form only in *Hydra*); some form colonies
Scyphozoa Jellyfish	Mainly marine; typically inhabit coastal water, free-swimming medusa most prominent form; polyp stage often reduced
Cubozoa "Box jellyfish"	Inhabit tropical and semitropical waters; have polyp stage, but medusa form most prominent; square shape when viewed from above; actively hunt prey; complex eyes that form blurred images
Anthozoa Sea anemones, corals, sea fans	Marine; solitary or colonial polyps; in most no medusa stage; gastrovascular cavity divided by partitions into chambers, increasing area for digestion; sessile

Cnidarians have two body shapes: the polyp and the medusa (Fig. 29-10). The **polyp** form, represented by *Hydra,* typically has a dorsal mouth surrounded by tentacles. In the **medusa** (pl., *medusae*), or jellyfish form, the mouth is located in the lower concave, or *oral,* surface; the convex upper surface is the *aboral* surface. Some cnidarians have the polyp shape during one stage of their life cycle and the medusa form during another stage. The Portuguese man-of-war and some other cnidarians consist of colonies of many individuals, some of which are polyps and others medusae.

Cnidarians get their name from specialized cells, called **cnidocytes** (from a Greek word meaning "sea nettles"), that contain stinging organelles. Cnidocytes are located mainly in the epidermis, especially on the tentacles. The cnidocytes contain stinging "thread capsules," or **nematocysts** (Fig. 29-11). When stimulated, a nematocyst releases a coiled, hollow thread. Some types of nematocyst threads are sticky. Others are long and coil around prey. A third type bears barbs or spines that can inject a protein toxin that paralyzes prey animals, such as small crustaceans. Each cnidocyte has a small, projecting trigger (*cnidocil*) on its outer surface. Stimuli such as touch or chemicals dissolved in the water stimulate the nematocyst to fire its thread.

Cnidarians use their tentacles to capture prey and push it into the mouth. The mouth leads into the **gastrovascular cavity,** where digestion takes place. The mouth is the only opening into the gastrovascular cavity and so must serve for both ingestion of food and expulsion of wastes. Gas exchange and excretion occur by diffusion. The body wall is thin enough that no cell is far from the surface.

More highly organized than sponges, cnidarians are diploblastic; that is, they have two definite tissue layers. The ectoderm gives rise to the outer **epidermis,** a protective layer covering the body. The endoderm gives rise to the inner **gastrodermis,** which lines the gastrovascular cavity and functions in digestion. These thin layers are separated by a gelatinous, mainly acellular **mesoglea.**

Cnidarians have nerve cells that form **nerve nets** connecting sensory cells in the body wall to contractile and gland cells. Sense organs—for example, photoreceptors that detect light—are positioned around the edge of the body. An impulse set up by one sensory cell passes in all directions more or less equally. Nerve cells are not organized to form a brain or nerve cord.

Both the epidermis and gastrodermis have cells specialized to contract (however, they are not true muscle cells). Contractile fibers in the epidermal cells are arranged lengthwise, and those in the gastrodermis are arranged in a circular pattern. These two sets of contractile cells act on the water-filled gastrovascular cavity, which forms a **hydrostatic skeleton.** This skeleton supports the body and allows movement. By contracting one set of contractile cells or the other, the hydra can shorten, lengthen, or bend its body (see Fig. 39-2).

Class Hydrozoa includes solitary and colonial forms

Although not really typical, the solitary *Hydra* is the cnidarian that beginning biology students most often study. To the naked eye, *Hydra* looks like a bit of frayed string. This tiny animal is found in freshwater ponds (Fig. 29-12). Because it has a remarkable ability to regenerate, biologists named *Hydra* after the multiheaded monster of Greek mythology that could grow two new heads for each head cut off. When *Hydra* is cut into several pieces, each piece can regenerate all the missing parts and become a whole animal.

Hydra lives in fresh water and typically attaches to a rock, aquatic plant, or detritus by a disc of cells at its base. Hydras reproduce asexually by budding during periods when environmental conditions are optimal. However, they differentiate as males and females and reproduce sexually in the fall or when pond water becomes stagnant. The zygote may become covered with a shell that protects it through the winter or until conditions become more favorable.

Many hydrozoans form colonies consisting of hundreds or thousands of individuals. A colony begins with a single polyp that reproduces asexually by budding. However, instead of separating from the parent, the bud remains attached and eventually forms additional buds. Several types of individuals may arise in the same colony, some specialized for feeding, some for reproduction, and others for defense.

Some marine cnidarians are remarkable for their alternation of sexual and asexual stages. Their life cycle differs from the alternation of generations in plants in that both sexual and asexual forms are diploid; only sperm and eggs are haploid. The life cycle of the colonial marine hydrozoan *Obelia* illustrates alternation of sexual and asexual stages (Fig. 29-13).

Class Scyphozoa includes the "true" jellyfish

Among the jellyfish, the medusa is the dominant body form. Scyphozoan medusae are generally larger than hydrozoan medusae, and they have a thick, viscous mesoglea that gives firmness to the body. In scyphozoans, the polyp stage is small and inconspicuous or may even be absent. The largest jellyfish, *Cyanea,* may be more than 2 m (6.5 ft) in diameter and have tentacles 30 m (98 ft) long. These orange and blue "monsters," among the largest invertebrates, are dangerous to swimmers in the North Atlantic Ocean.

Class Cubozoa includes the "box jellyfish"

When viewed from above, cubozoans have a square shape. They have four tentacles, or groups of tentacles. These fast-swimming jellyfish have complex eyes that form blurred images, and they actively hunt for prey. Found in waters off the northern Australian coast, the sea wasp (*Chironex fleckeri*) has long tentacles that can extend more than 3 m (10 ft). The sea wasp produces a toxin that can cause respiratory failure and cardiac arrest in humans. Fatalities are mainly associated with severe stings caused by contact with tentacles over a large area of the body.

David M. Phillips/Visuals Unlimited

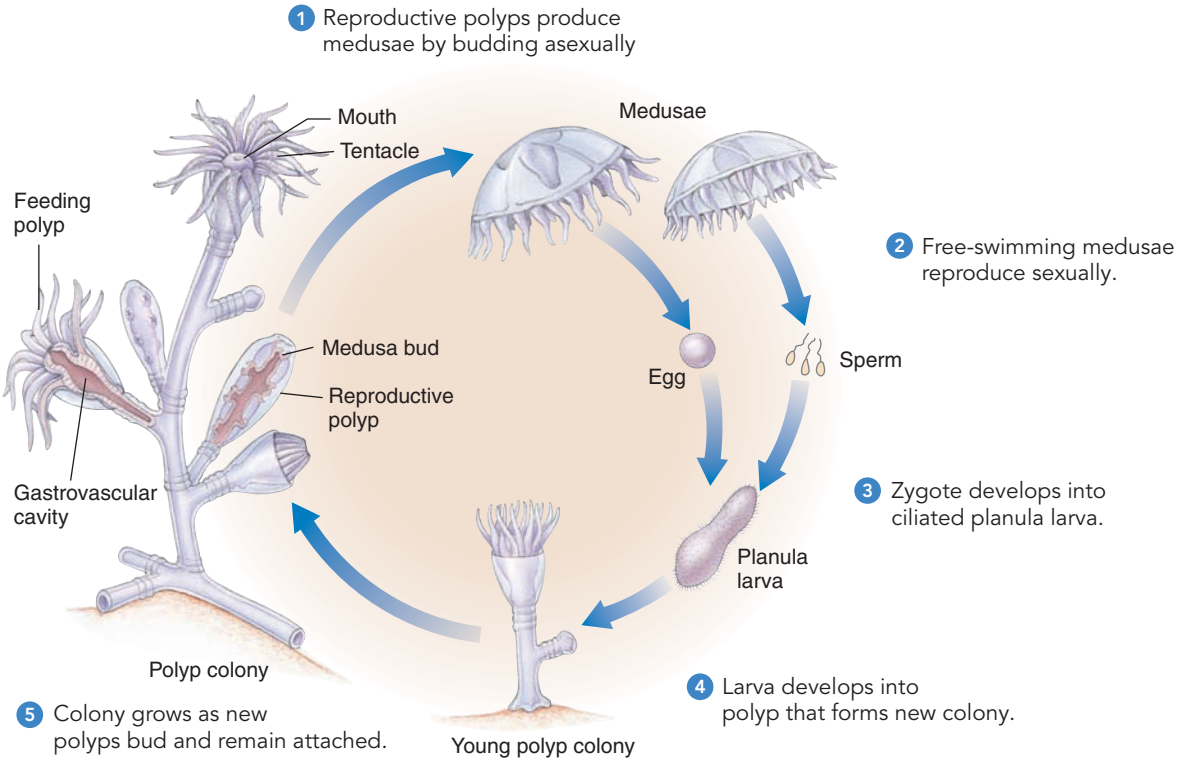
(a) LM of *Obelia*. Some polyps have tentacles and are specialized for feeding, whereas others are specialized for reproduction.

Class Anthozoa includes only polyps

Sea anemones and corals, members of class Anthozoa, have either individual or colonial polyps but no free-swimming medusa stage. The polyp produces eggs and sperm, and the fertilized egg develops into a small, ciliated larva called a **planula.** This larval form may swim to a new location before attaching to develop into a polyp.

Anthozoans differ from hydrozoans in that a series of vertical partitions partially divides the gastrovascular cavity into connected chambers. The partitions increase the surface area for digestion, enabling an anemone to digest an animal as large as a crab. Although corals can capture prey, many tropical species depend for nutrition on photosynthetic algae (*zooxanthellae*) that live within cells lining the coral's digestive cavity (see Chapter 25 and Fig. 53-11). The relationship between coral and zooxanthellae is symbiotic and mutually beneficial. The algae provide the coral with oxygen and with carbon and nitrogen compounds. In exchange, the coral supplies the algae with waste products such as ammonia, from which the algae make nitrogenous compounds for both partners.

In warm, shallow seas, much of the bottom is covered with coral or anemones, most of them brightly colored. Coral reefs consist of colonies of millions of corals and of certain algae (mainly coralline red algae). Living colonies occur only in the uppermost regions of such reefs, adding their own skeletons to the forming rock. Coral reefs are among the most productive of all ecosystems, rivaling tropical rain forests in species diversity (see



(b) Life cycle of *Obelia*.

Figure 29-13 ***Animated*** *Obelia*, a marine colonial hydrozoan

Figure 29-14 Bleached staghorn coral

This staghorn coral (*Acropora*) was photographed off Heron Island on the Great Barrier Reef off the coast of Australia.

Fig. 55-22). A single reef can serve as home for more than 3000 species of fishes and other marine organisms, and an estimated one fourth of all marine species depend on coral reefs.

During the past several years many coral reefs, especially those in coastal waters, have suffered serious damage from human activities. These include overfishing, mining reefs for building materials, polluting coastal waters with industrial chemicals, and smothering coral with the silt washed downstream from clear-cut forests. **Coral bleaching** is the stress-induced loss of the colorful symbiotic algae that inhabit coral cells (Fig. 29-14). Without their algae, coral become malnourished and die. Environmental factors suspected to contribute to coral bleaching include unusually low or high (associated with global warming) temperatures, pollution, changes in salinity, disease, and high doses of ultraviolet radiation (associated with the destruction of the ozone layer).

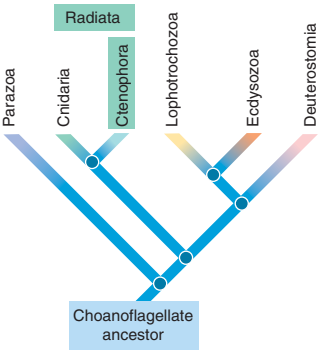
Comb jellies have adhesive glue cells that trap prey

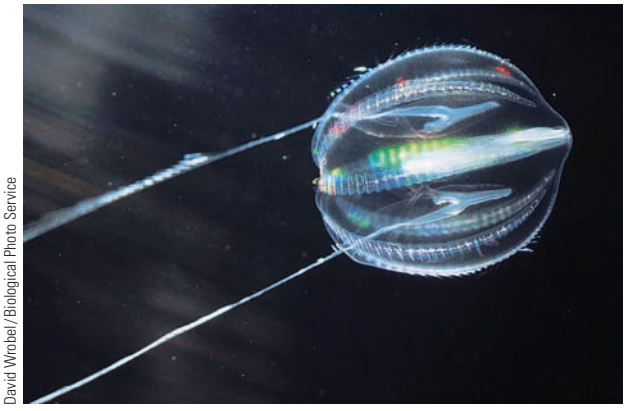
The approximately 100 species of phylum **Ctenophora,** the comb jellies, are fragile, luminescent marine animals. Some species are as small as a pea, whereas others are larger than a tomato. The outer surface of a ctenophore bears eight rows of cilia that resemble combs (Fig. 29-15). The coordinated beating of the cilia in these combs moves the animal through the water. A sense organ functions in balance and helps the animal orient itself. Some ctenophores have two tentacles. They do not have the stinging nematocysts characteristic of the cnidarians. However, their tentacles are equipped with adhesive glue cells. When prey comes in contact with the tentacle, the glue cells burst open, releasing sticky threads that trap the prey.

Ctenophores are biradially symmetrical, meaning you could obtain equal halves by cutting through the body axis in two different ways. Because ctenophores have radial symmetry and feeding tentacles, their body plan is somewhat similar to that of a cnidarian medusa. Ctenophores are also like cnidarians in that they consist of two cell layers separated by a thick, jellylike mesoglea. Because of these similarities, biologists classify ctenophores near the cnidarians. However, their development is different, and unlike cnidarians, their digestive system has a mouth for food intake at one end and two anal pores for the egestion of water and wastes at the other end. The similarities between ctenophores and cnidarians may be a result of convergent evolution from living in a similar environment, the ocean. Where, then, do the ctenophores belong on our cladogram (see Fig. 29-8)? Systematists will decide as they gather new data.

Review

- In what ways do cnidarians differ from sponges?
- Sketch the major events of the life cycle of *Obelia.*
- How is a ctenophore like a cnidarian? In what ways is it different?





David Wrobel/Biological Photo Service

Figure 29-15 Ctenophore (comb jelly)

Ctenophores are free-swimming, bioluminescent hermaphrodites capable of self-fertilization. The sea gooseberry (*Pleurobrachia*) has two long tentacles with adhesive cells used to capture prey.

SUMMARY WITH KEY TERMS

Learning Objectives

1 Describe several characters common to most animals (page 620).

- Members of **kingdom Animalia** are eukaryotic, multicellular, heterotrophic organisms with cells specialized to perform specific functions.
- Animals have diverse body plans. The **body plan** is the basic structure and functional design of the body.
- Most animals are capable of locomotion at some time during their life cycle, can respond adaptively to external stimuli, and can reproduce sexually.
- In sexual reproduction, sperm and egg unite to form a **zygote.** The zygote undergoes **cleavage,** a series of cell divisions that produce a hollow ball of cells called a **blastula.** The blastula undergoes **gastrulation,** forming embryonic tissues.

ThomsonNOW™ **Explore the characteristics of animals by clicking on the figures in ThomsonNOW.**

2 Compare the advantages and disadvantages of life in the ocean, in fresh water, and on land (page 620).

- Marine environments have relatively stable temperatures, provide buoyancy, and provide readily available food. Fluid and salt balance are more easily maintained than in fresh water. Currents and other water movements are a disadvantage.
- Fresh water offers a less constant environment and less food. Because fresh water is hypotonic to tissue fluid, animals must osmoregulate.
- Terrestrial animals must have adaptations that protect them from drying out and from temperature changes. They also require adaptations to protect their gametes and embryos.

3 Use current hypotheses to trace the early evolution of animals (page 621).

- Biologists hypothesize, based on molecular data, that most animal clades actually diverged over a long period during the Proterozoic eon.
- During the **Cambrian Radiation** new animal body plans rapidly evolved among clades already existing. Fossils of these animals are first found in Cambrian fossil sites.
- The *Hox* gene group controls early development in animal groups. Many of the *Hox* genes had evolved by the beginning of the Cambrian period, and mutations in these genes could have resulted in rapid changes in animal body plans.

4 Describe how biologists use structural characters (including variations in body symmetry, number of tissue layers, and type of body cavity) and patterns of early development to infer relationships among animal phyla (page 622).

- Biologists hypothesize that cnidarians and ctenophores are closely related because they share **radial symmetry;** most other animals exhibit **bilateral symmetry,** at least in their larval stages. **Cephalization,** the development of a head, evolved along with bilateral symmetry.
- Biologists have also inferred relationships based on level of tissue development and type of body cavity. Embryonic tissues, called **germ layers,** include the outer layer, **ectoderm,** which gives rise to the body covering and the nervous system; the inner layer, **endoderm,** which lines the gut and other digestive organs; and a middle layer, **mesoderm,** which gives rise to most other body structures.
- Bilateral animals have traditionally been classified as **acoelomate** (no body cavity); **pseudocoelomate** (body cavity not completely lined with mesoderm); or **coelomate,** an animal with a true **coelom** (a body cavity completely lined with mesoderm).
- Two major evolutionary branches of bilateral animals are **Protostomia** (mollusks, annelids, and arthropods) and **Deuterostomia** (echinoderms and chordates). In protostomes the **blastopore,** the opening from the embryonic gut to the outside, develops into the mouth; in deuterostomes the blastopore typically becomes the anus.
- Protostomes undergo **spiral cleavage,** in which early cell divisions are diagonal to the polar axis. Deuterostomes undergo **radial cleavage,** in which the early cell divisions are either parallel or at right angles to the polar axis, so the cells lie directly above or below one another.
- Protostomes undergo **determinate cleavage,** in which the fate of each embryonic cell is fixed very early. Deuterostomes undergo **indeterminate cleavage,** in which the fate of each cell in early development is more flexible.

5 Describe three major contributions to animal phylogeny made by molecular systematics. Include the identification of three major clades of bilateral animals (page 622).

- Molecular systematics has confirmed much of animal phylogeny based on structural characters, including the axiom that animal body plans usually evolved from simple to complex.
- Molecular systematics has provided evidence for exceptions to the "simple-to-complex" rule. For example, molecular data indicate that flatworms and ribbon worms evolved from more complex animals and became simpler over time. Molecular data further suggest that pseudocoelomate animals do not form a natural group and probably evolved from coelomate ancestors.
- Many biologists now subdivide the protostomes into two clades based on molecular data: **Lophotrochozoa** and **Ecdysozoa.** The Lophotrochozoa include the flatworms, ribbon worms, mollusks, annelids, the lophophorate phyla (groups that have a ciliated ring of tentacles surrounding the mouth), and rotifers. The Ecdysozoa, animals that molt, include the nematodes and arthropods. Thus, the three major clades of bilateral animals are Lophotrochozoa, Ecdysozoa, and Deuterostomia.

6 Identify distinguishing characteristics of phylum Porifera (page 630).

- Phylum **Porifera** consists of the sponges, animals characterized by flagellate **collar cells (choanocytes).** Sponges are the only members of the **Parazoa,** the sister group of the Eumetazoa.
- The sponge body is a sac with tiny openings through which water enters; a central cavity, or **spongocoel;** and an open end, or **osculum,** through which water exits. The cells of sponges are loosely associated; they do not form true tissues.

ThomsonNOW™ **Learn more about sponge structure by clicking on the figure in ThomsonNOW.**

7 Identify distinguishing characteristics of phylum Cnidaria, describe four classes of this phylum, and give examples of animals that belong to each class (page 631).

- Phylum **Cnidaria** is characterized by radial symmetry, two tissue layers, and **cnidocytes,** cells that contain stinging organelles called **nematocysts.** The **gastrovascular cavity** has a single opening that serves as both mouth and anus. Nerve cells form irregular, nondirectional **nerve nets** that connect sensory cells with contractile and gland cells.
- The life cycle of many cnidarians includes a sessile **polyp** stage (a form with a dorsal mouth surrounded by tentacles) and a free-swimming **medusa** (jellyfish) stage.
- Phylum Cnidaria includes four classes. Class **Hydrozoa** (hydras, hydroids, and the Portuguese man-of-war) are typically polyps and may be solitary or colonial. Class **Scyphozoa** (the jellyfish) are generally medusae. Class **Cubozoa,** the "box jellyfish," have complex eyes that form blurred images. Class **Anthozoa** (sea anemones and corals) are polyps and may be solitary or colonial; anthozoans differ from hydrozoans in the organization of the gastrovascular cavity.

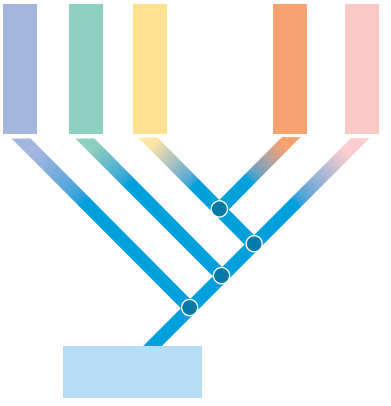
ThomsonNOW™ Learn more about cnidarian body forms, nematocysts, and life cycles by clicking on the figures in ThomsonNOW.

8 Identify distinguishing characteristics of phylum Ctenophora (page 631).

- Phylum **Ctenophora** consists of the comb jellies, fragile, luminescent marine predators with biradial symmetry. Ctenophores have eight rows of cilia that resemble combs. They are diploblastic and have tentacles with adhesive glue cells.

TEST YOUR UNDERSTANDING

1. Which of the following is *not* a defining characteristic of animals? (a) heterotrophic (b) multicellular (c) eukaryotic (d) presence of a coelom (e) formation of a zygote that undergoes cleavage
2. Which of the following is *not* an adaptation to terrestrial living? (a) internal fertilization (b) shell surrounding egg (c) adaptations for maintaining body temperature (d) surface for gas exchange deep in body (e) ability to maintain location
3. The Parazoa (a) are coelomates (b) include cnidarians (c) include all animals with radial symmetry (d) do not form true tissues (e) have a pseudocoelom
4. Cephalization (a) evolved along with bilateral symmetry (b) is the development of a digestive system (c) is characteristic of cnidarians (d) involves a concentration of excretory organs (e) first evolved in deuterostomes
5. The germ layer that gives rise to the outer covering of the body and the nervous system is the (a) gastrodermis (b) ectoderm (c) contractile layer (d) endoderm (e) mesoderm
6. Radial symmetry is characteristic of (a) protostomes (b) acoelomates (c) deuterostomes (d) cnidarians (e) poriferans
7. A true coelom is completely lined with (a) flagella (b) ectoderm (c) a contractile layer (d) endoderm (e) mesoderm
8. Protostomes are characterized by (a) spiral cleavage (b) indeterminate cleavage (c) enterocoely (d) radial symmetry (e) a distinctive body plan that includes a pseudocoelom
9. The evolution of animals (a) followed an orderly progression from simple to complex (b) will be better understood as biologists continue to collect molecular and other types of data (c) has been determined by studying classification (d) began with the ctenophores (e) began with their common ancestor, a parazoan
10. During cleavage, a zygote (a) undergoes metamorphosis (b) becomes a larva (c) undergoes a series of mitotic divisions and becomes a blastula (d) becomes diploid (e) reproduces sexually
11. Collar cells (choanocytes) are characteristic of (a) phylum Porifera (b) Cnidaria (c) most coelomates (d) Lophotrochozoa (e) Ecdysozoa
12. Which of the following is an example of a deuterostome? (a) a lophotrochozoan (b) a coral (c) a chordate (d) a planarian (e) a pseudocoelomate
13. Cnidocytes (a) are characteristic of sponges (b) are found among cells lining the gastrovascular cavity (c) contain stinging organelles (d) are lined with mesoderm (e) have two main shapes
14. The marine hydrozoan *Obelia* (a) is seen mainly in the medusa form (b) lacks cnidocytes (c) has reproductive polyps that produce eggs and sperm (d) is one of the largest jellyfish known (e) alternates sexual and asexual stages during its life cycle
15. Corals (a) are coelomates (b) form symbiotic relationships with certain algae (c) lack a polyp stage (d) are remarkably resistant to environmental stressors (e) have bilateral symmetry
16. Ctenophores (a) tend to be sessile (b) have a digestive system with only one opening (c) exhibit bilateral symmetry (d) are characterized by adhesive glue cells on their tentacles (e) are free-swimming polyps
17. Label the branches of the diagram. Use Figure 29-8b to check your answers.



CRITICAL THINKING

1. Imagine that you discover a new animal in a rain forest. How would you decide to which phylum it belongs? What are some characteristics that might contribute to your decision?
2. Several international monitoring projects are gathering data to help us understand coral reef destruction. Why is it important to take action to protect coral reefs?
3. **Evolution Link.** Biologists traditionally used the type of body cavity to infer relationships among animal groups. In what ways has molecular systematics challenged some of those hypotheses?
4. **Evolution Link.** Animal body plans have generally evolved from simple to more complex. How can we explain the exceptions?
5. **Analyzing Data.** Imagine that a biologist discovers that ctenophores actually branched off from some ancestor that gave rise to the deuterostomes. Where would you place the ctenophore branch on Figure 29-8a?

The Animal Kingdom: The Protostomes

Marty Snyderman / Visuals Unlimited

A bearded fireworm (*Hermodice carunculata*). The fireworm is a segmented worm (an annelid) up to 30 cm (11.8 in) long. It lives in shallow marine waters—in coral reefs, in beds of turtle grass, or under rocks. Fireworm bristles, which are filled with venom, can break off in the skin and cause irritation.

KEY CONCEPTS

The evolution of the coelom has been associated with important innovations in body plan, including cephalization, the tube-within-a-tube body plan, compartmentalization, and segmentation.

Protostomes are a monophyletic group that gave rise to two major clades: Lophotrochozoa and Ecdysozoa.

The most biologically successful protostomes in terms of diversity and numbers are the mollusks and the arthropods.

The remarkable biological success of the insects can be attributed to the evolution of complex body plans and life cycles, for example, their exoskeleton, segmentation, specialized jointed appendages, ability to fly, and metamorphosis.

In Chapter 29 we introduced the animal kingdom and discussed Parazoa (sponges) and the radially symmetrical cnidarians and ctenophores. We explored animal phylogeny, examining differences in a purely structural approach and then a structural approach informed by molecular data. Both approaches hypothesize that bilateral animals form two major branches: protostomes and deuterostomes. Molecular data show that the protostomes evolved along two branches: the Lophotrochozoa and the Ecdysozoa. These three clades—Lophotrochozoa, Ecdysozoa, and Deuterostomia—are sometimes referred to as *superphyla*.

In this chapter we begin our discussion of bilateral animals, the most familiar and by far the most numerous animals on Earth. More than 99% of animal species belong to the Bilateria. These diverse forms have adapted to life in almost every imaginable habitat in the ocean and in freshwater and terrestrial environments. The bearded fireworm shown in the photograph is an example of the diverse animals found among the Bilateria.

The remarkable success of the bilateral animals can be attributed to the evolution of adaptations that facilitated food capture, escape from predators, and reproduction. Among their key adaptations are cephalization, a central nervous system, muscles, a coelom, a tube-within-a-tube body plan, and compartmentalization of the body. Large animals developed body systems for gas exchange, waste disposal, and internal transport of nutrients, respiratory gases, wastes, and other materials. In this chapter we focus on the evolution, innovations in body plans, phylogenetic relationships, and life histories of several phyla of the Lophotrochozoa and Ecdysozoa. ■

IMPORTANCE OF THE COELOM

Learning Objective

1 Cite specific examples of the evolutionary significance of the coelom.

The true **coelom,** one of the most important early animal adaptations, is a fluid-filled body cavity completely lined by mesoderm that lies between the digestive tube and the outer body wall (see Chapter 29). During the Proterozoic eon, animals were small, simple forms. Evolution of the coelom was an important step in the evolution of larger, more complex animals.

With the evolution of the coelom came a new body design, the **tube-within-a-tube body plan.** The body wall is the outer tube. The inner tube is the digestive tube, which is attached to the body wall at its ends. Typically, the digestive tube has a mouth at one end for taking in food and an anus at the other end for eliminating wastes. Because the coelom separates the muscles of the body wall from those in the wall of the digestive tract, the digestive tube can move food along independently of body movements.

Recall that a **pseudocoelom** is a body cavity that is not lined with mesoderm. Animals with a coelom, and to a lesser extent those with a pseudocoelom, have another major advantage over acoelomate animals. Because it is an enclosed compartment (or series of compartments) of fluid under pressure, the coelom can serve as a **hydrostatic skeleton** in which contracting muscles push against a tube of fluid. In many coelomates, such as the fireworm (shown in the chapter opening photograph), a hydrostatic skeleton permits a greater range of movement than is possible for acoelomate animals. The hydrostatic skeleton also shapes the body of soft animals. The evolution of various shapes and divisions of the coelom provided the opportunity for animals to become specialized in swimming, crawling, or walking. Animals that can move quickly to capture food or avoid predators are more likely to survive.

Evolution of the coelom provided a space where internal organs could develop. Most coelomate animals have well-developed circulatory, excretory, and nervous systems. Many internal organs are suspended within folds of the tissue lining the coelom and can move independently of the outer body wall. For example, the pumping action of the heart is possible because of the surrounding space the coelom provides. The fluid-filled coelom also protects internal organs by cushioning them. In addition, the coelom provides space for the gonads to develop. During the breeding season of many animals, such as birds, the gonads enlarge within the coelom as they fill with ripe gametes.

In some animals, fluid within the coelom helps transport materials such as food, oxygen, and wastes. Cells bathed by the coelomic fluid can exchange materials with it. The cells receive nutrients and oxygen from the coelomic fluid and excrete wastes into it. Some coelomates have excretory structures that remove wastes directly from the coelomic fluid.

Review

- What are four major modifications in body plan that evolved along with the coelom?

THE LOPHOTROCHOZOA

Learning Objectives

2 Characterize the protostomes, describe their two main evolutionary branches, and give examples of animals assigned to each branch.
3 Identify distinguishing characteristics of phylum Nemertea and phylum Platyhelminthes; describe the main classes of phylum Platyhelminthes, giving examples of animals that belong to each class.
4 Describe the adaptive advantages of cephalization.
5 Describe the distinguishing characteristics of phylum Mollusca and the four molluscan classes discussed, giving examples.
6 Describe the distinguishing characteristics of phylum Annelida and the three annelid classes discussed, giving examples.
7 Describe the distinguishing characteristics of the lophophorate phyla.

The **Lophotrochozoa** include the platyhelminths, nemerteans (ribbon worms), mollusks, annelids, the lophophorate phyla, and the rotifers (see Fig. 29-8). Recall from Chapter 29 that the name *Lophotrochozoa* comes from the names of two major animal groups included: the Lophophorata and the Trochozoa. The *Lophophorata* include the lophophorate phyla, which are characterized by a lophophore, a ciliated ring of tentacles surrounding the mouth. The name *Trochozoa* refers to the trochophore larva that characterizes its two major groups—the mollusks and annelids.

Flatworms are bilateral acoelomates

Members of phylum **Platyhelminthes,** the **flatworms,** are the simplest bilaterally symmetrical, triploblastic (having three embryonic tissue layers) animals. Their flat, elongated bodies are solid. Thus, they are **acoelomate,** meaning that they have no body cavity. These soft-bodied animals left few fossils to provide clues to their evolutionary history.

Biologists historically assigned the 20,000 species to four classes. Class **Turbellaria** consists of the free-living flatworms, including planarians and their relatives. Classes **Trematoda** and **Monogenea** include the flukes, which are either internal or external parasites. Class **Cestoda** includes the tapeworms, which as adults are intestinal parasites of vertebrates (▮ Table 30-1).

Historically, the flatworms were thought to be a basal group. However, molecular data, specifically 18S ribosomal RNA sequences, indicate that phylum Platyhelminthes, as traditionally classified, is not a monophyletic group. Systematists have reclassified two orders (from class Turbellaria), based on this molecular data, that differ significantly from other flatworms. These two orders have been given their own phylum (Acoelomorpha). This group may be closely related to the common ancestor that linked radially symmetrical animals with bilateral animals.

The remaining flatworms appear more closely related to coelomates. If so, they originally had a body cavity, but their body plan became simplified later in their evolutionary history. Many biologists currently classify them as lophotrochozoans.

TABLE 30-1

Classes of Phylum Platyhelminthes

Class and Representative Animals	Characteristics
Turbellaria Planarians	Mainly free-living; mainly marine; body covered by ciliated epidermis; typically carnivorous; prey on tiny invertebrates
Trematoda and Monogenea Flukes	All parasites with a wide range of vertebrate and invertebrate hosts; may require intermediate hosts; adults have suckers for attachment to host
Cestoda Tapeworms	Parasites of vertebrates; complex life cycle usually with one or two intermediate hosts; larval host may be invertebrate; typically have suckers and sometimes hooks for attachment to host; eggs produced within proglottids, which are shed; no digestive or nervous systems

This phylogeny is controversial. As biologists consider new data, their assessment of the phylogenetic relationships of flatworms may change.

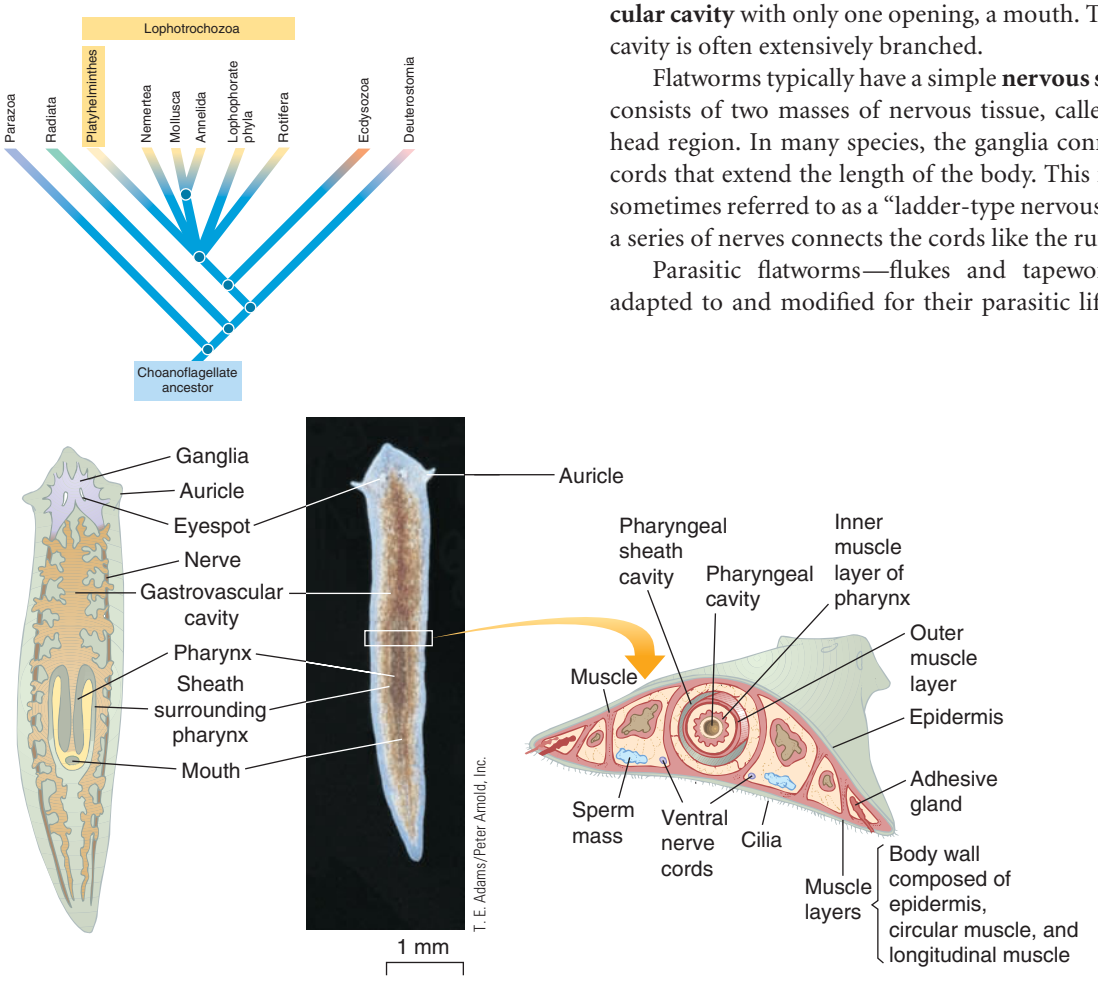
Flatworms have definite anterior and posterior ends. They exhibit **cephalization,** the evolution of a head with a concentration of sense organs at the anterior end. A simple brain and paired sense organs are concentrated in the "head" region. An animal with a front end generally moves forward. With a concentration of sense organs in the part of the body that first meets its environment, the animal can find food, shelter, and mates or detect an enemy quickly.

Flatworms are triploblastic, that is, they have three definite tissue layers. In addition to its outer epidermis derived from ectoderm, and an inner endodermis derived from endoderm, the flatworm has a middle tissue layer that develops from mesoderm.

Flatworms have no organs for circulation or gas exchange. These functions depend largely on diffusion through the body wall. The activities of some organs are coordinated and form simple organ systems, for example, the digestive and nervous systems. As in the cnidarians, the digestive system is a **gastrovascular cavity** with only one opening, a mouth. The gastrovascular cavity is often extensively branched.

Flatworms typically have a simple **nervous system.** The brain consists of two masses of nervous tissue, called **ganglia,** in the head region. In many species, the ganglia connect to two nerve cords that extend the length of the body. This nervous system is sometimes referred to as a "ladder-type nervous system," because a series of nerves connects the cords like the rungs of a ladder.

Parasitic flatworms—flukes and tapeworms—are highly adapted to and modified for their parasitic lifestyle. They have



(a) Internal structure.

(b) LM of a living planarian (*Dugesia dorotocephala*). Note the prominent auricles, used to locate food.

(c) Cross section through a planarian.

Figure 30-1 ***Animated*** The common planarian, *Dugesia*

suckers or hooks for holding on to their hosts. The bodies of those that live in digestive tracts resist the digestive enzymes secreted by their hosts. Many have complicated life cycles and produce large numbers of eggs. Other adaptations include the loss of certain structures such as sense organs. Tapeworms have also lost the digestive system.

Turbellarians are free-living flatworms

Most members of class Turbellaria are free-living, marine flatworms. However, many inhabit freshwater habitats, and some are terrestrial. Turbellarian flatworms typically have a muscular pharynx that takes in food; a simple brain, eyespots, and other sensory organs in the head; **protonephridia,** structures that function in *osmoregulation* (fluid balance) and metabolic waste disposal (excretion); and reproductive organs.

Planarians are turbellarian flatworms found in ponds and quiet streams throughout the world. The common American planarian *Dugesia* is about 15 mm (0.6 in) long, with what appear to be crossed eyes and flapping "ears" called **auricles** (Fig. 30-1). The auricles actually serve as organs of chemoreception, important in locating food. Planarians are capable of learning. Memory is not localized within the ganglia but appears to be retained throughout the nervous system.

Planarians are carnivorous; they trap small animals in a mucous secretion. The digestive system consists of a single opening (the mouth); a tubelike, muscular **pharynx** (the first portion of the digestive tube); and a branched gastrovascular cavity. A planarian projects its pharynx outward through its mouth, using it to suck in prey. The long, highly branched gastrovascular cavity distributes food to all parts of the body so each cell can receive nutrients by diffusion.

Although excretion also takes place mainly by diffusion, some metabolic wastes are excreted by the protonephridia. Protonephridia are blind tubules that end in **flame bulbs,** collecting cells equipped with cilia. The beating of the cilia channels waste through the system of tubules and eventually out of the body through excretory pores. Osmoregulation and protonephridia are discussed further in Chapter 47 (see Fig. 47-2).

Planarians reproduce either asexually or sexually. In asexual reproduction, an individual constricts in the middle and divides into two planarians. Each regenerates its missing parts. Sexually, these animals are **hermaphrodites.** During the warm months of the year, each is equipped with a complete set of male and female organs. Two planarians come together in copulation and exchange sperm cells so that their eggs are cross-fertilized.

Flukes parasitize other animals

Although their body plan resembles that of the free-living flatworms, the **flukes,** members of classes Trematoda and Monogenea, have structures, such as hooks and suckers, for attachment to their host. Flukes also have extremely prolific reproductive organs.

Flukes that are parasitic in humans include blood flukes, widespread in tropical areas of the world, and liver flukes, common in Asia, particularly in areas where humans use their own feces for fertilizing crops. Blood flukes of the genus *Schistosoma* infect about 200 million people who live in tropical areas. Both blood flukes and liver flukes go through complicated life cycles involving several different forms. There is an alternation of sexual and asexual stages, and parasitism on one or more intermediate hosts, such as snails and fishes (Fig. 30-2). The aquatic snails that serve as intermediate hosts thrive in ponds, rice paddies, and the marshy areas that develop when dams are built.

Tapeworms inhabit the intestine of vertebrates

Adult members of the more than 5000 species of class Cestoda live as parasites in the intestine of probably every kind of vertebrate, including humans. Tapeworms are long, flat, ribbonlike animals strikingly specialized for their parasitic mode of life. Among their many adaptations are suckers and sometimes hooks on the "head," or **scolex,** that enable the parasite to attach to the host's intestine (Fig. 30-3).

The reproductive adaptations and abilities of tapeworms are extraordinary. The body of the tapeworm consists of a long chain of segments called **proglottids.** Each proglottid is an entire reproductive machine equipped with both male and female reproductive organs and contains up to 100,000 eggs. Because an adult tapeworm may have as many as 2000 segments, its reproductive potential is staggering. A single tapeworm can produce 600 million eggs per year! Proglottids farthest from the tapeworm's head contain the ripest eggs; these segments are shed from the host's body along with the feces.

The tapeworm has no mouth or digestive system. Digested food from the host is absorbed across the worm's body wall. The tapeworm also lacks well-developed sense organs. Some tapeworms have complex life cycles, spending their larval stage within the body of an intermediate host and their adult life within the body of a different, final host. Figure 30-4 illustrates the life cycle of the beef tapeworm, which can infect humans when they eat undercooked beef containing the larvae.

Phylum Nemertea is characterized by the proboscis

Phylum **Nemertea,** the ribbon worms or proboscis worms, is a relatively small group (about 1200 species) of free-living animals (Fig. 30-5 on page 646). Most burrow in marine sediments, but a few species inhabit deep sea water, fresh water, or damp soil. Many nemerteans are carnivorous, feeding on crustaceans and annelids. Nemerteans have long, narrow bodies, either cylindrical or flattened, ranging in length from 1 mm to more than 30 m (100 ft). Some are a vivid orange, red, or green, with black or colored stripes.

Their most remarkable organ, the **proboscis,** from which one of their common names, *proboscis worms,* derives, is a long, hollow, muscular tube that can be rapidly everted (turned inside out) from the anterior end of the body. Used to capture prey, the sticky proboscis can be wrapped around a small animal. In some species the proboscis is sharp, and in various species it secretes

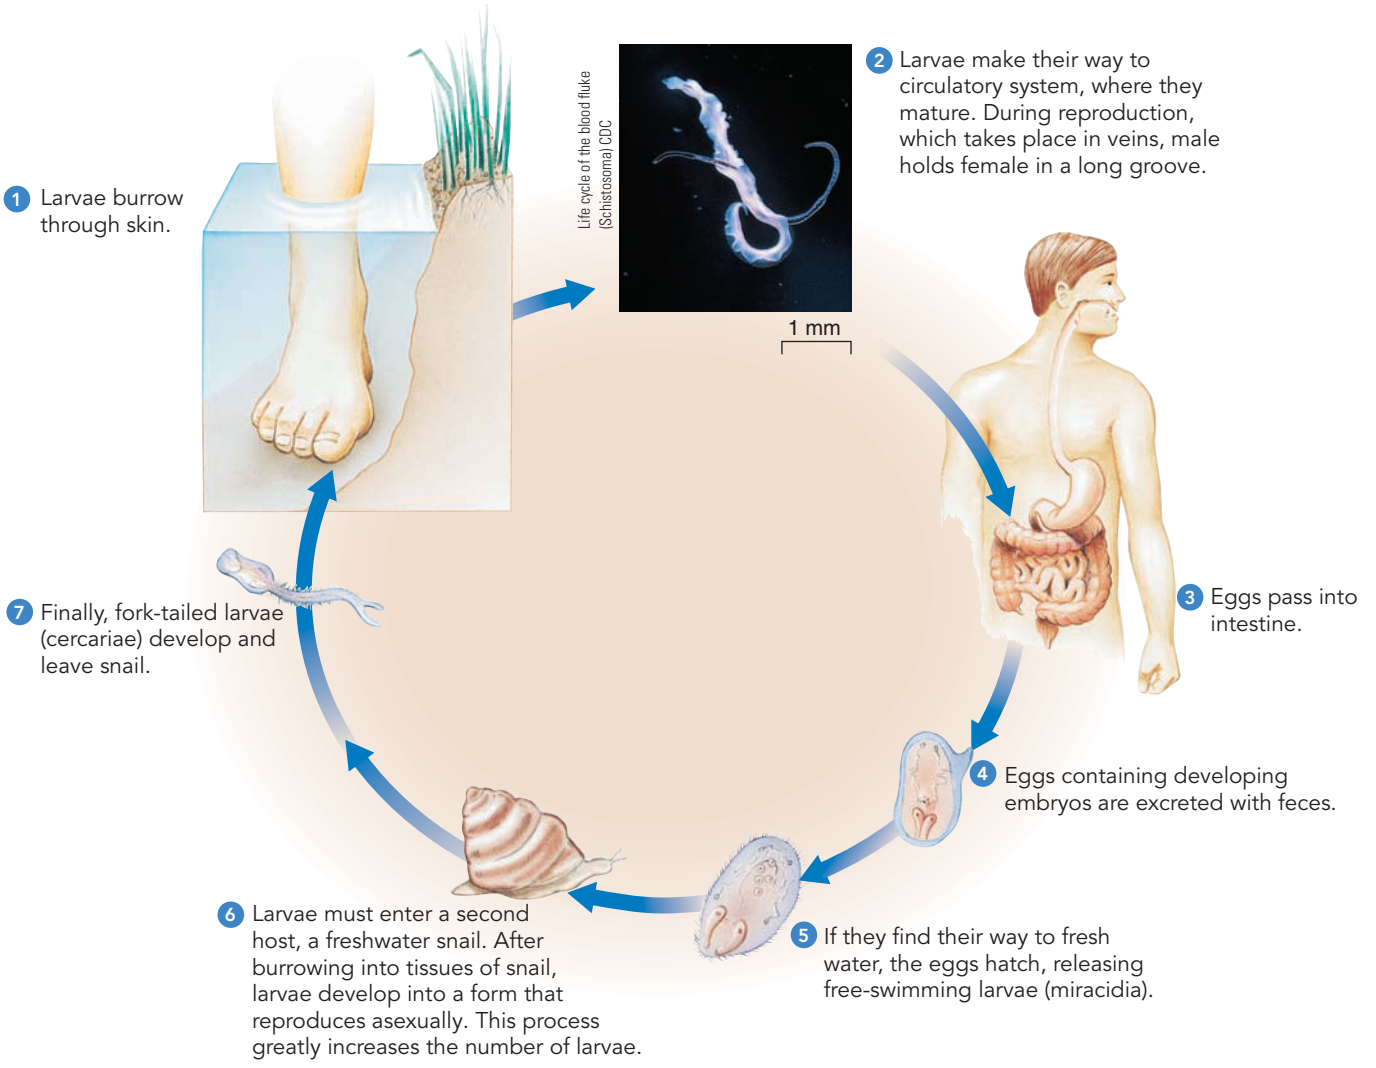


Figure 30-2 ***Animated*** Life cycle of the blood fluke (*Schistosoma*)
The LM shows an adult male enfolding a smaller female.

toxic fluid that immobilizes prey. The proboscis is a *derived character* that distinguishes nemerteans from all other invertebrate groups.

Historically, the nemerteans were of special evolutionary interest because biologists thought they were the earliest animals to have a circulatory system and a complete digestive tract. Nemerteans have no heart; blood is circulated by contractions of muscular blood vessels and by movements of the body. Although the nemerteans are functionally acoelomate, the system of blood vessels may be homologous to the coelom of other coelomate animals.

The chamber surrounding the proboscis is a true coelomic space, known as a **rhynchocoel.** It develops in the embryo as the coelom does in coelomate protostomes (see Chapter 29). Biologists now view the rhynchocoel as a remnant of the coelom of a coelomate ancestor. Because of its presence and recent molecular evidence, biologists now classify nemerteans with the lophotrochozoans.

Mollusks have a muscular foot, visceral mass, and mantle

Phylum **Mollusca** includes clams, oysters, snails, slugs, octopods, and the largest of all the invertebrates, the giant squid, which averages 9 to 16 m (about 30 to 53 ft) in length, including its tentacles. More than 50,000 living species and 35,000 fossil species (second only to the arthropods in number) have been described. In this chapter we discuss four of the eight recognized classes. We illustrate representatives of these classes in Figure 30-6 and describe them in Table 30-2.

Although most mollusks are marine, many snails and clams live in fresh water, and some species of snails and slugs inhabit the land. Mollusks probably evolved early in the history of the protostome clade, soon after the evolution of the coelom but before the origin of the segmented body that is characteristic of annelids. Although mollusks vary widely in outward appearance, most share six basic characteristics:

Cath Ellis /Science Photo Library/Photo Researchers, Inc.

Figure 30-3 Scolex of a tapeworm

The small tapeworm (*Acanthrocirrus retrisrostris*) reaches maturity in the intestine of wading birds that eat barnacles. The color-enhanced SEM shows the pistonlike cluster of hooks that can be withdrawn into the head or thrust out and buried in the host's tissue. You can see two of the four powerful suckers beneath the hooks.

1. A soft body, usually covered by a dorsal shell composed mainly of calcium carbonate.
2. A broad, flat, muscular **foot,** located ventrally, which is used for locomotion.
3. The body organs (viscera) concentrated as a **visceral mass** located above the foot.
4. A **mantle,** a thin sheet of tissue that covers the visceral mass and usually contains glands that secrete a shell. The mantle generally overhangs the visceral mass, forming a mantle cavity that contains gills and other structures.
5. A rasplike structure called a **radula,** which is a belt of teeth in the mouth region. (The radula is not present in clams or their relatives, which are suspension feeders.)
6. A coelom, generally reduced to small compartments around certain organs, including the heart and excretory organs (*metanephridia*). The main body cavity is typically a **hemocoel,** a space containing blood (see following discussion of open circulatory system). The hemocoel is not a coelom.

Mollusks have all of the organ systems typical of complex animals. The digestive system is a tube, often coiled, consisting of a mouth, buccal cavity (mouth cavity), esophagus, stomach, intestine, and anus. The mollusk radula, located within the buccal cavity, projects out of the mouth and is used to scrape particles of food from the surface of rocks or the ocean floor. Sometimes the radula is used to drill a hole in the shell of a prey animal or to tear off pieces of a plant.

Most mollusks have an **open circulatory system** in which the blood, called **hemolymph,** bathes the tissues directly. The heart pumps blood into a single blood vessel, the aorta, which may branch into other vessels. Eventually, blood flows into a network of large spaces called *sinuses,* bringing the blood into direct contact with the tissues. This network makes up the hemocoel, or blood cavity. From the sinuses, blood drains into vessels that conduct it to the gills, where it is recharged with oxygen. After passing through the gills, the blood returns to the heart. Thus, blood flow in a mollusk follows this pattern:

Heart ⟶ aorta ⟶ smaller blood vessels ⟶ blood sinuses (hemocoel) ⟶ blood vessels to gills ⟶ heart

In open circulatory systems, blood pressure tends to below, and tissues are not very efficiently oxygenated. Because

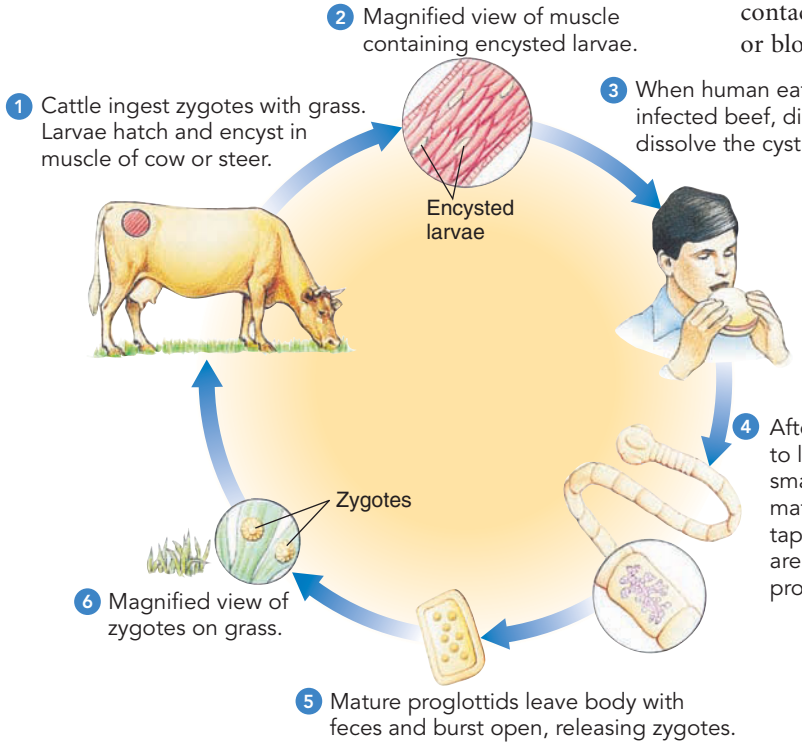

Figure 30-4 ***Animated*** Life cycle of the beef tapeworm

(b) Lateral view of a typical nemertean. Note the complete digestive tract that extends from mouth to anus, giving this animal a tube-within-a-tube body plan.

Figure 30-5 Nemerteans (proboscis worms)

most mollusks are slow-moving animals with low metabolic rates, this type of circulatory system is adequate. The active cephalopods (the class that includes the squids and octopods), have a **closed circulatory system** in which blood flows through a complete circuit of blood vessels.

Most marine mollusks pass through one or more larval stages. The first stage is typically a **trochophore larva,** a free-swimming, top-shaped larva with two bands of cilia around its middle (Fig. 30-7). In many mollusks (gastropods such as snails and bivalves such as clams), the trochophore larva develops into a **veliger larva,** which has a shell, foot, and mantle. The veliger larva is unique to the mollusks.

Chitons may be similar to ancestral mollusks

Class **Polyplacophora** (meaning "many plates") consists of the **chitons,** marine animals with flattened bodies (see Fig. 30-6a). Their most distinctive feature is a shell composed of eight separate but overlapping dorsal plates. The head is reduced, and there are no eyes or tentacles.

The chiton inhabits rocky intertidal zones, using its broad, flat foot to move and to hold on firmly to rocks. By pressing its mantle against the substratum and lifting the inner edge of the mantle, the chiton can produce a partial vacuum. The resulting suction lets the animal adhere powerfully to its perch. Using its radula for grazing, the chiton scrapes algae and other small organisms off rocks and shells.

Gastropods are the largest group of mollusks

Class **Gastropoda,** which includes snails, slugs, conchs, sea slugs, and their relatives, is the largest and most diverse group of mollusks (see Fig. 30-6b). In fact, with more than 70,000 extant species, gastropods constitute the second-largest class in the animal kingdom, second only to insects. Most gastropods inhabit marine waters, but others make their homes in brackish or fresh water or on land. We think of snails as having a single, spirally coiled shell into which they can withdraw the body, and many do. However, other gastropods, such as limpets, have shells like flattened dunce caps. Still others, such as garden slugs and the beautiful marine slugs known as **nudibranchs,** have no shell at all (Fig. 30-8).

Many gastropods have a well-developed head with tentacles. Two simple eyes may be located on stalks that extend from the head. The gastropod uses its broad, flat foot for creeping. Most land snails do not have gills. Instead, the mantle is highly vascularized and functions as a lung. Biologists describe these garden snails and slugs as **pulmonate** ("having a lung").

TABLE 30-2

Major Classes of Phylum Mollusca

Class and Representative Animals	Characteristics
Polyplacophora Chitons	Primitive marine animals with shell consisting of eight separate transverse plates; head reduced; broad foot used for locomotion
Gastropoda Snails, slugs, nudibranchs	Marine, freshwater, or terrestrial; coiled shell in many species; torsion of visceral mass; well-developed head with tentacles and eyes
Bivalvia Clams, oysters, mussels	Marine or freshwater; body laterally compressed; two-part shell hinged dorsally; hatchet-shaped foot; suspension feeders
Cephalopoda Squids, octopods	Marine; predatory; foot modified into tentacles, usually bearing suckers; well-developed eyes; closed circulatory system

Figure 30-6 ***Animated***
The mollusk body plan

(a) Chitons are sluggish marine animals with shells composed of eight overlapping plates. This sea cradle chiton (*Tonicella lineata*), which reaches about 5 cm (2 in) in length, inhabits rocks covered with corraline algae in coastal waters off the U.S. Pacific Northwest. **(b)** The broad, flat foot of the gastropod is an adaptation to its mobile lifestyle. The mystery snail (*Pomacea bridgesi*) inhabits fresh water and can be found burrowing in the mud. **(c)** The compressed body of the horseneck clam (*Tresus capax*) is adapted for burrowing in the North Pacific mud. Its shell grows to about 20 cm (8 in) in length. **(d)** The squid body is streamlined for swimming. To avoid being seen by potential predators, the squid can change color to blend with its background. This northern shortfin squid (*Illex illecebrosus*), which grows to a mantle length of up to about 31 cm (about 1 ft), inhabits the North Atlantic ocean.

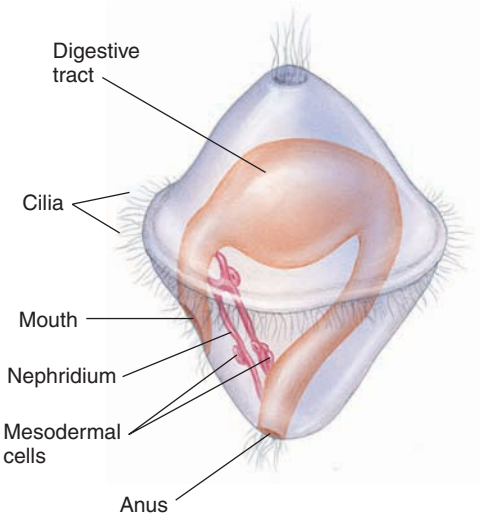

Figure 30-7 A trochophore larva

The first larval stage of a marine mollusk, the trochophore larva, is also characteristic of annelids. Just above the mouth a band of ciliated cells functions as a swimming organ and, in some species, collects suspended food particles.

Figure 30-8 Nudibranch

A nudibranch (*Chromodoris porterae*) feeds on a lightbulb tunicate (*Clavelina huntsmani*).

Torsion, a twisting of the visceral mass, is a unique feature of gastropods. This twisting is unrelated to the coiling of the shell. As the bilateral larva develops, one side of the visceral mass grows more rapidly than the other side. This uneven growth rotates the visceral mass. The visceral mass and mantle twist permanently up to 180 degrees relative to the head. As a result, the digestive tract becomes somewhat U shaped, and the anus comes to lie above the head and gill (Fig. 30-9). Subsequent growth is dorsal and usually in a spiral coil. Torsion limits space in the body, and typically the gill, metanephridium (excretory organ), and gonad

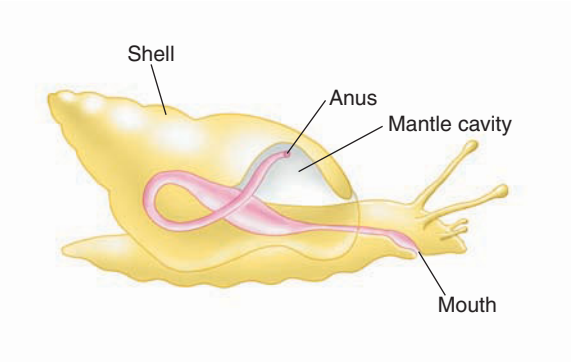

Figure 30-9 ***Animated*** Torsion in a gastropod

As the bilateral larva develops, the visceral mass twists 180 degrees relative to the head. The digestive tube coils, and the anus becomes relocated near the mouth.

are absent on one side. Some biologists hypothesize that torsion is an adaptation that protects the head by allowing it to enter the shell first during withdrawal from potential predators. Without torsion, the foot would be withdrawn first.

Bivalves typically burrow in the mud

Class **Bivalvia** includes the clams, oysters, mussels, scallops, and their relatives (see Fig. 30-6c). Typically, the soft body of members of class Bivalvia is laterally compressed and completely enclosed by a two-part shell that hinges dorsally and opens ventrally (Fig. 30-10). This arrangement allows the hatchet-shaped foot to protrude ventrally for locomotion and for burrowing in mud. The two parts, or **valves,** of the shell are connected by an elastic ligament. Stretching of the ligament opens the shell. Large, strong adductor muscles attached to the shell permit the animal to close its shell.

The inner, pearly layer of the bivalve shell is made of calcium carbonate secreted in thin sheets by the epithelial cells of the mantle. Known as *mother-of-pearl,* this material is valued for making jewelry and buttons. Should a bit of foreign matter lodge between the shell and the mantle, the epithelial cells covering the mantle secrete concentric layers of calcium carbonate around the intruding particle. Many species of oysters and clams form pearls in this way.

Some bivalves, such as oysters, attach permanently to the substrate. Others burrow slowly through rock or wood, seeking protected dwellings. The shipworm, *Teredo,* a clam that damages dock pilings and other marine installations, is just looking for a home. A few bivalves, such as scallops, swim rapidly by clapping their two shells together with the contraction of a large adductor muscle (the part of the scallop that humans eat).

Clams and oysters are suspension feeders that trap food particles in sea water. They take water in through an extension of the mantle called the **incurrent siphon.** Water leaves by way of an **excurrent siphon.** As the water passes over the gills, mucus secreted by the gills traps food particles in the stream of water. Cilia move the food to the mouth. An oyster can filter more than 30 L (about

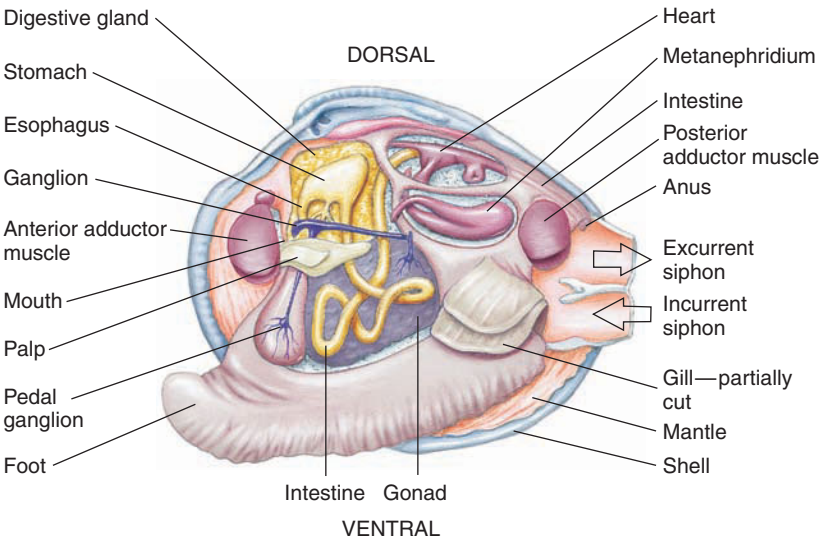

Figure 30-10 ***Animated*** Internal anatomy of a clam

The two shells of a bivalve hinge dorsally and open ventrally.

32 qt) of water per hour! As suspension feeders, bivalves have no need for a radula, and indeed they are the only group of mollusks that lack this structure.

Cephalopods are active, predatory animals

In contrast with most other mollusks, members of class **Cephalopoda** (meaning "head-foot") are fast-swimming predatory animals (see Fig. 30-6d). The cephalopod mouth is surrounded by tentacles, or arms: 8 in octopods, 10 in squids, and as many as 90 in the chambered nautilus. The large head has well-developed eyes that form images. Although they develop differently, their complex eyes are structurally similar to vertebrate eyes and function in much the same way. The octopus has no shell; and the shell of the squid, located inside the body, is greatly reduced.

Nautilus has a coiled shell consisting of many chambers built up over time. Each year the animal lives in the newest and largest chamber of the series. *Nautilus* secretes a mixture of gases similar to air into the other chambers. By regulating the amount of gas in the chambers, the animal controls its depth in the ocean.

The tentacles of squids, octopods, and cuttlefish are covered with suckers for seizing and holding prey. In addition to a radula, the mouth has two strong, horny beaks used to kill prey and tear it to bits. The thick, muscular mantle is fitted with a funnel-like **siphon.** By filling the cavity with water and ejecting it through the siphon, the cephalopod achieves forceful jet propulsion. Squids and cuttlefish have streamlined bodies adapted for efficient swimming.

In addition to speed, the cephalopod has two other adaptations that facilitate escape from its predators, which include certain whales and moray eels. It can confuse the enemy by rapidly changing colors. By expanding and contracting *chromatophores*, cells in the skin that contain pigment granules, the cephalopod can display an impressive variety of mottled colors. Another defense mechanism is its **ink sac,** which produces a thick, black liquid the animal releases in a dark cloud when alarmed. While its enemy pauses, temporarily blinded and confused, the cephalopod escapes. The ink inactivates the chemical receptors of some predators, making them incapable of detecting their prey.

The octopus feeds on crabs and other arthropods, catching and killing them with a poisonous secretion of its salivary glands. During the day the octopus usually hides among the rocks; in the evening it emerges to hunt for food. Its motion is incredibly fluid, giving little hint of the considerable strength in its eight arms.

Small octopods survive well in aquariums and have been studied extensively. Because octopods are relatively intelligent and can make associations among stimuli, researchers have used them as models for studying learning and memory. Their highly adaptable behavior more closely resembles that of the vertebrates than the more stereotypic patterns of behavior seen in other invertebrates (see Chapter 51).

Annelids are segmented worms

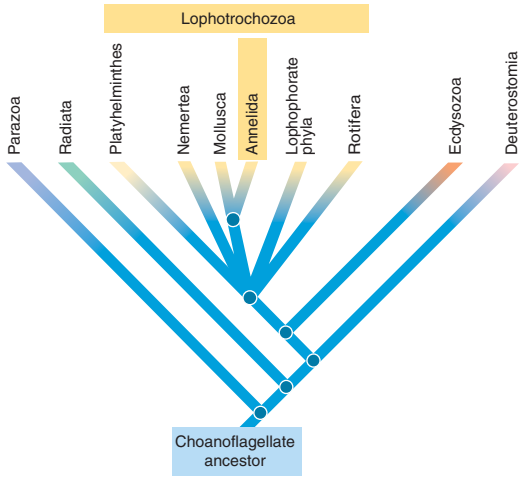
Members of phylum **Annelida,** the segmented worms, have bilateral symmetry and a tubular body that may be partitioned into more than 100 ringlike segments. This phylum, composed of about 15,000 species, includes three main classes: the polychaetes, a group of marine and freshwater worms; the earthworms; and the leeches (▮ Table 30-3 and ▮ Fig. 30-11).

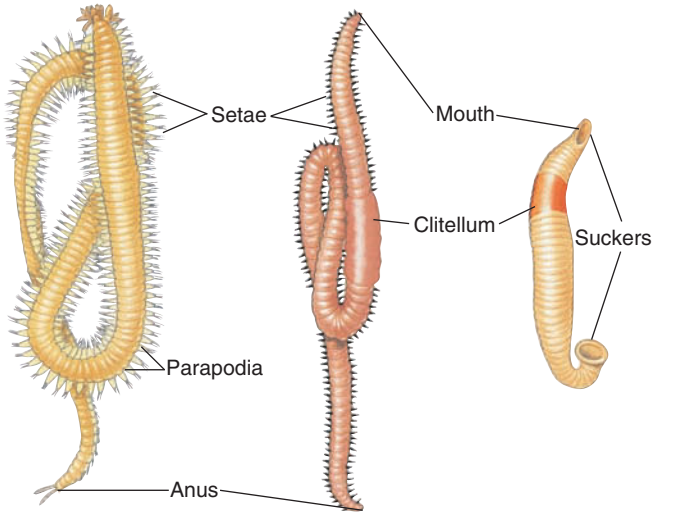
The term *Annelida* (meaning "ringed") refers to the series of rings, or segments, that make up the annelid body. Both the body wall and many of the internal organs are segmented. Some structures, such as the digestive tract and certain nerves, extend the length of the body, passing through successive segments. Other structures, such as excretory organs, are repeated in each segment. In polychaetes and earthworms, segments are separated from one another internally by transverse partitions called **septa.**

TABLE 30-3

Major Classes of Phylum Annelida

Class and Representative Animals	Characteristics
Polychaeta Sandworms, tubeworms	Mainly marine; each segment bears a pair of parapodia with many setae; well-developed head; separate sexes; trochophore larva
Oligochaeta Earthworms	Terrestrial and freshwater worms; few setae per segment; lack well-developed head; hermaphroditic
Hirudinea Leeches	Most are blood-sucking parasites that inhabit fresh water; appendages and setae absent; prominent muscular suckers





(a) Class Polychaeta. Polychaetes are marine worms with paddle-shaped parapodia.

(b) Class Oligochaeta. Oligochaetes, which include the earthworms, inhabit fresh water and moist terrestrial areas.

(c) Class Hirudinea. Many leeches are parasites that feed on blood.

Figure 30-11 Three major classes of annelids

An important advantage of **segmentation** is that it facilitates locomotion. The coelom is divided into segments, and each segment has its own muscles. This arrangement allows the animal to elongate one part of its body while shortening another part. The annelid's hydrostatic skeleton is important in movement. In polychaetes and earthworms, bristlelike structures called **setae** (sing., *seta*), located on each segment, provide traction as the worm moves along by alternating contraction of its longitudinal and circular muscles.

The annelid nervous system generally is a ventral nerve cord and a simple brain consisting of a pair of ganglia. A pair of ganglia and lateral nerves is repeated in each segment. Annelids have a large, well-developed coelom, a closed circulatory system, and a complete digestive tract extending from mouth to anus. Respiration is *cutaneous,* that is, through the skin, or by gills. Typically, a pair of excretory tubules called **metanephridia** is located in each segment (described in Chapter 47).

Most polychaetes are marine worms with parapodia

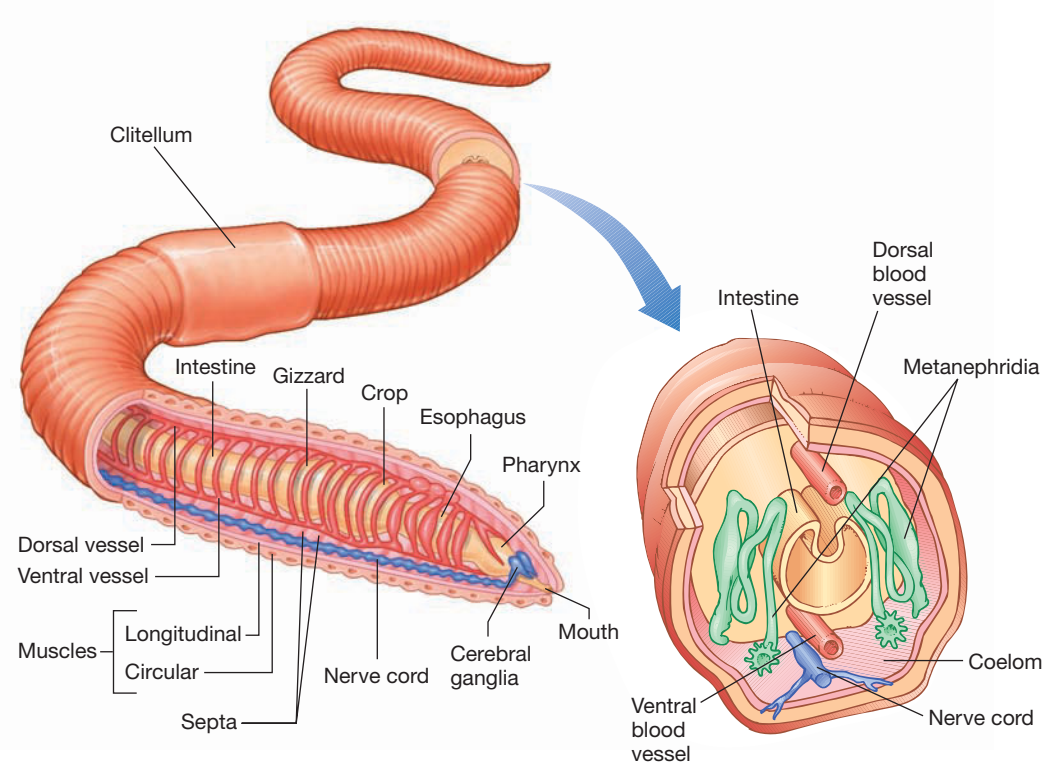
Class **Polychaeta** includes marine worms that swim freely in the sea, burrow in the mud near the shore, or live in tubes they secrete or make by cementing bits of shell and sand together with mucus. Each body segment typically bears a pair of paddle-shaped appendages called **parapodia** (sing., *parapodium*) that function in locomotion and in gas exchange. These fleshy structures bear many stiff setae (the term *polychaete* means "many bristles"; see the fireworm in the chapter opening photograph). Most polychaetes have a well-developed head with eyes and antennae. The head may also be equipped with tentacles and palps (feelers). Polychaetes develop from free-swimming trochophore larvae similar to those of mollusks.

Behavioral patterns that ensure fertilization have evolved in many polychaete species. By responding to certain rhythmic variations, or cycles, in the environment, nearly all the females and males of a given species release their gametes into the water at the same time. For example, more than 90% of reef-dwelling *Palolo* worms of the South Pacific shed their eggs and sperm within a 2-hour period on one night of the year. The posterior portion of the *Palolo* worm, loaded with eggs or sperm, breaks off from the rest of the body. It comes to the surface and bursts, releasing its gametes. This mass reproductive event occurs in October or November at the beginning of the last lunar quarter. Local islanders gather great numbers of the swarming polychaetes, which they bake or eat raw.

Earthworms help maintain fertile soil

The approximately 3000 species of class **Oligochaeta** live almost exclusively in fresh water and in moist terrestrial habitats. These worms lack parapodia, have few bristles per segment (the term *oligochaete* means "few bristles"), and lack a well-developed head. All oligochaetes are hermaphroditic.

Lumbricus terrestris, the common earthworm, is about 20 cm (8 in) long. Its body has more than 100 segments, separated externally by grooves that indicate the internal position of the septa (Fig. 30-12). The earthworm's body is somewhat protected from drying by a thin, transparent **cuticle** secreted by the cells of the epidermis. Mucus secreted by gland cells of the epidermis forms an additional protective layer over the body surface. The body



(a) The internal structure has been exposed at the anterior end of an earthworm.

(b) Cross section of an earthworm.

Figure 30-12 ***Animated*** Body plan of an earthworm

wall has an outer layer of circular muscles and an inner layer of longitudinal muscles.

An earthworm literally eats its way through the soil. It ingests its own weight in soil and nutritious decaying vegetation every 24 hours! Earthworms enhance the formation and maintenance of fertile soil. As they move about, earthworms turn and aerate the soil and enrich it with nitrogenous wastes.

The earthworm processes its meal of soil in a complex digestive system. Food is swallowed through the muscular **pharynx** and passes through the **esophagus,** which is modified to form a thin-walled **crop** where food is stored and a thick-walled, muscular **gizzard.** In the gizzard, food is ground to bits by sand grains consumed along with the meal. The rest of the digestive system is a long, straight **intestine** that chemically digests food and absorbs nutrients. Wastes pass out of the intestine to the exterior through the **anus.**

The efficient closed circulatory system consists of two main blood vessels that extend longitudinally. The dorsal blood vessel, just above the digestive tract, collects blood from vessels in the segments, then contracts to pump the blood anteriorly. In the region of the esophagus, five pairs of blood vessels propel blood from the dorsal to the ventral blood vessel. Located just below the digestive tract, the ventral blood vessel carries blood posteriorly. Small vessels branch from it and deliver blood to the various structures in each segment, as well as to the body wall. Within these structures blood flows through tiny capillaries before returning to the dorsal blood vessel.

Gas exchange takes place through the moist skin. Oxygen is transported by hemoglobin, the respiratory pigment in the blood plasma (the liquid part of the blood). The excretory system consists of paired metanephridia, repeated in almost every segment of the body.

The nervous system consists of a pair of **cerebral ganglia** (a simple brain) just above the pharynx and a subpharyngeal ganglion just below the pharynx. A ring of nerve fibers connects these ganglia. From the lower ganglion a ventral nerve cord extends beneath the digestive tract to the posterior end of the body. A pair of fused ganglia is present in each segment along the nerve cord. Nerves extend laterally from the ganglia to the muscles and other structures of that segment. The ganglia coordinate muscle contractions of the body wall, allowing the worm to creep along.

Like other oligochaetes, earthworms are hermaphroditic. During copulation, two worms, headed in opposite directions, press their ventral surfaces together. These surfaces become glued together by the thick mucous secretions of each worm's *clitellum,* a thickened ring of epidermis. Sperm are then exchanged and stored in the *seminal receptacles* (small sacs) of the other worm. A few days later each clitellum secretes a membranous cocoon containing a sticky fluid. As the cocoon is slipped forward, eggs are laid in it. Sperm are added as the cocoon passes over the

Figure 30-13 Leeches

openings of the seminal receptacles. As the cocoon slips free over the worm's head, its openings constrict so that a spindle-shaped capsule is formed. The fertilized eggs develop into tiny worms within this capsule. This reproductive pattern is an adaptation to terrestrial life; the cocoon protects the delicate gametes and young worms from drying out.

Many leeches are blood-sucking parasites

Most leeches, members of class **Hirudinea,** inhabit fresh water, but some live in the sea or in moist areas on land. About 75% of the known species of leeches are blood-sucking parasites. Some leeches are nonparasitic predators that capture small invertebrates such as earthworms and snails. Leeches differ from other annelids in having neither setae nor parapodia.

Leeches have muscular suckers at both the anterior and posterior ends of their body. Most parasitic leeches attach themselves to a vertebrate host, bite through the skin, and suck out a quantity of blood, which is stored in pouches in the digestive tract. *Hirudin,* an anticoagulant secreted by glands in the crop, ensures leeches a full meal of blood. In 30 minutes, a leech can suck out as much as 10 times its own weight in blood! Some leeches feed only about twice each year because they digest their food slowly over several months.

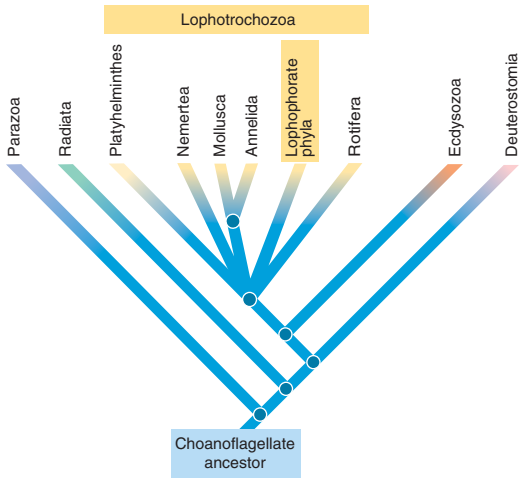
Leeches have been used since ancient times for drawing blood from areas swollen by poisonous stings and bites. During the 19th century they were widely used to remove "bad blood," thought to be the cause of many diseases. Leeches are used in modern medicine to remove excess fluid and blood that accumulate within body tissues as a result of injury, disease, or surgery (Fig. 30-13). The leech attaches its sucker near the site of injury, makes an incision, and secretes hirudin. The hirudin prevents the blood from clotting and dissolves clots already existing.

The lophophorate phyla are distinguished by a ciliated ring of tentacles

With a few exceptions, lophophorates are marine animals adapted for life on the ocean floor. These coelomates are distinguished by their **lophophore,** a ring of ciliated tentacles that surrounds the mouth. The lophophore is an adaptation for capturing suspended particles in the water. Lophophorates do not have a distinct head.

Biologists are still debating the evolutionary position of the **lophophorate phyla.** They were traditionally considered a monophyletic group and a sister group to the deuterostomes, based on certain structural similarities. However, brachiopods and bryozoans have bristles composed of chitin, suggesting a relationship with the annelids and other lophotrochozoans. Although their phylogeny is still being debated, based on molecular data (18S rDNA nucleotide sequences), the lophophorate phyla are now classified as Lophotrochozoa.

The lophophorate phyla include Brachiopoda, Phoronida, and Bryozoa. **Brachiopods,** or lampshells, are solitary marine animals that inhabit cold water. Until the mid-19th century, they were thought to be mollusks because they are suspension feeders that superficially resemble clams and other bivalve mollusks. Their body is enclosed between two shells and has a mantle and mantle cavity (Fig. 30-14a). However, they differ from bivalve



Stan Elems/Visuals Unlimited

(b) Phylum Phoronida. A single lophophore of the phoronid (*Phoronopsis viridis*). This animal is about 20 cm (8 in) long, but only 3 mm (1/8 in) in diameter.

(a) Phylum Brachiopoda. Like other brachiopods, these northern lamp shells (*Terebratulina septentrionalis*) superficially resemble clams.

M. I. Walker/Photo Researchers, Inc.

(c) Phylum Bryozoa (ectoprocts). Like many bryozoans, this freshwater species (*Cristatella mucedo*) forms colonies by asexual budding.

Figure 30-14 Representative lophophorates

mollusks in that the shells are dorsal and ventral rather than lateral; each shell is symmetrical about the midline, and the two shell valves are typically of unequal size.

Brachiopods attach to the substrate by a long stalk. Cilia on the lophophore beat, bringing water laden with food into the slightly opened shell. Although there are now only about 350 living species, brachiopods were abundant and diversified during the Paleozoic era. Paleobiologists have described about 30,000 fossil species.

Only about 20 extant species of **phoronids** are known. They are wormlike, sessile animals found in coastal marine sediments. Adult phoronids secrete chitinous tubes in which they live (Fig. 30-14b). They extend their lophophores from their tubes for feeding. Phoronids vary in length from 2 cm to more than 20 cm (less than 1 in to about 8 in), but they are only 1 to 3 mm in diameter.

Bryozoans, also known as ectoprocts or "moss animals," are microscopic aquatic animals. They form sessile colonies by asexual budding (Fig. 30-14c). Each colony can consist of millions of individuals and can extend in length up to about 30 cm (about 1 ft). The colonies typically appear plantlike, but some have the appearance of coral. Approximately 5000 extant species are known.

Rotifers have a crown of cilia

Among the less familiar invertebrates are the "wheel animals" of phylum **Rotifera.** Although no larger than many protozoa, these aquatic, microscopic animals are multicellular. About 2000 species have been described. Most inhabit fresh water, but some live in marine environments or damp soil. Marine rotifers are very important in cycling nutrients in marine ecosystems.

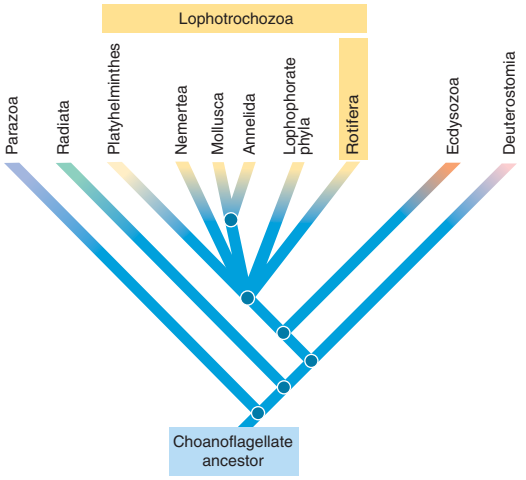
Rotifers were formerly classified as pseudocoelomates, but many biologists now think that rotifers evolved from animals with a coelom (see Figs. 29-7 and 29-8). Because rotifers have a cuticle, some systematists classify them as ecdysozoans related to nematodes and arthropods. However, other systematists classify rotifers with the lophotrochozoans.

Rotifers have a characteristic crown of cilia on their anterior end. The cilia beat rapidly during swimming and feeding, giving the appearance of a spinning wheel (Fig. 30-15). Rotifers feed on tiny organisms suspended in the stream of water drawn into the mouth by the cilia. A muscular organ posterior to the mouth grinds the food. The complete digestive tract ends in an anus through which wastes are eliminated.

Rotifers have a nervous system with a "brain" and sense organs, including eyespots. Protonephridia with flame cells remove excess water from the body and may also excrete metabolic wastes.

Biologists have discovered that rotifers, like some other animals with a pseudocoelom, are "cell constant." Each member of a given species has exactly the same number of cells. Indeed, each part of the body has a precisely fixed number of cells arranged in a characteristic pattern. Cell division does not take place after embryonic development, and mitosis cannot be induced. Growth results from an increase in cell size. One of the challenging problems of biological research is discovering the difference between such nondividing cells and the dividing cells of other animals. Do you think rotifers could develop cancer?

Another interesting characteristic of rotifers is their ability to survive very dry conditions and temperature extremes. These interesting animals can remain in a dormant state for months or years. When conditions become favorable, they recover and become active once again.



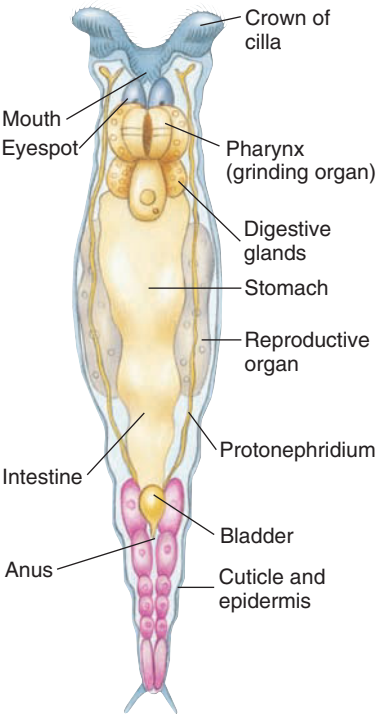


Figure 30-15 ***Animated*** Rotifers (wheel animals)

Review

- What are some advantages of bilateral symmetry and cephalization?
- On what basis have biologists now classified nemerteans as lophotrochozoans?
- How does the lifestyle of a gastropod differ from that of a cephalopod? Identify adaptations that have evolved in each for its particular lifestyle.
- What are two distinguishing characteristics for each of the following: (1) mollusks, (2) annelids, and (3) nematodes?

THE ECDYSOZOA

Learning Objectives

8 List the distinguishing characteristics of phylum Nematoda.
9 Describe the distinguishing characteristics of phylum Arthropoda, and distinguish among the subphyla and classes of this phylum; give examples of animals that belong to each group.
10 Identify adaptations that have contributed to the biological success of insects.

The **Ecdysozoa** include the nematodes (roundworms) and arthropods, animals characterized by a cuticle, a noncellular body covering secreted by the epidermis. The name *Ecdysozoa* refers to the process of **ecdysis,** or **molting,** characteristic of animals in this group. During ecdysis, an animal sheds its cuticle. The taxonomic validity of the Ecdysozoa has been supported by many types of data, most notably by a 2001 study that analyzed more than 300 ribosomal RNA genes and 138 structural characters.

Roundworms are of great ecological importance

Members of phylum **Nematoda,** the **roundworms,** play key ecological roles as decomposers and predators of smaller organisms. Many soil nematodes eat bacteria. Nematodes are numerous and widely distributed in soil and in marine and freshwater sediments. More than 20,000 species have been described, and many more remain to be discovered. The nematodes rival the insects in number of individuals. A spadeful of soil may contain more than a million of these mainly microscopic worms, which thrash around, coiling and uncoiling. *Caenorhabditis elegans,* a free-living soil nematode, is an important model research organism for biologists studying the genetic control of development (see Chapter 17).

The elongated, cylindrical, threadlike nematode body is pointed at both ends and covered with a tough, flexible cuticle (Fig. 30-16). Secreted by the underlying epidermis, the thick cuticle gives the nematode body shape and offers some protection. The epidermis is unusual in that it does not consist of distinct cells.

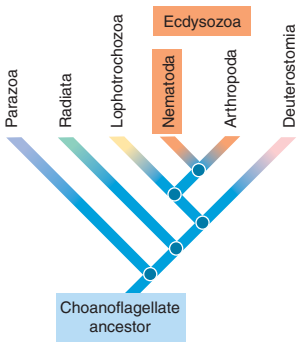

Figure 30-16 LM of a free-living nematode

This unidentified aquatic nematode is shown among the cyanobacterium *Oscillatoria*, which it eats.

Nematodes have a fluid-filled pseudocoelom that serves as a hydrostatic skeleton. It transmits the force of muscle contraction to the enclosed fluid. Movement of fluid in the pseudocoelom is also important in nutrient transport and distribution. Like ribbon worms, nematodes exhibit bilateral symmetry, a complete digestive tract, three definite tissue layers, and definite organ systems; however, they lack specific circulatory structures. The sexes are usually separate, and the male is generally smaller than the female.

Traditionally, biologists classified nematodes as a single phylum based on the pseudocoelom, wormlike body structure, and other characters such as absence of a well-defined head (see Fig. 29-7). However, molecular evidence suggests that nematodes are not a monophyletic group and that they evolved from more complex animals by a simplification in body plan. Systematists now classify nematodes with the Ecdysozoa (see Fig. 29-8). Like arthropods and other ecdysozoans, the nematode sheds its cuticle periodically.

Although most nematodes are free-living, others are important parasites in plants and animals. More than 50 species of roundworms are human parasites, including *Ascaris*, hookworms, pinworms, and the trichina worm. The common intestinal parasite ***Ascaris*** spends its adult life in the human intestine, where it ingests partly digested food (Fig. 30-17). *Ascaris* is a white worm about 25 cm (10 in) long. Like most parasites, it has remarkable reproductive adaptations that ensure survival of its species. A mature female may produce as many as 200,000 eggs per day!

Hookworms attach to the lining of the intestine and suck blood, potentially causing serious tissue damage and blood loss. **Pinworms** are the most common worms found in children. The tiny pinworm eggs are often ingested by eating with hands contaminated with them. The **trichina worm** lives inside a variety of animals, including pigs, rats, and bears. Humans typically become infected by eating undercooked, infected meat. Larvae encyst in skeletal muscle.

Arthropods are characterized by jointed appendages and an exoskeleton of chitin

Phylum **Arthropoda,** the most biologically successful group of animals, includes more than 1 million species, and biologists predict millions more will be identified. More than 80% of all known animals are arthropods! They are more diverse and live in a greater range of habitats than do the members of any other animal phylum. The following adaptations have greatly contributed to their success:

1. The arthropod body, like that of the annelid, is segmented. *Segmentation* is important from an evolutionary perspective because it provides the opportunity for specialization of body regions. In arthropods, groups of segments are specialized, by virtue of their shape, muscles, or the appendages they bear, to perform particular functions.
2. A hard **exoskeleton,** composed of chitin and protein, covers the entire body and appendages. The exoskeleton serves as a coat of armor that protects against predators and helps prevent excessive loss of moisture. It also supports the underlying soft tissues. Arthropods move effectively because distinct muscles attach to the inner surface of the exoskeleton and operate the joints of the body and appendages.

   A disadvantage of the exoskeleton is that it is nonliving, and the arthropod periodically outgrows it. *Molting* is the process of shedding an old exoskeleton and growing a larger one. The shed exoskeleton represents a net metabolic loss, and molting also leaves the arthropod temporarily vulnerable to predators.
3. **Paired, jointed appendages,** from which this phylum gets its name (*arthropod* means "jointed foot"), are modified for many functions. They serve as swimming paddles, walking legs, mouthparts for capturing and manipulating food, sensory structures, or organs for transferring sperm.
4. The nervous system, which resembles that of the annelids, consists of a "brain" (cerebral ganglia) and ventral nerve cord with ganglia. In some arthropods, successive ganglia may fuse. Arthropods have a variety of very effective sense organs. Many have organs of hearing and **antennae** that sense taste and touch. Most insects and many crustaceans have **compound eyes** composed of many light-sensitive units called **ommatidia** (see Fig. 42-17). The compound eye can form an image and is especially adapted for detecting movement.

Arthropods have an *open circulatory system.* A dorsal, tubular heart pumps hemolymph into a dorsal artery, which may branch

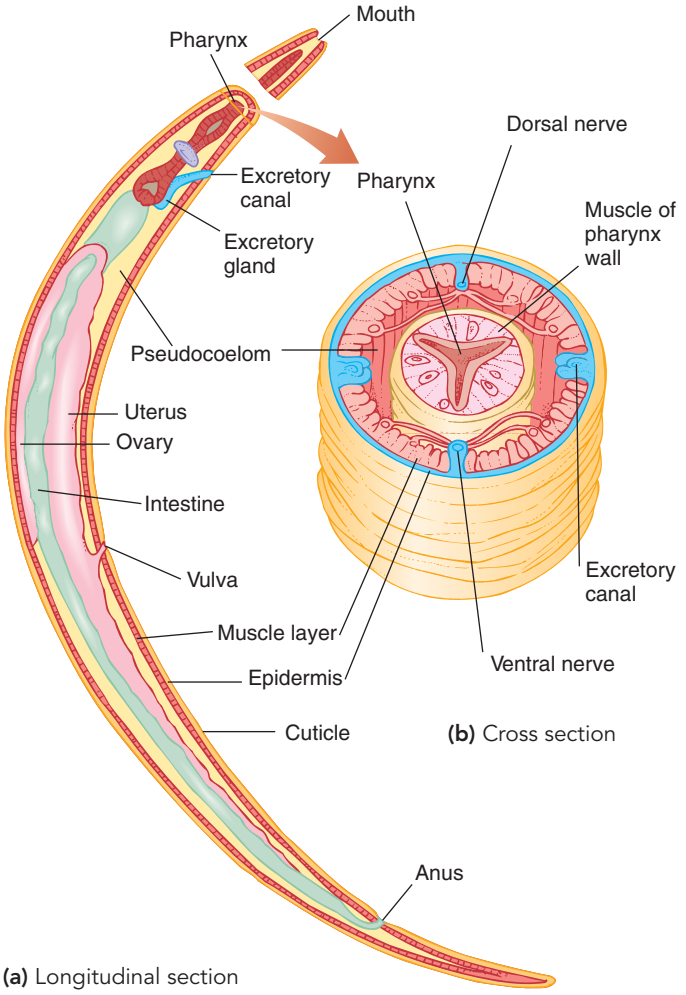

Figure 30-17 ***Animated*** The roundworm *Ascaris*

(a) Note the complete digestive tract that extends from mouth to anus. **(b)** This cross section through *Ascaris* shows the tube-within-a-tube body plan. The protective cuticle that covers the body helps the animal resist drying.

into smaller arteries. From the arteries, hemolymph flows into large spaces that collectively make up the hemocoel. Eventually hemolymph re-enters the heart through openings, called *ostia,* in its walls.

The exoskeleton presents a barrier to diffusion of oxygen and carbon dioxide through the body wall, necessitating the evolution of specialized respiratory systems for gas exchange. Most aquatic arthropods have gills that function in gas exchange, whereas many terrestrial forms have a system of internal branching air tubes called **tracheae,** or **tracheal tubes.** Other terrestrial arthropods have platelike **book lungs.**

The coelom is small and filled chiefly by the organs of the reproductive system. The arthropod digestive system is a tube similar to that of the earthworm. Excretory structures vary somewhat from class to class.

Arthropod evolution and classification are controversial

Two groups of animals thought to be closely related to arthropods are the onychophorans and the tardigrades (Fig. 30-18). Like arthropods, onychophorans and tardigrades have a thick cuticle and must molt in order to grow. The body is segmented in all three groups, and all share similarities in the circulatory system.

The wormlike members of phylum **Onychophora,** or velvet worms, most likely branched early from the arthropod line. They have paired appendages, but they are not jointed. As in arthropods, their jaws are derived from appendages. Some biologists place the tardigrades, or water bears, as the sister taxon of the arthropods (see Fig. 2-12). Assigned to phylum **Tardigrada,** these tiny animals have unbranched, clawed legs.

Arthropod fossils have been identified that date back to the Proterozoic eon. Early in their evolutionary history, more than 540 million years ago (mya), arthropods diverged into several groups. Arthropods evolved rapidly during the Cambrian Radiation, as evidenced by many diverse fossils in the Burgess Shale and other ancient sites.

We discuss five main arthropod groups, based on emerging molecular and other data: the extinct trilobites, and the extant Myriapoda, Chelicerata, Crustacea, and Hexapoda (Table 30-4). Some systematists consider each of these groups a phylum; others view them as subphyla or classes. In this edition, we classify these groups as subphyla. However, as you study the following sections, bear in mind that arthropod systematics is a work in progress. Both the relationship of arthropods to other protostomes and the relationships among arthropods continue to be topics of lively debate.

Trilobites were early arthropods

Among the earliest arthropods to evolve, **trilobites** inhabited shallow Paleozoic seas more than 500 mya. These arthropods, which have been extinct for about 250 million years, lived on the

Dr. Morley Read/Photo Researchers, Inc.

(a) Onychophoran. Note the soft segmented body and series of non-jointed legs. Extant onychophorans live in humid forests, although many extinct species inhabited the ocean.

Andrew Syred/Photo Researchers, Inc.

(b) Tardigrades. Commonly known as water bears, tardigrades normally live in moist habitats, such as thin films of water on mosses. Most are less than 0.5 mm long.

Figure 30-18 Onychophorans and tardigrades

These animals are not arthropods but are thought to be close relatives.

TABLE 30-4

Extant Arthropod Subphyla

Subphylum and Selected Classes	Body Divisions	Appendages: Antennae, Mouthparts	Appendages: Legs	Gas Exchange	Development	Main Habitat
Myriapoda Class Chilopoda (centipedes) Class Diplopoda (millipedes)	Head with segmented body	Uniramous. Antennae: one pair Mouthparts: mandibles, maxillae	Chilopods: one pair/segment Diplopods: usually two pairs/segment	Tracheae	Direct	Terrestrial
Chelicerata Class Merostoma (horseshoe crabs) Class Arachnida (spiders, scorpions, ticks, mites)	Cephalothorax and abdomen	Uniramous. Antennae: none Mouthparts: chelicerae, pedipalps	Merostomes: five pairs of walking legs Arachnids: four pairs on cephalothorax	Merostomes: gills Arachnids: book lungs or tracheae	Direct, except mites and ticks	Merostomes: marine Arachnids: mainly terrestrial
Crustacea Class Malacostraca (lobsters, crabs, shrimp, isopods) Class Cirripedia (barnacles) Class Copepoda (copepods)	Head, thorax, and abdomen	Biramous. Antennae: two pairs Mouthparts: mandibles, two pairs of maxillae (for handling food)	Typically one pair/segment	Gills	Usually larval stages (nauplius larva)	Marine or freshwater; a few are terrestrial
Hexapoda Class Insecta (bees, ants, grasshoppers, roaches, flies, beetles)	Head, thorax, and abdomen	Uniramous. Antennae: one pair Mouthparts: mandibles, maxillae	Three pairs on thorax	Tracheae	Typically, larval stages; most with complete metamorphosis	Mainly terrestrial

sea bottom and filtered mud to obtain food. Most ranged from 3 to 10 cm (about 1 to 4 in), but a few reached almost 1 m (39 in) in length.

Covered by a hard, segmented exoskeleton, the trilobite body was a flattened oval divided into three parts: an anterior head bearing a pair of antennae and a pair of compound eyes; a thorax; and a posterior abdomen (Fig. 30-19; also see introduction to Chapter 21). At right angles to these divisions, two dorsal grooves extended the length of the animal, dividing the body into a median lobe and two lateral lobes. (The name *trilobite* derives from this division of the body into three longitudinal parts.) Each segment had a pair of segmented **biramous appendages,** appendages with two jointed branches extending from their base. In trilobites, each appendage consisted of an inner walking leg and an outer branch with gills.

Subphylum Myriapoda includes centipedes and millipedes

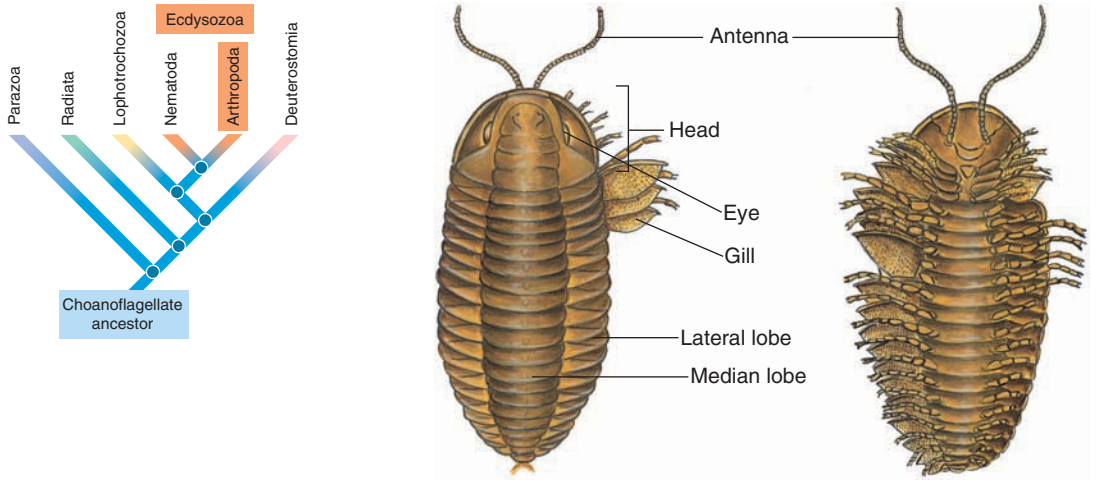
Members of subphylum **Myriapoda** are characterized by unbranched appendages called **uniramous appendages,** jawlike **mandibles,** and a single pair of antennae. Centipedes (class **Chilopoda**) and millipedes (class **Diplopoda**) are terrestrial and are typically found beneath stones or wood in the soil in both temperate and tropical regions. Both of these animals have a head and an elongated trunk with many segments, each bearing uniramous legs (Fig. 30-20).

Centipedes ("hundred-legged") have one pair of legs on each segment behind the head. Most centipedes do not have enough legs to merit their name; typically, they have approximately 30, although a few species have 100 or more. Because centipedes have long legs, they are able to run rapidly. Centipedes are carnivorous and feed on other animals, mostly insects. Larger centipedes eat snakes, mice, and frogs. Using their poison claws located just behind the head on the first trunk segment, centipedes capture and kill their prey.

Millipedes ("thousand-legged") have two pairs of legs on most body segments. Diplopods are not as agile as chilopods, and most species can crawl only slowly over the ground. However, they can powerfully force their way through earth and rotting wood. Millipedes are generally herbivorous and feed on both living and dead vegetation.

Chelicerates have no antennae

Subphylum **Chelicerata** includes the merostomes (horseshoe crabs) and the arachnids. The chelicerate body consists of a *cephalothorax* (fused head and thorax) and an abdomen. Chelicerates are the only arthropods without antennae. They have no chewing mandibles. Instead, the first appendages, located immediately anterior to the mouth, are a pair of **chelicerae** (sing., *chelicera*), fanglike feeding appendages. The second appendages are the **pedipalps.** The chelicerae and pedipalps are modified to perform different functions in various groups, including manipulation of



(a) Dorsal view of a trilobite. **(b)** Ventral view.

Figure 30-19 Trilobites

Biologists consider these extinct marine arthropods the most primitive members of the phylum.

(a) Centipede (*Lithobius*), a member of class Chilopoda. Centipedes have one pair of uniramous appendages per segment.

John R. MacGregor/Peter Arnold, Inc.

(b) Millipede (*Diplopoda pachydesmus*), a member of class Diplopoda. Millipedes have two pairs of uniramous appendages per segment.

Figure 30-20 Myriapods

food, locomotion, defense, and copulation. The four pairs of legs on the cephalothorax are specialized for walking.

Almost all the **merostomes** are extinct. Only the horseshoe crabs have survived, essentially unchanged for more than 350 million years. *Limulus polyphemus,* the species common along the shore of North America, is horseshoe shaped (Fig. 30-21a). Its long, spikelike tail is used in locomotion, not for defense or offense. Horseshoe crabs feed on mollusks, worms, and other invertebrates that they find on the sandy ocean floor.

Arachnids include spiders, scorpions, ticks, harvestmen (daddy longlegs), and mites (Fig. 30-21b and c). Most of the approximately 65,000 named species are carnivorous and prey on insects and other small arthropods. Arachnids have six pairs of jointed appendages. In spiders, the first appendages, the chelicerae, are used to penetrate prey; some species use the chelicerae to inject poison into their prey. Spiders use the second pair of appendages, the pedipalps, to hold and chew food. Many arachnid species have pedipalps modified as sense organs for tasting food or for reproduction (for sperm transfer and courtship displays). Scorpions use their very large pedipalps as pincers for capturing prey. Chelicerates use the remaining four pairs of appendages for walking.

Typically, spiders have eight eyes arranged in two rows of four each along the anterior dorsal edge of the cephalothorax. The eyes detect movement, locate objects, and in some species form a relatively sharp image.

Gas exchange in arachnids takes place by either tracheal tubes, book lungs, or both. A *book lung* consists of 15 to 20 plates (like pages of a book) that contain tiny blood vessels. Air enters the body through abdominal slits and circulates between the plates. As air passes over the blood vessels in the plates, oxygen diffuses into the blood and carbon dioxide diffuses out of the blood into the air. As many as four pairs of book lungs provide an extensive surface area for gas exchange.

(b) A female black widow spider (*Latrodectus mactans*) rests on her web. The venom of the black widow spider is a neurotoxin.

Figure 30-21 Chelicerates

The spider has unique glands in its abdomen that secrete silk, an elastic protein that is spun into fibers by organs called *spinnerets*. The silk is liquid as it emerges from the spinnerets but hardens after it leaves the body. Spiders use silk to build nests, to encase their eggs in a cocoon, and in some species, to trap prey in a web. Many spiders lay down a silken dragline that serves both as a safety line and a means of communication between members of a species. From the type of dragline, another spider can determine the sex and maturity level of the spinner.

Although all spiders (and scorpions) have poison glands useful in capturing prey, only a few produce poison toxic to humans. The most widely distributed poisonous spider in the United States is the black widow (see Fig. 30-21b). Its venom is a neurotoxin that interferes with transmission of messages from nerves to muscles. The shiny black female is about 3.8 cm (1.5 in) long with a red or orange hourglass-shaped marking on the underside of its abdomen. Adult male black widow spiders are smaller and are harmless. After mating, the female sometimes kills and eats the male.

The brown recluse spider (*Loxosceles reclusa*) is more slender than the black widow and has a violin-shaped dorsal stripe on its cephalothorax. Its venom destroys the tissues surrounding the bite. Although painful, spider bites cause fewer than five fatalities per year in the United States.

Although some mites contribute to soil fertility by breaking down organic matter, many are serious nuisances. They eat crops, infest livestock and pets, and inhabit our own bodies. Certain mites cause mange in dogs and other domestic animals. Chiggers (red bugs), the larval form of red mites, attach themselves to the skin and secrete an irritating digestive fluid that may cause itchy red welts.

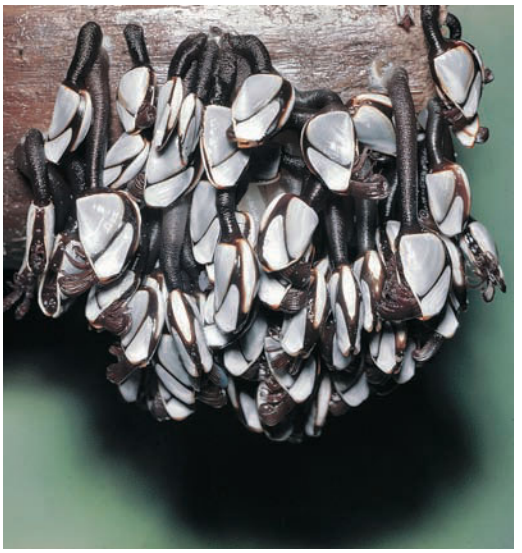
Larger than mites, ticks are parasites on dogs, deer, and many other animals. They transmit diseases such as Rocky Mountain spotted fever, Texas cattle fever, relapsing fever, and Lyme disease (see Fig. 53-1).

Crustaceans are vital members of marine food webs

Subphylum **Crustacea** includes lobsters, crabs, shrimp, barnacles, and their relatives (Fig. 30-22). Paleobiologists have dated crustacean fossils back to the Cambrian period (more than 505 mya). At present, most biologists agree that crustaceans form a clade with members of subphylum Hexapoda (insects); these two subphyla are sister taxa (see Chapter 23).

Many crustaceans are primary consumers of algae and detritus. Countless billions of microscopic crustaceans are part of marine zooplankton, the free-floating, mainly microscopic organisms in the upper layers of the ocean. These crustaceans are food for many fishes and other marine animals, such as certain baleen whales.

A distinctive feature of crustaceans is the *nauplius larva,* which is often the first stage after hatching. This larva has only the most anterior three pairs of appendages. Crustaceans are



Tim Dyes

Fred Bavendam/Peter Arnold, Inc.

(b) This sponge crab (*Criptodromia octodenta*), photographed in Australia, wears a living sponge on its back as camouflage.

Figure 30-22 Crustaceans

Isopods are mainly tiny (5 to 15 mm in length) marine crustaceans that inhabit the ocean floor. However, this group includes some familiar terrestrial animals: pill bugs and sow bugs. The typically microscopic *copepods* are the most abundant crustaceans. Marine copepods are the most numerous component of zooplankton.

The largest and most familiar order of crustaceans, Decapoda, contains more than 10,000 species of lobsters, crayfish, crabs, and shrimp. Most decapods are marine, but a few, such as the crayfish, certain shrimp, and a few crabs, live in fresh water. The crustaceans in general and the decapods in particular show striking specialization and differentiation of parts in the various regions of the animal. In the lobster, the appendages in the different parts of the body differ markedly in form and function (Fig. 30-23).

also characterized by mandibles, biramous appendages, and two pairs of antennae. Their antennae serve as sensory organs for touch and taste. Most adult crustaceans have compound eyes, and many crustaceans have **statocysts,** sense organs that detect gravity (see Fig. 42-6).

The hard **mandibles,** used for biting and grinding food, are the third pair of appendages; they lie on each side of the ventral mouth. Posterior to the mandibles are two pairs of appendages, the first and second **maxillae,** used for manipulating and holding food. Several other pairs of appendages are present. Some are modified for walking. Others may be specialized for swimming, sperm transmission, carrying eggs and young, or sensation.

Crustaceans are the only group of arthropods that are primarily aquatic; not surprisingly, they typically have gills for gas exchange. Two large glands located in the head excrete metabolic wastes and regulate salt balance. Most crustaceans have separate sexes. During copulation, the male uses specialized appendages to transfer sperm into the female. Newly hatched animals may resemble adults, or they may undergo successive molts as they pass through a series of larval stages before they develop an adult body.

Barnacles, the only sessile crustaceans, differ markedly in external anatomy from other members of the subphylum. They are marine suspension feeders that secrete limestone cups within which they live (see Fig. 30-22a). The larvae of barnacles are free-swimming forms that go through several molts. They eventually become sessile and develop into the adult form. The 19th-century naturalist Louis Agassiz described the barnacle as "nothing more than a little shrimplike animal standing on its head in a limestone house and kicking food into its mouth." The bane of marine boaters, barnacles can proliferate on ship bottoms in great numbers. Their presence can reduce the speed of a ship by more than 30%.

The five segments of the lobster's head and the eight segments of its thorax are fused into a cephalothorax, which is covered on the top and sides by a shield, the **carapace,** composed of chitin impregnated with calcium salts. The two pairs of antennae serve as chemoreceptors and tactile sense organs. The mandibles are short and heavy, with opposing surfaces used in grinding and biting food. Behind the mandibles are two pairs of accessory feeding appendages: the first and second maxillae.

The appendages of the first three segments of the thorax are the maxillipeds, which aid in chopping up food and passing it to the mouth. The fourth segment of the thorax has a pair of large **chelipeds,** or pinching claws. The last four thoracic segments bear walking legs.

The appendages of the first abdominal segment are part of the reproductive system and function in the male as sperm-transferring structures. The following four abdominal segments bear paired **swimmerets,** small paddlelike structures used by some decapods for swimming and by the females of all species for holding eggs. Each branch of the sixth abdominal appendages consists of a large flattened structure. Together with the flattened posterior end of the abdomen, they form a tail fan used for swimming backward.

Insects belong to subphylum Hexapoda

With more than 1 million described species (and perhaps millions more not yet identified), class **Insecta** of subphylum **Hexapoda** is the most successful group of animals on our planet in terms of diversity, geographic distribution, number of species, and num-

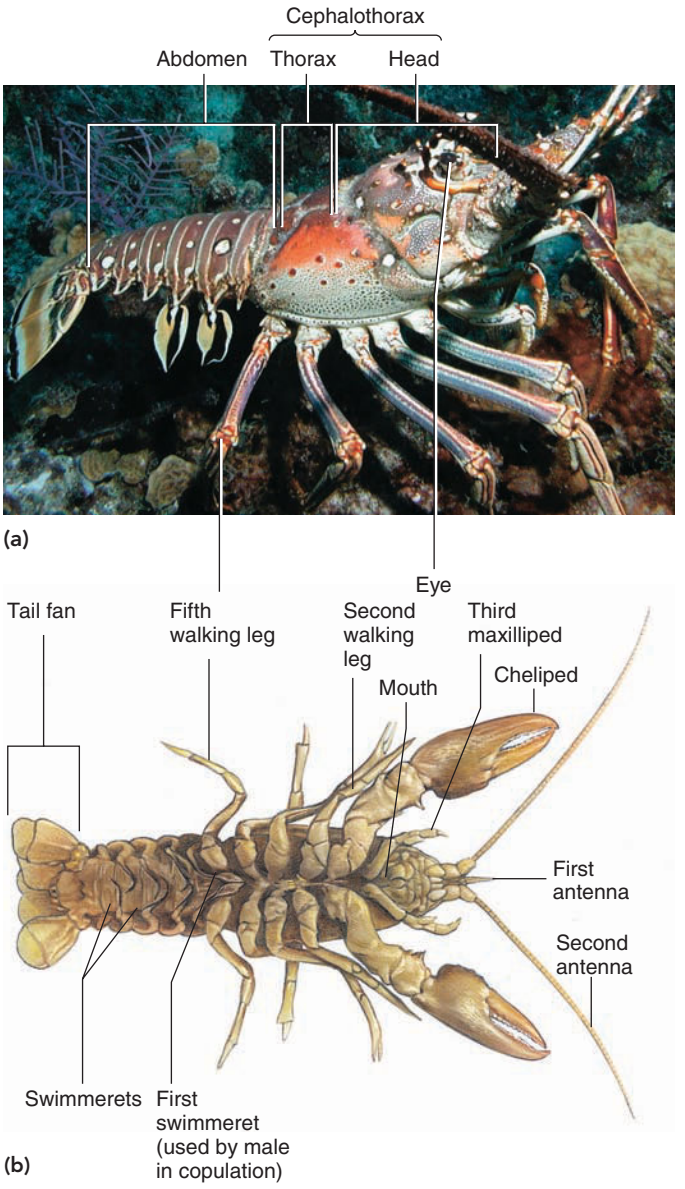

Figure 30-23 Anatomy of the lobster

(a) Like other decapods, the spiny lobster (*Panulirus argus*) has five pairs of walking legs. The first pair of walking legs is modified as chelipeds (*large claws*). Photographed in Grand Cayman. **(b)** Ventral view of a lobster. Note the variety of specialized appendages.

Key Point

Insects, the most successful of all animals, are articulated, tracheated hexapods.

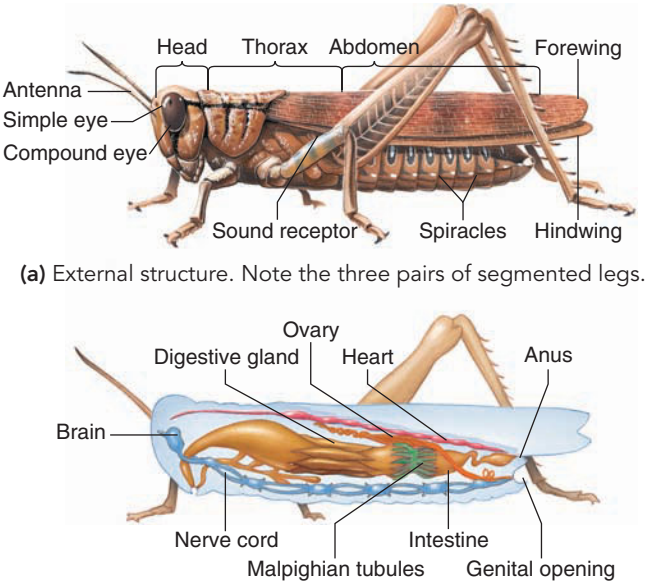

Figure 30-24 ***Animated*** Anatomy of the grasshopper

ber of individuals (▮ Table 30-5).What they lack in size, insects make up in sheer numbers. If we could weigh all the insects in the world, their weight would exceed that of all the remaining terrestrial animals. Although primarily terrestrial, some insect species live in fresh water, a few are truly marine, and others inhabit the shore between the tides.

The earliest fossil insects—primitive, wingless species—date to the Devonian period more than 360 mya. Insect fossils from the Carboniferous period more than 300 mya include both wingless and primitive winged species. Cockroaches, mayflies, and cicadas are among the insects that have survived relatively unchanged from the Carboniferous period to the present day. Until recently, biologists thought that insects made up a monophyletic taxon and were closely related to myriapods (centipedes and millipedes). Recent molecular and developmental studies suggest that insects are not a monophyletic group and are more closely related to crustaceans. Molecular data also suggest that a group of wingless soil organisms known as *springtails* (order Collembola) may have evolved independently of the insects. Some evidence suggests that springtails branched earlier than crustaceans off the line leading to insects. Unlike insects, springtails have internal mouthparts.

We describe an insect as an **articulated** (jointed), **tracheated** (having tracheal tubes for gas exchange) **hexapod** (having six feet). The insect body consists of three distinct parts: head, thorax, and abdomen (▮ Fig. 30-24). An insect's uniramous (unbranched) appendages include three pairs of legs that extend from the adult thorax and, in many orders, one or two pairs of wings. One pair of antennae protrudes from the head, and the sense organs include both simple and compound eyes. The complex mouthparts, which include mandibles and maxillae, are adapted for piercing, chewing, sucking, or lapping.

The tracheal system of insects has made an important contribution to their diversity. Air enters the tracheal tubes, or tracheae, through **spiracles,** tiny openings in the body wall. Oxygen passes directly to the internal organs. This effective oxygen delivery system permits insects to have the high metabolic rate neces-

TABLE 30-5

Some Orders of Insects

Order, Number of Species, Some Characteristics, and Representative Adult

Insects with Incomplete Metamorphosis (egg ⟶ larva ⟶ adult)

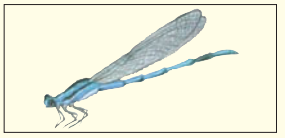
Homoptera (43,000)

Aphids, leafhoppers, cicadas, scale insects
Two pairs of membranous wings; piercing–sucking mouthparts form beak; parasites of plants; vectors of plant diseases

Buffalo treehopper
Stictocephala bubalus

Odonata (6000)

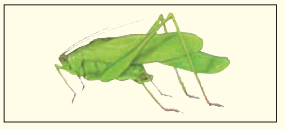
Dragonflies, damselflies
Two pairs of long membranous wings; chewing mouthparts; large, compound eyes; active predators; larvae very different from adult



Damselfly
Ischnura

Orthoptera (20,000)

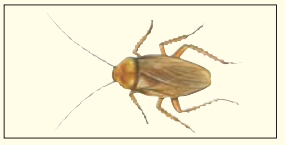
Grasshoppers, crickets
Forewings leathery, hindwings membranous; chewing mouthparts; most herbivorous, some cause crop damage; some predatory



Fork-tailed bush katydid
Scudderia furcata

Blattaria (3700)

Cockroaches
When wings present, forewings leathery, hindwings membranous; chewing mouthparts; legs adapted for running



American cockroach
Periplaneta americana

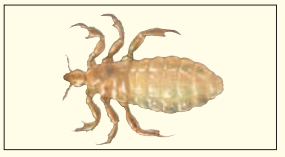
Isoptera (2000)

Termites
Two pairs of wings, or none; wings shed by sexual forms after mating; chewing mouthparts; social insects, form large colonies; eat wood

Eastern subterranean termite
Reticulitermes flavipes

Phthiraptera (3000)

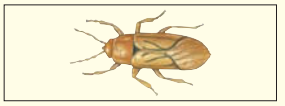
Sucking lice
No wings; piercing–sucking mouthparts; ectoparasites of mammals; head and body louse and crab louse are human parasites; vectors of typhus fever



Human head and body louse
Pediculus humanus

Hemiptera (true bugs) (68,000)

Chinch bugs, bedbugs, water striders
Hindwings membranous; forewings smaller; piercing–sucking mouthparts form beak; most herbivorous; some parasitic

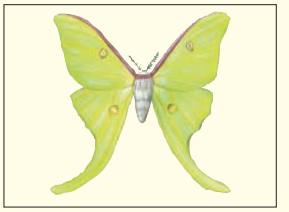


Chinch bug
Blissus leucopterus

Insects with Complete Metamorphosis (egg ⟶ larva ⟶ pupa ⟶ adult)

Lepidoptera (140,000)

Moths, butterflies
Usually two pairs of membranous, colorful, scaled wings; sucking mouthparts; larvae are wormlike caterpillars that eat plants; adults suck flower nectar; important pollinators



Luna moth
Aetias luna

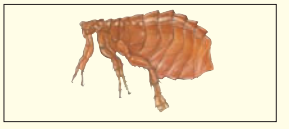
Diptera (150,000)

Houseflies, mosquitoes
Only forewings functional in flying; hindwings small, knoblike balancing organs (halteres); mouthparts usually adapted for sucking (and piercing in some); larvae are maggots that damage domestic animals or food; adults transmit diseases such as sleeping sickness, yellow fever, and malaria

Deerfly
Chrysops vittatus

Siphonaptera (1750)

Fleas
No wings; piercing–sucking mouthparts; legs adapted for clinging and jumping; parasites on birds and mammals; vectors of bubonic plague and typhus



Dog flea
Ctenocephalides canis

Coleoptera (350,000)

Beetles, weevils
Forewings modified as protective coverings for membranous hindwings (which are sometimes absent); chewing mouthparts; largest order of insects; most herbivorous; some aquatic

Colorado potato beetle
Leptinotarsa decemlineata

Hymenoptera (190,000)

Ants, bees, wasps
Usually two pairs of membranous wings; mouthparts may be modified for sucking or lapping nectar; many are social insects; some sting; important pollinators

Bald-faced hornet
Vespula maculata

Insects with No Metamorphosis (egg ⟶ immature form ⟶ adult)

Thysanura (320)

Silverfish
No wings; biting–chewing mouthparts; two to three "tails" extend from posterior tip of abdomen; inhabit dead leaves; eat starch in books

Silverfish
Lepisma saccharina

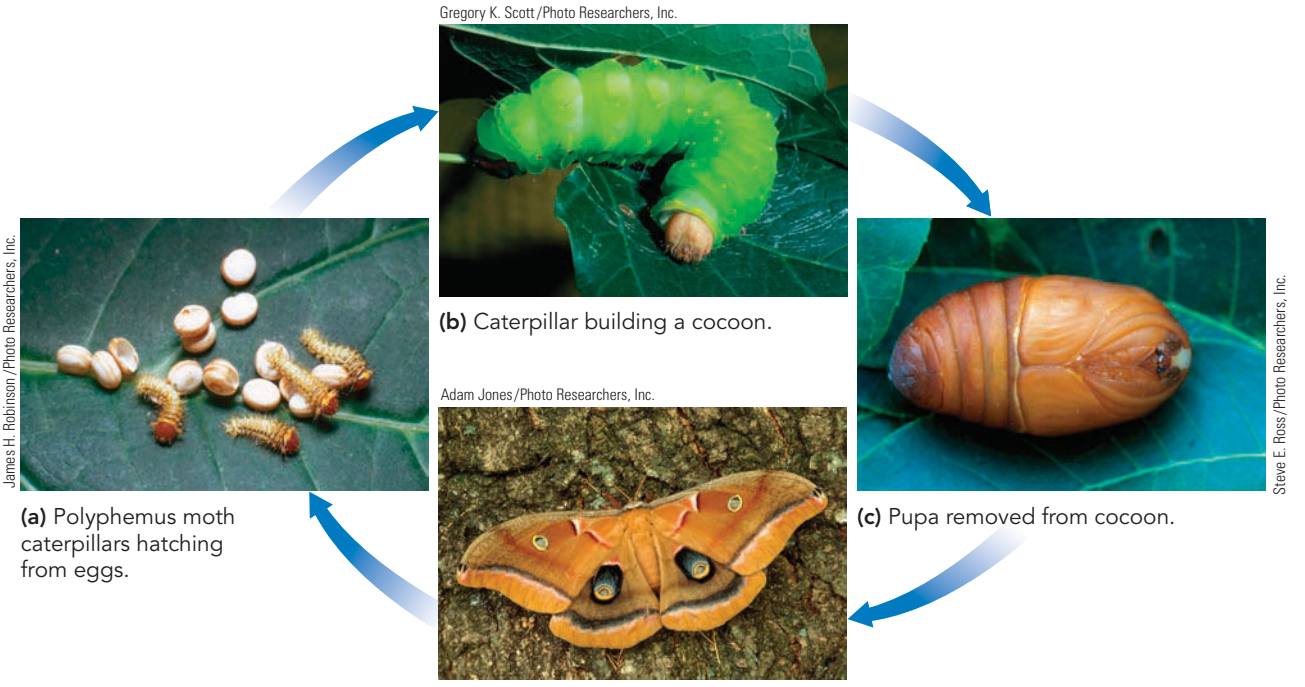


Figure 30-25 ***Animated*** Complete metamorphosis in a Polyphemus moth

This moth (*Antheraea polyphemus*) belongs to the family of giant silk moths.

sary for activities such as flight, even though they have an open circulatory system.

Excretion is accomplished by two or more **Malpighian tubules,** which receive metabolic wastes from the blood, concentrate the wastes, and discharge them into the intestine. Unique to terrestrial arthropods, Malpighian tubules also perform the extremely important function of conserving water (see Fig. 47-4).

The sexes are separate, and fertilization takes place internally. Several molts occur during development. The immature stages between molts are called **instars.** Primitive insects with no wings, such as silverfish, have direct, or simple, development: the young hatch as juveniles that resemble the adult form. Other insects, such as grasshoppers and cockroaches, undergo **incomplete metamorphosis** in which the egg gives rise to a larva that resembles the adult in many ways but lacks functional wings and reproductive structures. The larva goes through a series of molts during which it becomes more like the adult.

Most insects, including bees, butterflies, and fleas, undergo **complete metamorphosis** with four distinct stages in the life cycle: **egg, larva, pupa,** and **adult** (Fig. 30-25). The wormlike larva does not look at all like the adult. For example, caterpillars have a body form entirely different from that of butterflies. Typically, an insect spends most of its life as a larva. Eventually the larva stops feeding, molts, and enters a pupal stage, usually within a protective cocoon or underground burrow. The pupa does not feed and typically cannot defend itself. Energy reserves stored during the larval stage are spent remodeling its body. When it emerges as an adult, it is equipped with functional wings and reproductive organs.

Certain species of bees, ants, and termites exist as colonies or societies made up of several different types of individuals, each adapted for some particular function. The members of some insect societies communicate with one another by "dances" and by means of **pheromones,** substances secreted to the external environment. Social insects and their communication are discussed in Chapter 51.

Adaptations that contribute to the biological success of insects. What are the secrets of insect success? The tough exoskeleton protects insects from predators and helps prevent water loss. Segmentation allows mobility and flexibility and permits regional specialization of the body. For example, cephalization and highly developed sense organs are important in both offense and defense.

The insect body plan has been modified and specialized in so many ways that insects are adapted to a remarkable number of lifestyles. The jointed appendages are specialized for various types of feeding, sensory functions, and different types of locomotion (walking, jumping, swimming). For example, grasshopper mouthparts are adapted for biting and chewing leaves. Moth and butterfly mouthparts are adapted for sucking nectar from flowers, and mosquito mouthparts are adapted for sucking blood. Aphids and leafhoppers have mouthparts specialized to pierce plants and feed on plant juices.

Another adaptation that contributes to insect success is the ability to fly. Unlike other terrestrial invertebrates, which creep slowly along on or under the ground, many insects fly rapidly through the air. Their wings and small size facilitate their wide

distribution and, in many instances, their immediate survival. For example, when a pond dries up, adult aquatic insects can fly to another habitat.

The reproductive capacity of insects is remarkable. Under ideal conditions, the fruit fly *Drosophila* can produce 25 generations in a single year! Insect eggs are protected by a thick membrane, and several eggs may, in addition, be enclosed in a protective egg case. By dividing the insect life cycle into different stages, metamorphosis reduces intraspecific competition; larval forms have different lifestyles, so they do not compete with adults for food or habitats.

Insects have many interesting adaptations for offense and defense (see Fig. 7-8).We all are familiar with the stingers of bees and wasps, which are specialized egg-laying structures (ovipositors). Many insects have **cryptic coloration,** which allows them to blend into the background of their habitat; some look like dead twigs or leaves. Others mimic poisonous insects, deriving protection from this resemblance. Still others "play dead" by remaining motionless.

Insects communicate by tactile, auditory, visual, or chemical signals. For example, certain ant species use pheromones to mark trails and to warn of danger. Other insects use pheromones to attract a mate.

Impact of insects on humans. Not all insects compete with humans for food or cause us to scratch, swell up, or recoil from their presence. Bees, wasps, beetles, and many other insects pollinate flowers of crops and fruit trees. Some insects destroy other insects that are harmful to humans. For example, dragonflies eat mosquitoes. And some organic farmers and home gardeners buy ladybird beetles, which are adept at ridding plants of aphids and other insect pests. Insects are important members of many food webs. Many birds, mammals, amphibians, reptiles, and some fishes depend on insects for food. Some beetles and the larvae (maggots) of flies are detritus feeders—they break down dead plants and animals and their wastes, permitting nutrients to be recycled.

Various insect products are useful to humans. Bees produce honey as well as beeswax, which we use to make candles, lubricants, and other products. Shellac is made from lac, a substance given off by certain scale insects that feed on the sap of trees. And the labor of silkworms provides us with beautiful fabric.

On the negative side, insects destroy billions of dollars worth of crops each year. Termites destroy buildings, and moths damage clothing. Fire ants not only inflict painful stings but cause farmers serious economic loss because of their large mounds, which damage mowers and other farm equipment. Blood-sucking flies, screwworms, lice, fleas, and other insects annoy and transmit disease in humans and domestic animals. Mosquitoes are vectors of yellow fever and malaria (see Fig. 25-10). Body lice transmit the typhus rickettsia, and houseflies sometimes transmit typhoid fever and dysentery. Tsetse flies transmit African sleeping sickness, and fleas may be vectors of bubonic plague.

Review

- What functions does the pseudocoelom have in nematodes?
- What are four key arthropod characteristics, and how does each contribute to arthropod success?
- How do myriapods differ from chelicerates?
- What are the functions of each of these appendages in a lobster: maxillae, chelipeds, and swimmerets?
- Define an insect. What are four adaptations that have contributed to insect success?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Cite specific examples of the evolutionary significance of the coelom (page 641).

- The true **coelom** is a fluid-filled body cavity completely lined by mesoderm that lies between the digestive tube and the outer body wall. The coelom allows the **tube-within-a-tube body plan.** The body wall is the outer tube. The inner tube is the digestive tube.
- Because the coelom is an enclosed compartment (or series of compartments) of fluid under pressure, it can serve as a **hydrostatic skeleton** in which contracting muscles push against a tube of fluid.
- The coelom is a space in which internal organs, including gonads, can develop. The coelom helps transport materials and protects internal organs.

2 Characterize the protostomes, describe their two main evolutionary branches, and give examples of animals assigned to each branch (page 641).

- The **protostomes** are characterized by spiral cleavage, determinate cleavage, and the development of the mouth from the blastopore.
- The protostomes include two main branches: Lophotrochozoa and Ecdysozoa. The **Lophotrochozoa** include the platyhelminths, nemerteans, mollusks, annelids, the lophophorate phyla, and the rotifers. The **Ecdysozoa** include the nematodes (roundworms) and arthropods.

3 Identify distinguishing characteristics of phylum Nemertea and phylum Platyhelminthes; describe the main classes of phylum Platyhelminthes, giving examples of animals that belong to each class (page 641).

- Phylum **Nemertea** (ribbon worms) is characterized by the **proboscis,** a muscular tube used in capturing food and in defense. The coelom is reduced; it consists of the **rhynchocoel,** a space surrounding the proboscis. Nemerteans have a tube-within-a-tube body plan, a complete digestive tract with mouth and anus, and a circulatory system.
- Members of phylum **Platyhelminthes,** the **flatworms,** are **acoelomate** animals with bilateral symmetry, **cephalization,** three definite tissue layers, and well-developed organs. Many flatworms are **hermaphrodites;** a single animal produces both sperm and eggs. Flatworms have a ladder-type nervous system, typically consisting of sense organs and a simple brain composed of two **ganglia** connected to two nerve cords that extend the length of the body. They have **protonephridia,** organs that function in osmoregulation and disposal of metabolic wastes.

- Phylum Platyhelminthes includes four classes: Class **Turbellaria** comprises free-living flatworms, including **planarians.** Classes **Trematoda** and **Monogenea** include the parasitic **flukes;** the parasitic tapeworms compose class **Cestoda.** The parasitic flukes and tapeworms typically have suckers or hooks for holding on to their hosts; they have complicated life cycles with intermediate hosts and produce large numbers of eggs.

ThomsonNOW™ Watch the fluke and tapeworm life cycles by clicking on the figures in ThomsonNOW.

4 Describe the adaptive advantages of cephalization (page 641).
- Flatworms show the beginnings of cephalization, the evolution of a head with the concentration of sense organs and nerve cells (a simple brain) at the anterior end. Cephalization increases the effectiveness of a bilateral animal to actively find food, shelter, and mates and to detect enemies.

5 Describe the distinguishing characteristics of phylum Mollusca and the four molluscan classes discussed, giving examples (page 641).
- Members of phylum **Mollusca** are soft-bodied animals usually covered by a shell. They have a ventral **foot** for locomotion and a **mantle** that covers the **visceral mass,** a concentration of body organs.
- Mollusks have an **open circulatory system** with the exception of cephalopods, which have a **closed circulatory system.** A rasplike **radula** functions as a scraper in feeding in all groups except the bivalves, which are suspension feeders. Typically, marine mollusks have a free-swimming, ciliated **trochophore larva.**
- Class **Polyplacophora** includes the marine **chitons,** which have shells that consist of eight overlapping plates. Class **Gastropoda,** the largest group of mollusks, includes the snails, slugs, and their relatives. In gastropods, the body undergoes **torsion,** a twisting of the visceral mass. Class **Bivalvia** includes the aquatic clams, scallops, and oysters; a two-part shell, hinged dorsally, encloses the bodies of these suspension feeders. Class **Cephalopoda** includes the squids, octopods, and *Nautilus.* Cephalopods are active, predatory swimmers. Tentacles surround the mouth, which is located in the large head.

6 Describe the distinguishing characteristics of phylum Annelida and the three annelid classes discussed, giving examples (page 641).
- Phylum **Annelida,** the segmented worms, includes many aquatic worms, earthworms, and leeches. Annelids have conspicuously long bodies with **segmentation** both internally and externally; their large, compartmentalized coelom serves as a hydrostatic skeleton.
- Class **Polychaeta** consists of marine worms characterized by **parapodia,** appendages used for locomotion and gas exchange. The parapodia bear many bristlelike structures called **setae.** Polychaetes also differ from other annelids in having a well-defined head with sense organs. Class **Oligochaeta,** which comprises the earthworms, is characterized by a few short setae per segment. The body is divided into more than 100 segments separated internally by **septa.** Class **Hirudinea,** the leeches, is characterized by the absence of setae and appendages. Parasitic leeches are equipped with suckers for holding on to their host.

7 Describe the distinguishing characteristics of the lophophorate phyla (page 641).
- The **lophophorate phyla,** marine animals that have a lophophore, include the **brachiopods, phoronids,** and **bryozoans.** The **lophophore,** a ciliated ring of tentacles surrounding the mouth, is specialized for capturing suspended particles in the water.

8 List the distinguishing characteristics of phylum Nematoda (page 654).
- Phylum **Nematoda,** the **roundworms,** consists of highly successful ecdysozoans. Nematodes have a pseudocoelom. The body is covered by a tough **cuticle** that helps prevent desiccation. Parasitic nematodes in humans include ***Ascaris,*** **hookworms, trichina worms,** and **pinworms.**

9 Describe the distinguishing characteristics of phylum Arthropoda, and distinguish among the subphyla and classes of this phylum; give examples of animals that belong to each group (page 654).
- Phylum **Arthropoda** is composed of segmented animals with **paired, jointed appendages** and an armorlike **exoskeleton** of chitin. **Molting** is necessary for the arthropod to grow. Arthropods have an open circulatory system with a dorsal heart that pumps **hemolymph.** Aquatic forms have gills for gas exchange; terrestrial forms have either **tracheae** or **book lungs.**
- The **trilobites** are extinct marine arthropods covered by a hard, segmented shell. Each segment had a pair of **biramous appendages,** appendages with two jointed branches, an inner walking leg and an outer gill branch.
- Subphylum **Myriapoda** includes class **Chilopoda,** the centipedes, and class **Diplopoda,** the millipedes. Members of this subphylum have **uniramous** (unbranched) **appendages** and a single pair of antennae.
- Subphylum **Chelicerata** includes the **merostomes** (horseshoe crabs) and the **arachnids** (spiders, mites, and their relatives). The chelicerate body consists of a cephalothorax and abdomen; there are six pairs of uniramous, jointed appendages, of which four pairs serve as legs. The first appendages are **chelicerae;** the second are **pedipalps.** These appendages are adapted for manipulation of food, locomotion, defense, or copulation. Chelicerates have no antennae and no mandibles.
- Subphylum **Crustacea** includes lobsters, crabs, shrimp, pill bugs, and barnacles. The body consists of a cephalothorax and abdomen. Crustaceans typically have five pairs of walking legs. Appendages are biramous. Crustaceans have two pairs of **antennae** that sense taste and touch. The third appendages are **mandibles** used for chewing. Two pairs of **maxillae,** posterior to the mandibles, manipulate and hold food.
- Subphylum **Hexapoda** includes class **Insecta.** An insect is an **articulated, tracheated hexapod;** its body consists of head, thorax, and abdomen. Insects have uniramous appendages and a single pair of antennae. These arthropods have tracheae for gas exchange and **Malpighian tubules** for excretion.

10 Identify adaptations that have contributed to the biological success of insects (page 654).
- The biological success of the insects results from many adaptations, including a versatile exoskeleton, segmentation, specialized jointed appendages, highly developed sense organs, and ability to fly. **Metamorphosis,** transition from one developmental form to another, reduces intraspecific competition. Insects have developed effective reproductive strategies, effective mechanisms for defense and offense, and the ability to communicate.

ThomsonNOW™ Explore the body plans of the protostomes by clicking on the figures in ThomsonNOW.

TEST YOUR UNDERSTANDING

1. Which of the following is associated with the evolution of the coelom? (a) radial symmetry (b) tube-within-a-tube body plan (c) incomplete metamorphosis (d) bilateral symmetry (e) development of ganglia
2. Cephalization (a) evolved along with bilateral symmetry (b) refers to the development of a digestive system (c) is associated with radial symmetry (d) involves a concentration of excretory organs (e) first evolved in arthropods
3. Rudimentary cephalization, protonephridia, and auricles characterize some members of phylum (a) Arthropoda (b) Cnidaria (c) Platyhelminthes (d) Mollusca (e) Crustacea
4. Trochophore larvae are characteristic of (a) Arthropoda (b) Cnidaria (c) Platyhelminthes (d) Mollusca (e) Crustacea
5. Tapeworms are classified in phylum (a) Porifera (b) Cnidaria (c) Platyhelminthes (d) Ctenophora (e) Coelomata
6. Which of the following is *not* an adaptation to parasitic life? (a) production of a few well-protected eggs (b) hooks (c) suckers (d) reduced digestive system (e) intermediate host
7. The hydrostatic skeleton (a) results in torsion (b) permits contracting muscles to recover quickly (c) permits a greater range of movement than possible in acoelomate animals (d) is a unique characteristic of annelids (e) permits ecdysis
8. Which of the following is *not* characteristic of nemerteans (proboscis worms)? (a) large coelom (b) rhynchocoel (c) complete digestive tube (d) muscular tube for capturing food (e) circulatory system
9. Which of the following characteristics is associated with phylum Mollusca? (a) mandibles (b) mantle (c) pedipalps (d) chelipeds (e) setae
10. Which of the following belong to phylum Mollusca? (a) gastropods and crustaceans (b) oligochaetes and polychaetes (c) chelicerates and bryozoans (d) crustaceans and nemerteans (e) gastropods and cephalopods
11. Which of the following are classified as Ecdysozoa? (a) mollusks (b) annelids (c) nematodes (d) nemerteans (e) lophophorates
12. Which of the following is *not* a nematode? (a) hookworm (b) trichina worm (c) *Ascaris* (d) leech (e) pinworm
13. Which of the following is *not* true of the lophophorates? (a) this group includes the bryozoans (b) some have shells and look somewhat like mollusks (c) this group is characterized by a ciliated ring of tentacles at anterior end (d) this group consists mainly of marine animals (e) some of its members are articulated, tracheated hexapods
14. Torsion in mollusks (a) is characteristic of bivalves (b) is a twisting of the visceral mass (c) involves coiling of the molluscan shell (d) begins in the adult stage (e) depends on action of parapodia
15. Trilobites (a) were early mollusks (b) are members of phylum Onychophora (c) are characterized by parapodia and setae (d) were early arthropods (e) are an evolutionary link between annelids and arthropods
16. Which of the following belong to subphylum Hexapoda? (a) insects (b) horseshoe crabs (c) crustaceans (d) centipedes (e) spiders
17. The correct sequence in insect complete metamorphosis is (a) egg ⟶ immature form ⟶ adult (b) egg ⟶ trochophore larva ⟶ veliger larva ⟶ adult (c) egg ⟶ pupa ⟶ larva ⟶ adult (d) egg ⟶ larva ⟶ pupa ⟶ adult (e) adult ⟶ larva ⟶ egg ⟶ pupa
18. Which of the following is characteristic of insects? (a) biramous appendages (b) mandibles (c) chelicerae (d) eight legs (e) two pairs of antennae
19. Which of the following is *not* characteristic of arthropods? (a) exoskeleton (b) pseudocoelom (c) paired, jointed appendages (d) chitin (e) segmentation
20. Spiders are characterized by (a) mandibles and maxillae (b) six pairs of legs on the abdomen (c) one pair of antennae (d) biramous appendages (e) chelicerae and pedipalps

CRITICAL THINKING

1. In what ways are mollusks similar to platyhelminths? How are they different?
2. Hypothesize why oysters secrete calcium carbonate layers around foreign particles.
3. In what ways are nematodes similar to arthropods? How are they different?
4. **Evolution Link.** Discuss important adaptations made possible by the development of the coelom.
5. **Evolution Link.** Discuss the idea that every evolutionary adaptation has both advantages and disadvantages, using each of the following characters as an example: (a) cephalization, (b) the arthropod exoskeleton, and (c) segmentation with specialization.
6. **Evolution Link.** Insects that undergo complete metamorphosis outnumber those that do not by more than 10 to 1. Hypothesize an explanation.

The Animal Kingdom: The Deuterostomes

© Ed Robinson/Tom Stack & Associates

Representative deuterostomes. This marine habitat photographed in Hawaii includes an echinoderm known as a pencil urchin (*Heterocentrotrus mammilatus*); and chordates, represented by fishes, the clown wrasse (*Coris gaimard*) with its yellow tail and the Moorish idol (*Zanchus cornutus*).

KEY CONCEPTS

The echinoderms and the chordates are the two most successful deuterostome lineages in terms of diversity, number of species, and number of individuals.

Echinoderms are characterized by radial symmetry in adults, a water vascular system, tube feet, and spiny skin.

At some time in its life, a chordate has a notochord; dorsal, tubular nerve cord; pharyngeal slits; and a muscular postanal tail.

Shared derived characters of vertebrates include a vertebral column, cranium, neural crest cells, and an endoskeleton of cartilage or bone.

Jaws and fins were key adaptations that contributed to the success of jawed fishes.

Limbs, a body covering that retards water loss, and the amniotic egg, with its shell and amnion, were key adaptations that contributed to the success of terrestrial vertebrates.

What does a sea star have in common with a fish, lizard, hawk, or human? You may think it strange to group the echinoderms—the sea stars, sea urchins, and sand dollars—with the chordates, the phylum to which we humans and other animals with a backbone belong. However, even though these animals look and behave very differently, structural and molecular data suggest that chordates and echinoderms share a common ancestor and are closely related.

In Chapter 30 we discussed the two major protostome branches of the animal kingdom, the lophotrochozoans and the ecdysozoans. In this chapter we focus on the third major branch of the animal kingdom, the deuterostomes. Some biologists speculate that the common ancestor of the deuterostomes was an animal that obtained food by filtering ocean water. Today, the two major phyla assigned to the deuterostomes are the echinoderms and chordates. The largest chordate subphylum is Vertebrata, which includes the animals with which we are most familiar—fishes, amphibians, reptiles, birds, and mammals. Echinoderms are represented in the photograph by the pencil urchin, and chordates are represented by the fishes. ■

WHAT ARE DEUTEROSTOMES?

Learning Objective

1 Identify shared derived characters of deuterostomes.

Deuterostomia, the third major branch of the animal kingdom, includes the **echinoderms**—the sea stars, sea urchins, and sand dollars—and the **chordates,** the phylum to which we humans and other **vertebrates** (animals with a backbone) belong. Biologists also include the **hemichordates,** a small group of wormlike marine animals, with the deuterostomes. A three-part body including a proboscis, collar, and trunk is a shared character of hemichordates. The most familiar of the hemichordates are the **acorn worms,** animals that live buried in mud or sand. The hemichordates have a characteristic ring of cilia surrounding the mouth.

Deuterostomes evolved from a common ancestor during the Proterozoic eon more than 550 million years ago (mya). Deuterostomes are characterized by several **shared derived characters (synapomorphies),** evolutionary novelties absent in their common ancestor. Their defining characters are similarities in their patterns of development (see Chapter 29). For example, deuterostomes are characterized by radial, rather than spiral, cleavage. Their cleavage is indeterminate, which means the fate of their cells is fixed later in development than is the case in protostomes. In deuterostomes, the mouth does not develop from the blastopore as in protostomes. The blastopore of deuterostomes becomes the anus (or is located near the future site of the anus), and the mouth develops from a second opening at the anterior end of the embryo—thus the name *deuterostome,* which is derived from the Greek words for "second mouth." Pharyngeal slits are characteristic of deuterostomes, but the extant echinoderms have lost this character. Basal deuterostomes have a type of larva with a loop-shaped band of cilia used for locomotion.

Review

- What are three shared derived characters of deuterosomes?

ECHINODERMS

Learning Objective

2 Identify three shared derived characters of echinoderms, and describe the main classes of echinoderms.

The **echinoderms** (phylum **Echinodermata**) have one of the most highly derived body plans in the animal kingdom. Echinoderm larvae are bilaterally symmetrical, ciliated, and free-swimming. However, during development the body reorganizes, and the adult exhibits **pentaradial symmetry,** in which the body is arranged in five parts around a central axis.

The most unique derived character of echinoderms is the **water vascular system,** a network of fluid-filled canals and chambers. Sea water flows into and out of the water vascular system through an opening in the body wall. Cilia lining the canals of the system move the water along. The water vascular system functions in feeding and gas exchange and serves as a hydrostatic skeleton important in locomotion.

Branches of the water vascular system lead to numerous tiny **tube feet** that extend when filled with fluid. Each tube foot receives fluid from the main system of canals. A rounded muscular sac, or **ampulla,** at the base of the foot, stores fluid and is used to operate the tube foot. A valve separates each tube foot from other parts of the system. When the valve shuts, the ampulla contracts, forcing fluid into the tube foot so that it extends. At the bottom of the foot is a suction-type structure that presses against and adheres to whatever surface the tube foot is on.

Another unique echinoderm character is the **endoskeleton,** an internal skeleton, that is covered by a thin, ciliated epidermis. The endoskeleton consists of calcium carbonate ($CaCO_3$) plates and spines. The name *Echinodermata,* derived from words meaning "spiny skinned," was inspired by the spines that project outward from the endoskeleton. Some groups have pincerlike, modified spines called **pedicellariae** on the body surface. These structures, found only among the echinoderms, keep the surface of the animal free of debris.

Echinoderms have a well-developed coelom, and the coelomic fluid transports materials. Although its structure varies in different groups, the complete digestive system is the most prominent body system. A variety of respiratory structures are found in the various classes. No excretory organs are present. The nervous system is simple, generally consisting of a nerve ring with nerves that extend out from it. Echinoderms have no brain. The sexes are usually separate, and eggs and sperm are generally released into the water, where fertilization takes place.

The echinoderms evolved from bilaterally symmetrical ancestors, probably during the Early Cambrian period. They achieved maximum diversity by the middle of the Paleozoic era, about 400 mya. By the beginning of the Mesozoic era 251 mya, they had declined, leaving five main groups that have survived to the present day (Fig. 31-1): class Crinoidea, sea lilies and feather stars; class Asteroidea, sea stars; class Ophiuroidea, basket stars and brittle stars; class Echinoidea, sea urchins and sand dollars; and class Holothuroidea, sea cucumbers. All members of phylum Echinodermata inhabit marine environments. They are found in the ocean at all depths. Biologists have identified about 7000 living and more than 13,000 extinct species.

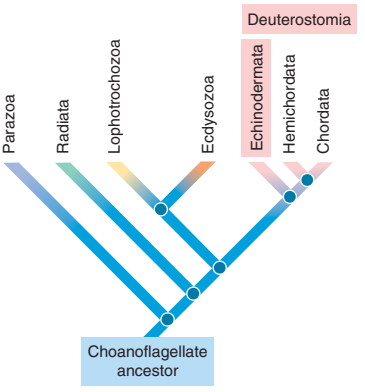
Members of class Crinoidea are suspension feeders

Class **Crinoidea,** the oldest class of living echinoderms, includes the feather stars and the sea lilies (see Fig. 31-1a). Although many extinct crinoids are known, there are relatively few living species. The feather stars are motile crinoids, although they often remain in the same location for long periods. Sea lilies are sessile and remain attached to the ocean floor by a stalk.

Crinoids remove suspended food from the water. In all other echinoderms, the mouth is located on the underside of the disc toward the substratum, but in crinoids the **oral surface** (mouth surface) is on the upper side of the disc. Several branched, feathery arms also extend upward. Numerous tube feet shaped like small tentacles are located along the feathery arms. These tube feet are coated with mucus that traps microscopic organisms.

Many members of class Asteroidea capture prey

Sea stars, or starfish, are members of class **Asteroidea** (see Fig. 31-1b). Their bodies consist of a central disc from which extend 5 to more than 20 arms, or rays (Fig. 31-2). The undersurface of each arm has hundreds of pairs of tube feet. The mouth lies in the center of the underside of the disc. The endoskeleton consists of a series of calcareous plates that permit some movement in the arms. Delicate dermal gills, small extensions of the body wall, carry on gas exchange.



Most sea stars are carnivorous predators and scavengers that feed on crustaceans, mollusks, annelids, and even other echinoderms. Occasionally they catch small fish. The sea star's water vascular system does not permit rapid movement, so its prey usually consists of slow-moving or stationary animals, such as clams.

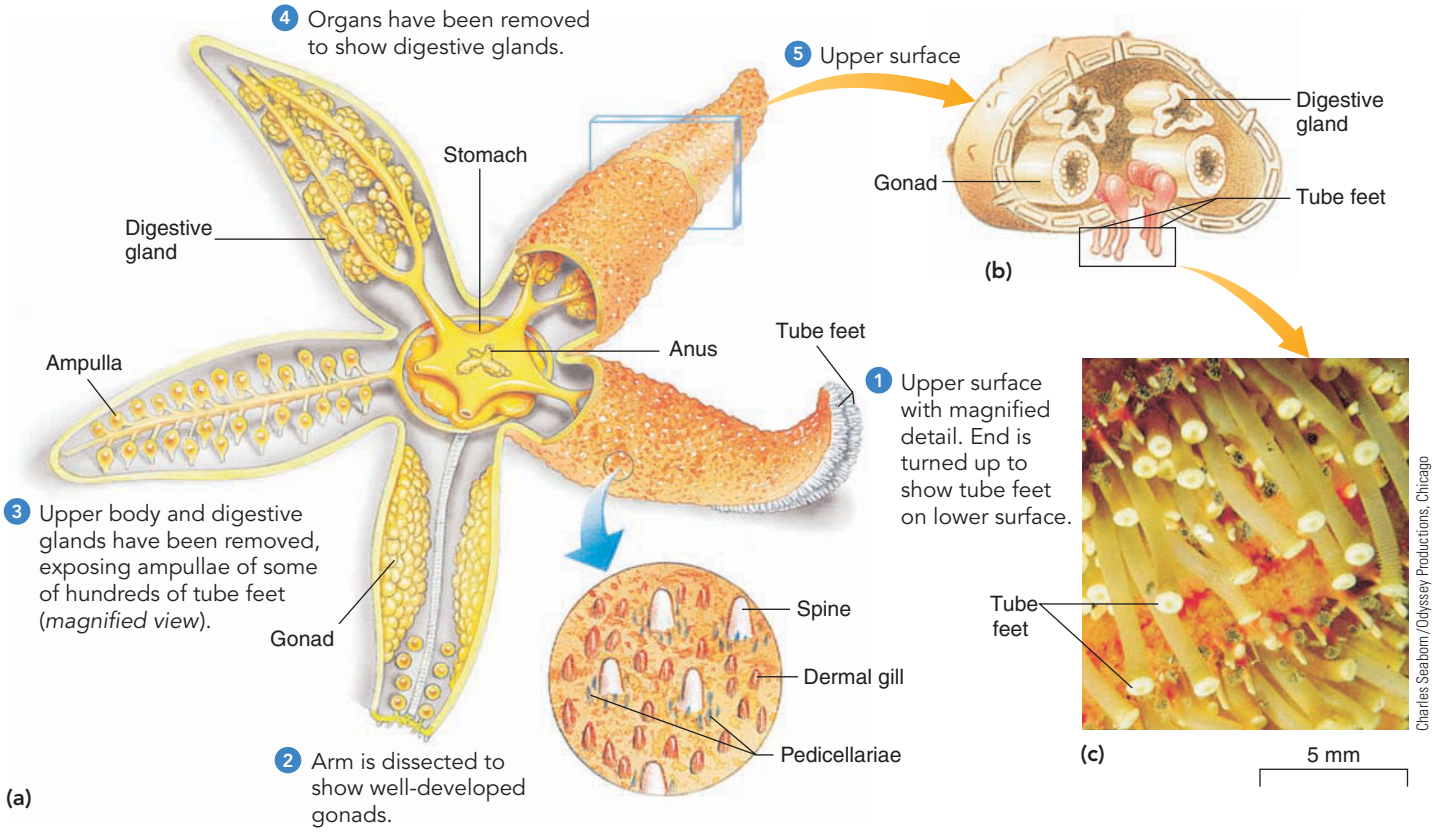

Figure 31-2 ***Animated*** Body plan of a sea star

(a) A sea star viewed from above, with its arms in various stages of dissection. Similar structures are present in each arm. The two-part stomach is in the central disc with the anus on the aboral (*upper*) surface and the mouth beneath on the oral surface. **(b)** Cross section through arm and tube feet. **(c)** LM of tube feet of a sea star.

To attack a clam or other bivalve mollusk, the sea star mounts it and assumes a humped position as it straddles the edge opposite the hinge. Then, holding itself in position with its tube feet, the sea star slides its thin, flexible stomach out through its mouth and between the closed, or slightly gaping, valves (shell parts) of the clam. The sea star secretes enzymes that digest the soft parts of the clam to the consistency of a thick soup while the clam is still in its own shell. The partly digested meal passes into the sea star body, where it is further digested by enzymes secreted from glands located in each arm.

The circulatory system in sea stars is poorly developed and probably of little help in circulating materials. Instead, the coelomic fluid, which fills the large coelom and bathes the internal tissues, assumes this function. Metabolic wastes pass to the outside by diffusion across the tube feet and dermal gills. The nervous system consists of a ring of nervous tissue encircling the mouth and a nerve extending from this ring into each arm.

Sea daisies are a curious group of echinoderms characterized by small, disc-shaped, flat bodies (less than 1 cm in diameter) with no arms or mouth. They inhabit bacteria-rich wood sunk in deep water and apparently absorb bacteria through their body surface. When sea daisies were discovered in 1986, biologists established a class (**Concentricycloidea**) to accommodate them. However, in 2005 they were reclassified as an order in the class Asteroidea.

Class Ophiuroidea is the largest class of echinoderms

Basket stars and brittle stars (serpent stars), members of class **Ophiuroidea,** are the largest group of echinoderms, both in number of species and of individuals (see Fig. 31-1c). These animals resemble sea stars in that their bodies consist of a central disc with arms. However, the arms are long and slender and more sharply set off from the central disc. Ophiuroids move more rapidly than sea stars by using their arms to perform rowing or even swimming movements. Their tube feet lack suckers and are not used in locomotion. Instead, they are used to collect and handle food and may also serve a sensory function, perhaps that of taste.

Members of class Echinoidea have movable spines

Sea urchins and sand dollars, the animals of class **Echinoidea,** have no arms (see Fig. 31-1d and chapter opening photograph). Their skeletal plates are flattened and fused to form a solid shell called a **test.** The flattened body of the sand dollar is adapted for burrowing in the sand, where it feeds on tiny organic particles. Sand dollars have smaller spines than do sea urchins.

The sea urchin body is covered with spines that in some species can penetrate flesh and are difficult to remove. So threaten-

ing are these spines that swimmers on tropical beaches are often cautioned to wear shoes when venturing offshore, where these living pincushions may live in abundance. Sea urchins use their tube feet for locomotion. They also push themselves along with their movable spines. Many sea urchins graze on algae, scraping the seafloor with their calcareous teeth.

Members of class Holothuroidea are elongated, sluggish animals

Sea cucumbers, members of class **Holothuroidea,** are appropriately named, for some species are about the size and shape of a cucumber. The elongated body is a flexible, muscular sac (see Fig. 31-1e). The mouth is usually surrounded by a circle of tentacles that are modified tube feet. The endoskeleton consists of microscopic plates embedded in the body wall. More highly developed than that of other echinoderms, the circulatory system functions to transport oxygen and perhaps nutrients.

Sea cucumbers are sluggish animals that usually live on the bottom of the sea, sometimes burrowing in the mud. Some graze with their tentacles, whereas others stretch their branched tentacles out in the water and wait for dinner to float by. Algae and other morsels are trapped in mucus along the tentacles.

An interesting habit of some sea cucumbers is evisceration, in which the digestive tract, respiratory structures, and gonads are ejected from the body, usually when environmental conditions are unfavorable. When conditions improve, the lost parts are regenerated. Even more curious is the fact that when certain sea cucumbers are irritated or attacked, they direct their rear end toward the enemy and shoot red tubules out of their anus! These unusual weapons are sticky, and the attacking animal may become hopelessly entangled. Some of the tubules release a toxic substance.

Review

- What are three derived characters of echinoderms? Describe each.
- How do sea stars differ from crinoids? From sea urchins?

CHORDATE CHARACTERS

Learning Objective

3 Describe five shared derived characters of chordates.

Biologists currently divide phylum **Chordata** into three subphyla: Urochordata, marine animals called *tunicates;* Cephalochordata, marine animals called *lancelets;* and Vertebrata, animals with backbones. Of these extant chordate groups, the urochordates were the earliest to evolve (Fig. 31-3).

Chordates are deuterostome coelomates with bilateral symmetry, a tube-within-a-tube body plan, and three well-developed germ layers (Fig. 31-4). Typically, chordates have an endoskeleton and a closed circulatory system with a ventral heart. Chordates have segmented bodies, but specialization is so pronounced that the basic segmentation of the body plan may not be apparent. For example, in vertebrates, although segmentation of the body is not obvious, muscles and nerves are segmentally organized.

Five shared derived characters distinguish the chordates. These characters, which evolved in connection with their evolving methods of locomotion and obtaining food, include the notochord; the dorsal, tubular nerve cord; pharyngeal slits; a postanal tail; and an endostyle or thyroid gland.

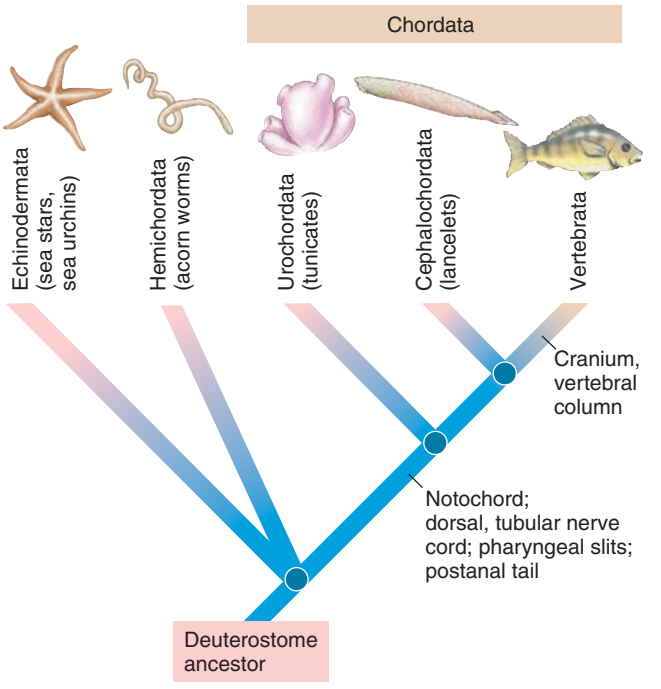

Figure 31-3 Evolutionary relationships of the chordates

This cladogram shows possible phylogenetic relationships among deuterostomes, including chordates (*tan region*), based on structural and DNA data.

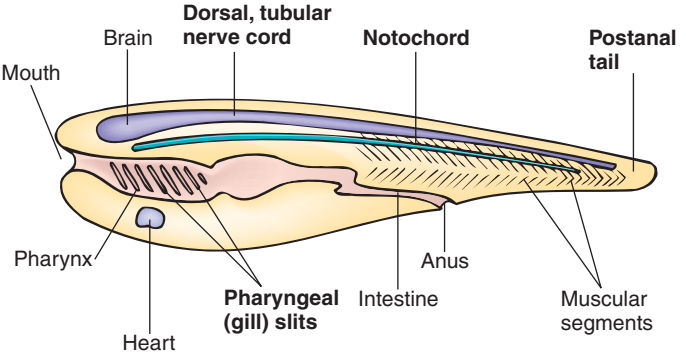

Figure 31-4 Generalized chordate body plan

Note the notochord; dorsal, tubular nerve cord; pharyngeal (gill) slits; and postanal tail.

1. All chordates have a **notochord** during some time in their life cycle. The notochord is a dorsal, longitudinal rod composed of cartilage; it is firm but flexible and supports the body.
2. At some time in their life cycle, chordates have a **dorsal, tubular nerve cord.** The chordate nerve cord differs from the nerve cord of most other animals in that it is located dorsally rather than ventrally, is hollow rather than solid, and is single rather than double.

3. Chordates have **pharyngeal slits** (also called *pharyngeal gill slits*) or pharyngeal pouches during some time in their life cycle. In the embryo, a series of alternating branchial (gill) arches and grooves develop in the body wall in the pharyngeal (throat) region. Pharyngeal pouches extend laterally from the anterior portion of the digestive tract toward the grooves.

   Early chordates, like many living chordates, were probably suspension feeders. The arrangement of pharyngeal pouches and slits permitted them to take water in through the mouth, concentrate small particles of food in the gut, and allow the water to exit from the body through the slits. In fishes and some other aquatic vertebrates, the pharyngeal slits and the arches supporting them became modified for gas exchange. Early in vertebrate evolution, anterior pharyngeal arches evolved into jaws.
4. Chordates have a larva or embryo with a muscular **postanal tail,** an appendage that extends posterior to the anus.
5. Another derived chordate character is the **endostyle** or its derivative, the thyroid gland. The endostyle is a groove in the floor of the pharynx. It secretes mucus and functions as a net that traps food particles in the sea water passing through the pharynx.

Review

- What is a notochord?
- What is the significance of pharyngeal slits?

INVERTEBRATE CHORDATES

Learning Objectives

4 Describe the invertebrate chordate subphyla.
5 Discuss the evolution of chordates.

Some chordates are not vertebrates. The invertebrate chordates include tunicates and lancelets. Biologists assign the tunicates to subphylum Urochordata and the lancelets to subphylum Cephalochordata.

Tunicates are common marine animals

The **tunicates,** which make up subphylum **Urochordata,** include the sea squirts and their relatives. Larval tunicates have typical chordate characteristics and superficially resemble tadpoles. The expanded body has a pharynx with slits, and the long muscular tail contains a notochord and a dorsal, tubular nerve cord. Some tunicates (*appendicularians*) retain their chordate features and ability to swim. These animals are common members of the zooplankton.

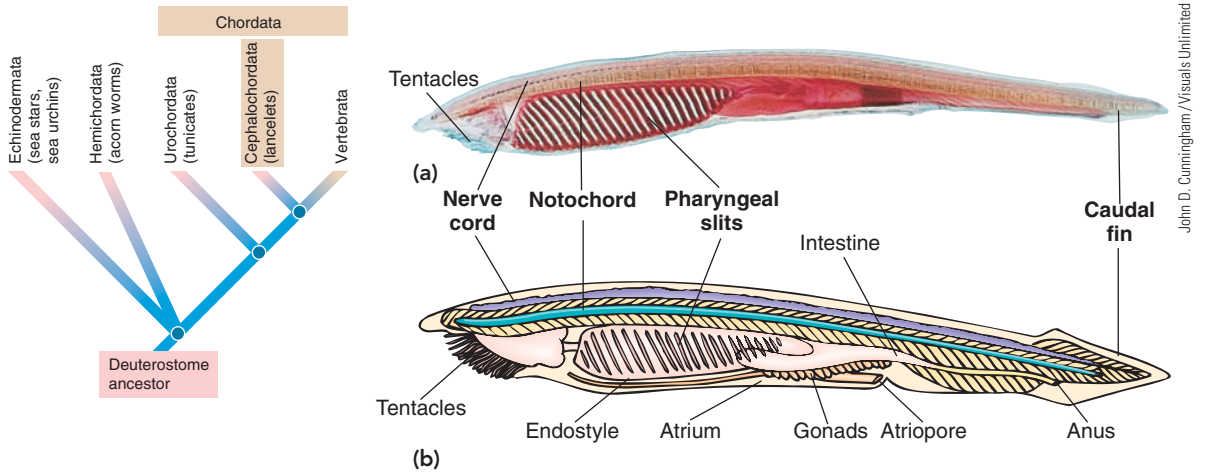

Figure 31-6 ***Animated*** Cephalochordate body plan

(a) Photograph of a lancelet, *Branchiostoma* (amphioxus). Note the prominent pharyngeal gill slits. **(b)** Longitudinal section showing internal structure.

Most tunicates are **ascidians,** commonly known as sea squirts (class Ascidiacea). A sea squirt larva swims for a time, then attaches itself to the sea bottom and loses its tail, notochord, and much of its nervous system. Adult sea squirts are barrel-shaped, sessile marine animals unlike other chordates. Indeed, they are often mistaken for sponges or cnidarians (Fig. 31-5). Only the pharyngeal slits, endostyle, and the structure of its larva indicate that the sea squirt is a chordate.

Adult tunicates develop a protective covering, or **tunic,** that may be soft and transparent or quite leathery. Curiously, the tunic consists of a carbohydrate much like cellulose. The tunic has two openings: the incurrent siphon, through which water and food enter; and the excurrent siphon, through which water, waste products, and gametes pass to the outside. Sea squirts get their name from their practice of forcefully expelling a stream of water from the excurrent siphon when irritated.

Tunicates are suspension feeders that remove plankton from the stream of water passing through the pharynx. Food particles are trapped in mucus secreted by cells of the *endostyle,* a groove that extends the length of the pharynx. Ciliated cells of the pharynx move the stream of food-laden mucus into the esophagus. Much of the water entering the pharynx passes out through the pharyngeal slits into an **atrium** (chamber) and is discharged through the excurrent siphon.

Some species of tunicates form large colonies in which members share a common tunic and excurrent siphon. Colonial forms often reproduce asexually by budding. Sexual forms are usually hermaphroditic.

Lancelets may be closely related to vertebrates

Most species of subphylum **Cephalochordata** belong to the genus *Branchiostoma,* which consists of animals commonly known as **lancelets,** or **amphioxus.** Lancelets are translucent, fish-shaped animals, 5 to 10 cm (2 to 4 in) long and pointed at both ends. They are widely distributed in shallow seas, either swimming freely or burrowing in the sand near the low-tide line. In some parts of the world, lancelets are an important source of food. One Chinese fishery reports an annual catch of 35 tons (about 1 billion lancelets)!

Chordate characteristics are highly developed in lancelets. The notochord extends from the anterior tip ("head"; hence the name *Cephalochordata*) to the posterior tip. Many pairs of pharyngeal slits are evident in the large pharyngeal region, and a dorsal, tubular nerve cord extends the entire length of the animal (Fig. 31-6). Although superficially similar to fishes, lancelets have a far simpler body plan. They do not have paired fins, jaws, sense organs, a heart, or a well-defined head or brain.

Like the tunicates, lancelets use their cilia to draw a current of water into the mouth and then strain out microscopic organisms. Food particles are trapped in mucus in the pharynx and are then carried back to the intestine.

Water passes through the pharyngeal slits into the atrium, a chamber with a ventral opening (the *atriopore*) just anterior to the anus. Metabolic wastes are excreted by segmentally arranged, ciliated *protonephridia* that open into the atrium. Unlike circulation in other invertebrates, the blood flows anteriorly in the ventral vessel and posteriorly in the dorsal vessel in lancelets. This circulatory pattern is similar to that of fishes.

Recent molecular and structural findings suggest that lancelets are the vertebrates' closest living relative. Important shared derived characters include the presence of the notochord, nerve cord, and postanal tail in the adults. Another is the presence of **somites,** a series of paired blocks of mesoderm that develop on each side of the notochord. Somites are temporary structures that define the segmentation of the embryo. In vertebrates, they give rise to the vertebrae, ribs, and certain skeletal muscles. Another similarity between cephalochordates and vertebrates is the lancelet nerve cord, which has specialized regions that correspond to the vertebrate forebrain and midbrain.

Systematists are making progress in understanding chordate phylogeny

Both structural and molecular data indicate that subphyla Cephalochordata and Vertebrata are **sister taxa,** groups that diverged from a recent common ancestor. That ancestor may have resembled a tunicate larva.

Researchers have sequenced the genome of the sea squirt *Ciona intestinalis,* the most-studied ascidian tunicate. *Ciona* is an excellent model organism for studying chordate development because its genome consists of only about 16,000 genes, about half the number found in vertebrates. Interestingly, about 80% of *Ciona*'s genes are found in vertebrates. In fact, *Ciona* has most vertebrate gene families, but in simplified form. For example, *Ciona* has only a single copy of each gene family involved in cell signaling and regulation of development, whereas vertebrates have two or more copies of these gene families. (Some of these "extra" copies probably evolved to code for new structures or functions.) *Ciona* also has genes for some vertebrate structures and processes, even though it does not express these genes. Biologists hypothesize, based on these molecular data, that the sea squirt genome may correspond to that of the chordate ancestor.

Fossils of early chordates also contribute to our understanding of chordate phylogeny. A lancelet-like animal, which biologists named *Pikaia,* was discovered in the Burgess Shale of British Columbia, Canada. This animal, which dates to the Cambrian period, had a primitive notochord with muscles attached to it that allowed for locomotion. About 4 cm (1.5 in) in length, *Pikaia* had a tail fin and probably filtered food from the water. *Pikaia* is considered an early chordate.

Many well-preserved fossils occur in **Chengjiang,** an Early Cambrian fossil site in China. At this site, fine-grained rocks about 530 million years old have preserved soft-bodied animals, such as *Yunnanozoon, Haikouella,* and *Haikouichthys,* in great detail. Some biologists have interpreted *Yunnanozoon,* which somewhat resembles *Pikaia,* as an early chordate, but other biologists think it was a hemichordate.

Haikouella was about 2 to 3 cm (approximately 1 in) long and had a nerve cord, notochord, gills, muscle segments, and a brain. Most biologists view *Haikouella* as an early chordate. *Haikouichthys* was a fishlike animal about 2.5 cm long. It had several characters found in vertebrates, and some researchers think it was an early vertebrate.

Conodonts were simple fishlike chordates with fins, large eyes, and complex toothlike hooks that were probably used in capturing prey. These animals had gill arches and muscular segments. Conodonts were abundant during the Precambrian to Late Triassic; they have been identified in several fossil beds around the world. Recent cladistic analyses suggest that conodonts were early vertebrates.

Review

- How are the main derived chordate characters evident in a tunicate larva, in an adult tunicate, and in a lancelet?
- How does sequencing animal genomes help clarify relationships among chordate groups?

INTRODUCING THE VERTEBRATES

Learning Objective

6 Describe four shared derived characters of vertebrates.

Consisting of about 48,000 species, the **vertebrates,** members of subphylum **Vertebrata,** are less diverse and much less numerous than the insects but rival them in their adaptations to an enormous variety of lifestyles (Fig. 31-7). In addition to the basic chordate characteristics, vertebrates have a number of shared derived characters not found in other groups.

The vertebral column is a key vertebrate character

The vertebrates are distinguished from other chordates in having a backbone, or **vertebral column,** that forms the skeletal axis of the body. This flexible support develops around the notochord, and in most species it largely replaces the notochord during embryonic development. The vertebral column consists of cartilaginous or bony segments called **vertebrae.** Dorsal projections of the vertebrae enclose the nerve cord along its length. Anterior to the vertebral column, a cartilaginous or bony **cranium,** or braincase, encloses and protects the brain, the enlarged anterior end of the nerve cord.

The cranium and vertebral column are part of the **endoskeleton.** In contrast with the nonliving exoskeleton of many invertebrates, the vertebrate endoskeleton is a living tissue that grows with the animal. Some vertebrates (jawless and cartilaginous fishes) have skeletons made of cartilage. However, in most vertebrates, the skeleton is mainly bone, a tissue that contains fibers made of the protein collagen. The hard matrix of bone consists of the compound hydroxyapatite, composed mainly of calcium phosphate.

Many characters common to vertebrates have been derived from a group of cells called **neural crest cells.** These cells, found only in vertebrates, appear early in development and migrate to various parts of the embryo. Neural crest cells give rise to or influence the development of many structures, including nerves, head muscles, cranium, and jaws.

Recall that invertebrates show an evolutionary trend toward **cephalization,** the concentration of nerve cells and sense organs in a definite head. Vertebrate evolution is characterized by *pronounced* cephalization. The brain has become larger and more elaborate, and its various regions have specialized to perform different functions. Either 10 or 12 pairs of **cranial nerves** emerge from the brain and extend to various organs of the body. Vertebrates have well-developed sense organs concentrated in the head: eyes; ears that serve as organs of balance and, in some vertebrates, for hearing as well; and organs of smell and taste.

Most vertebrates have two pairs of appendages. The fins of fishes are appendages that stabilize the fish in the water. Paired pectoral and pelvic fins are also used in steering. Biologists hypothesize that jointed appendages that facilitated locomotion on land evolved from the lobed (divided) fins of lungfishes.

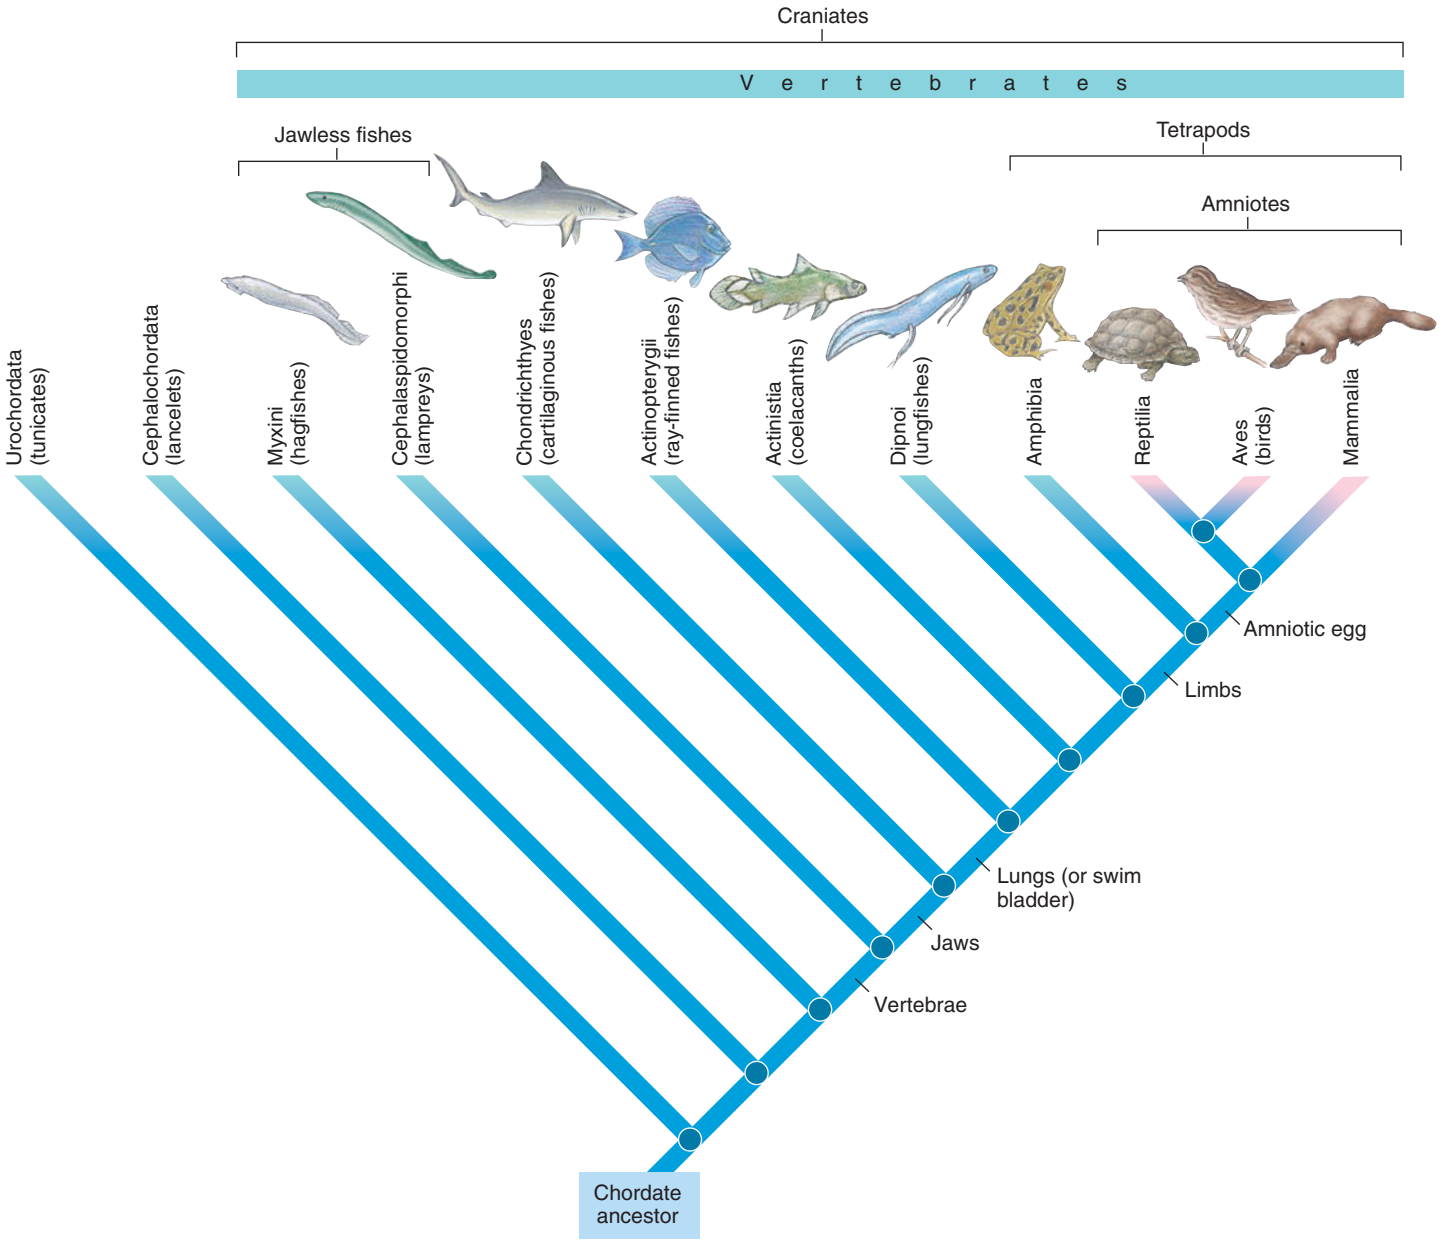

Figure 31-7 ***Animated*** Evolutionary relationships of vertebrates

This cladogram represents one phylogenetic interpretation of vertebrate phylogeny. Biologists have not yet reached a consensus as to whether hagfishes are true vertebrates. The relationships of the amniotes in this cladogram are highly simplified. Figure 31-20 is a more detailed cladogram for these groups. The evolution of certain key traits is indicated. This cladogram provides a framework for understanding the evolution of vertebrate diversity and adaptations to aquatic and terrestrial environments. As new data are collected and considered, details of the cladogram will likely change.

Vertebrates have a closed circulatory system with a ventral heart and blood containing hemoglobin. The complete digestive tract has specialized regions and large digestive glands (the liver and pancreas). Several **endocrine glands,** which are ductless glands, secrete hormones. Paired kidneys regulate fluid balance. The sexes are typically separate.

Early vertebrates were probably marine animals. As we have discussed, tunicates and cephalochordates use cilia to beat a stream of water into the mouth. They filter particles of food from the water. In contrast, vertebrates use muscles for feeding. Some use muscles to draw in a current of water from which both food and oxygen can be extracted. Muscles in the wall of the digestive tube are more powerful than cilia and probably contributed to an increase in both size and activity of early vertebrates. A muscular pharynx may have permitted animals to crush small prey after capture. The evolution of more effective sensory systems, a more complex brain, and organs that could support increased activity was important in the shift from filter-feeding to a more active lifestyle.

TABLE 31-1

Extant Vertebrate Classes

Class		Examples	Characteristics
Myxini		Hagfishes	Jawless, marine fishes that lack paired appendages; the notochord is their only axial support; lack vertebrae, so some biologists classify as craniates, but not as vertebrates
Cephalaspidomorphi		Lampreys	Jawless, freshwater and marine fishes with skeleton of cartilage; complete cranium and rudimentary vertebrae; hatch as small larvae
Chondrichthyes		Sharks, rays, skates, chimaeras	Jawed marine and freshwater fishes with skeleton of cartilage; notochord replaced by vertebrae in adult; gills; placoid scales; two pairs of fins; oviparous, ovoviparous, or viviparous (a few species); well-developed sense organs (including lateral line system)
Actinopterygii (ray-finned fishes)		Perch, salmon, tuna, trout	Bony, marine and freshwater fishes; gills; swim bladder; generally oviparous
Actinistia (lobe-finned fishes)		Coelacanths	Bony fishes; marine, nocturnal predators on fish; lobed fins
Dipnoi		Lungfishes	Bony freshwater fishes; four similarly sized limbs, which are similar in structure and position to those of tetrapods
Amphibia		Salamanders, frogs and toads, caecilians	Tetrapods; aquatic larva typically undergoes metamorphosis into terrestrial adult; gas exchange through lungs and/or moist skin; heart consists of two atria and single ventricle; systemic and pulmonary circulation
Reptilia		Turtles, lizards, snakes, alligators	Amniotes with horny scales; adapted for reproduction on land (internal fertilization, leathery shell, amnion); lungs; ventricles of heart partly divided*
Aves		Robins, pelicans, eagles, ducks, penguins, ostriches	Amniotes with feathers; anterior limbs modified as wings; compact, streamlined body; four-chambered heart; endothermic; vocal calls and complex songs
Mammalia		Monotremes (Holotheria), marsupials (Metatheria), placental mammals (Eutheria)	Amniotes with hair; females nourish young with mammary glands; differentiation of teeth; three middle-ear bones; diaphragm; four-chambered heart; endothermic; highly developed nervous system

*A cladistic classification of amniotes is shown in Figure 31-20.

Vertebrate taxonomy is a work in progress

The study of evolutionary relationships of vertebrates is an important focus of research. Biologists consider the vertebrates and lancelets as sister groups that diverged from a common ancestor. The earliest vertebrates to evolve were **agnathans** (*a,* "without"; and *gnathos,* "jaw"): the hagfishes, followed by the lampreys. Biologists assign hagfishes to class **Myxini** and lampreys to class **Cephalaspidomorphi.**

Some systematists have argued that the hagfishes do not quite qualify as vertebrates. Although they have many vertebrate characters, including a cranium, hagfishes have no trace of vertebrae. The notochord is their only axial support. Some biologists use the term **Craniata,** based on the presence of a cranium, to designate a clade that includes the vertebrates plus the hagfishes. They view the Myxini as the sister group of all other craniates. Recent molecular analyses, however, support classifying hagfishes as vertebrates.

If we include the Myxini, the extant vertebrates are currently assigned to 10 classes: 6 classes of fishes and 4 of tetrapods (four-limbed vertebrates) (▮ Table 31-1 and see Fig. 31-7). Some biologists give fishes and tetrapods superclass status: superclass **Pisces** (fishes) and superclass **Tetrapoda.** In this classification scheme, the fishes include the hagfishes, lampreys, and four classes of jawed fishes: Chondrichthyes, Actinopterygii, Actinistia, and Dipnoi.

The four-limbed land vertebrates, or **tetrapods,** include class Amphibia, the frogs, toads, and salamanders; class Reptilia, the lizards, snakes, turtles, and alligators; class Aves, the birds; and

class Mammalia, the mammals. As we discuss later in the chapter, many cladists classify birds with reptiles rather than assign them to a separate class. The reptiles, birds, and mammals form a clade known as *amniotes,* animals fully adapted to life on land.

Review

- What derived characters distinguish the vertebrates from the rest of the chordates?

JAWLESS FISHES

Learning Objective

7 Distinguish among the major groups of jawless fishes.

Some of the earliest known vertebrates, collectively referred to as **ostracoderms,** consisted of several groups of small, armored, jawless fishes that lived on the bottom and strained their food from the water (see Fig. 21-10). Thick bony plates protected their heads from predators, and thick scales covered their trunks and tails. Most ostracoderms lacked fins. Fragments of ostracoderm scales have been found in rocks from the Cambrian period, but most ostracoderm fossils are from the Ordovician and Silurian periods. They became extinct by the end of the Devonian period.

Like ostracoderms, present-day hagfishes and lampreys have neither jaws nor paired fins. They are eel-shaped animals, up to 1 m (about 3 ft) long. Their smooth skin lacks scales, and they are supported by a cartilaginous skeleton and well-developed notochord.

Hagfishes, assigned to class Myxini, are marine scavengers (Fig. 31-8). They burrow for worms and other invertebrates or prey on dead and disabled fishes. Hagfishes use toothlike projections from their tongue to pull off flesh from prey. For leverage, a hagfish can tie itself into a knot. As a defense mechanism, hagfishes secrete large amounts of fluid that forms sticky slime in sea water. The hagfish becomes so slippery that predators cannot grasp it.

Tom McHugh / Photo Researchers, Inc.

Figure 31-8 ***Animated*** Pacific hagfish (*Eptatretus stoutii*)

The hagfish exudes slime when alarmed.

Lampreys are jawless vertebrates assigned to class Cephalaspidomorphi. Some spend their adult lives in the ocean and return to fresh water to reproduce. Many species of adult lampreys are parasites on other fishes (Fig. 31-9). Adult parasitic lampreys have a circular sucking disc around the mouth, which lies on the ventral side of the anterior end of the body. Using this disc to attach to a fish, the lamprey bores through the skin of its host with horny (made of keratin rather than bone) teeth on the disc and tongue. Then the lamprey injects an anticoagulant into its host and sucks out blood and soft tissues.

As in hagfish, the notochord persists throughout life and is not replaced by a vertebral column. However, lampreys have ru-

- How do hagfishes differ from other fishes?

EVOLUTION OF JAWS AND LIMBS: JAWED FISHES AND AMPHIBIANS

Learning Objective

8 Trace the evolution of jawed fishes and early tetrapods, and identify major taxa of jawed fishes and amphibians.

Imagine trying to hunt for food and eat it without jaws or limbs. This was the challenge of early vertebrates and helps explain why the jawless fishes are mainly scavengers and parasites. The evolution of jaws from a portion of the gill arch skeleton and the development of fins allowed fishes to become active predators. With jaws an animal can grasp and hold on to live prey while eating it. The evolution of fins allowed fishes to swim faster and with more control. Fishes with jaws and fins had many new opportunities for capturing food.

Fossil evidence suggests that jaws and paired fins evolved during the Late Silurian and Devonian periods. Two early groups of jawed fishes, now extinct, were the **acanthodians,** armored fishes with paired spines and pectoral and pelvic fins, and **placoderms,** armored fishes with paired fins (Fig. 31-10). The success of the jawed vertebrates probably contributed to the extinction of the ostracoderms.

When the fins of certain fishes evolved into limbs about 370 mya, a different type of locomotion was possible. These fishes were able to move about in shallow waters and wetlands in search of food. When the first tetrapods—the amphibians—moved onto the land, new opportunities for habitats and food became available.

(a) *Climatius* was a spiny-skinned acanthodian with large fin spines and five pairs of accessory fins between the pectoral and pelvic pairs. *Climatius* was a small fish that reached a length of 8 cm (3 in).

(b) *Dinichthys* was a giant placoderm that grew to a length of 8 m (26 ft). (Most placoderms were only about 20 cm, or 8 in, long.) Its head and thorax were covered by bony armor, but the rest of the body and tail were naked.

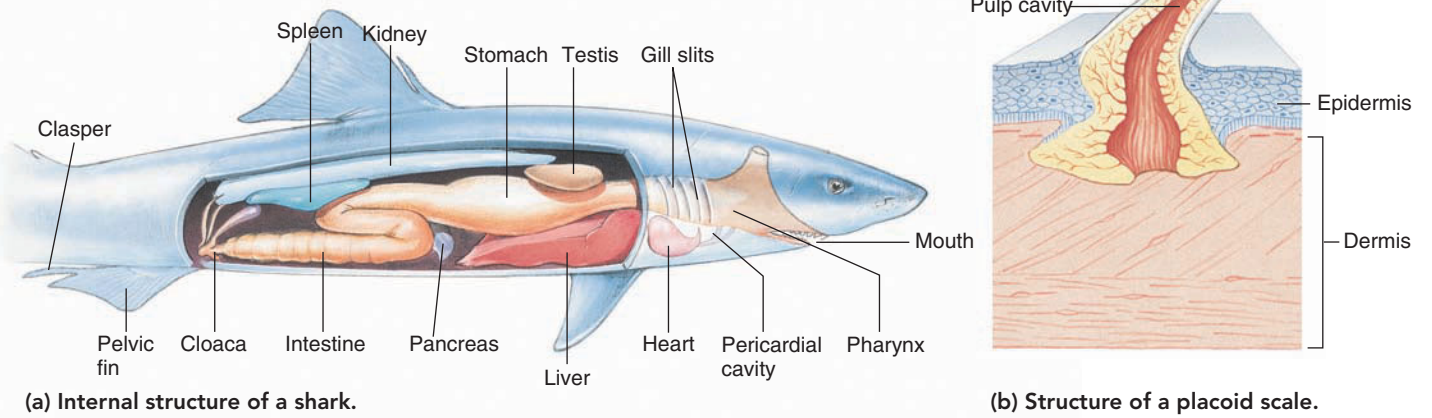
Figure 31-11 ***Animated*** Cartilaginous fishes

Members of class Chondrichthyes are cartilaginous fishes

Members of class **Chondrichthyes,** the cartilaginous fishes, evolved as successful marine forms in the Devonian period. Class Chondrichthyes, which is considered monophyletic, includes the sharks, rays, and skates (Figs. 31-11 and 31-12a). Most species are ocean dwellers, but a few have invaded fresh water. With the exception of whales, the sharks are the largest living vertebrates. Some whale sharks (*Rhincodon*) exceed 15 m (49 ft) in length, making them the largest fish.

Most rays and skates are flattened creatures that live partly buried in the sand. Their enormous pectoral fins propel them along the bottom, where they feed on mussels and clams. The stingray has a whiplike tail with a barbed spine at its base that can inflict a painful wound. The electric ray has electric organs on either side of the head. These modified muscles can discharge

Figure 31-12 Anatomy of a shark



(a) Internal structure of a shark.

(b) Structure of a placoid scale.

enough electric current (up to 200 volts) to stun fairly large fishes, as well as human swimmers.

The chondrichthyes retain their cartilaginous embryonic skeleton. Although this skeleton is not replaced by bone, a deposit of calcium salts may strengthen it. All chondrichthyes have paired jaws and two pairs of fins. The skin contains **placoid scales.** Each scale is a toothlike structure consisting of an outer layer of enamel and an inner layer of dentine (Fig. 31-12b). The lining of the mouth contains larger, but essentially similar, scales that serve as teeth. The teeth of other vertebrates are homologous with these scales. Shark teeth are embedded in the flesh and not attached to the jawbones; new teeth develop continuously in rows behind the functional teeth and migrate forward to replace any that are lost.

The shark body is adapted for swimming. Lift is provided by body shape and fins and by the action of swimming swiftly. The shark stores a great deal of oil in its large liver (which may account for up to 30% of the body weight). Fats and oils decrease the overall density of fishes and contribute to buoyancy. Even so, the shark body is denser than water, so sharks tend to sink unless they are actively swimming.

Most sharks are streamlined predators that swim actively and catch and eat other fishes as well as crustaceans and mollusks. The largest sharks and rays, like the largest whales, are suspension feeders that strain plankton from the water. They gulp water through the mouth. As the water passes through the pharynx and out the gill slits, food particles are trapped in a sievelike structure.

Predatory sharks are attracted to blood, so a wounded swimmer or a skin diver towing speared fish is a target. However, despite the common portrayal of sharks in books and films as monstrous enemies, most do not go out of their way to attack humans. In fact, of the approximately 350 known shark species, fewer than 30 are known to attack humans.

The shark has a complex brain and a spinal cord that is protected by vertebrae. The well-developed sense organs very effectively locate prey in the water. Sharks may detect other animals electrically before sensing them by sight or smell. **Electroreceptors** on the shark's head sense weak electric currents generated by the muscular activity of animals. The **lateral line organ,** found in all fishes, is a groove along each side of the body with many tiny openings to the outside. Sensory cells in the lateral line organ are sensitive to waves and other motion in the water, alerting the shark to the presence of predator or prey (see Fig. 42-7).

Cartilaginous fishes have no lungs. Gas exchange takes place through their five to seven pairs of gills. A current of water enters the mouth and passes over the gills and out the gill slits, constantly providing the fish with a fresh supply of dissolved oxygen. Sharks that actively swim depend on their motion to enhance gas exchange. Rays, skates, and sharks that spend time on the ocean floor use muscles of the jaw and pharynx to pump water over their gills.

The digestive tract of sharks consists of the mouth cavity; a long pharynx leading to the stomach; a short, straight intestine; and a **cloaca,** which opens on the underside of the body and is characteristic of many vertebrates (see Fig. 31-12a). The liver and pancreas discharge digestive juices into the intestine. The cloaca receives digestive wastes, as well as metabolic wastes from the urinary system. In females, the cloaca also serves as a reproductive organ.

The sexes are separate, and fertilization is internal. In the mature male, each pelvic fin has a slender, grooved section, known as a **clasper,** used to transfer sperm into the female's cloaca. The eggs are fertilized in the upper part of the female's oviducts. Part of the oviduct is modified as a shell gland, which secretes a protective coat around the egg.

Skates and some species of sharks are **oviparous;** that is, they lay eggs. Many species of sharks, however, are **ovoviviparous,** meaning their young are enclosed in eggs and incubated within the mother's body. During development, the young depend on stored yolk for their nourishment rather than on transfer of materials from the mother. The young are born after hatching from the eggs.

A few species of sharks are **viviparous.** Not only do the embryos develop within the uterus, but much of their nourishment is delivered to them by the mother's blood. Nutrients are transferred between the blood vessels in the lining of the uterus and the yolk sac surrounding each embryo.

The ray-finned fishes gave rise to modern bony fishes

Although bony fishes appear earlier in the fossil record than cartilaginous fishes, both groups may have evolved about the same time, during the Devonian period. The two groups share many characteristics (such as continuous tooth replacement), but they also differ in important ways.

Most bony fishes are characterized by a bony skeleton with many vertebrae. Bone has advantages over cartilage because it provides excellent support and effectively stores calcium. Most species have flexible median and paired fins, supported by long rays made of cartilage or bone. Overlapping, bony dermal scales cover the body. A lateral bony flap, the **operculum,** extends posteriorly from the head and protects the gills.

Unlike most sharks, bony fishes are oviparous. They lay an impressive number of eggs and fertilize them externally. The ocean sunfish, for example, lays more than 300 million eggs! Of course, most of the eggs and young become food for other animals. The probability of survival is increased by certain behavioral adaptations. For example, many species of fishes build nests for their eggs and protect them.

During the Devonian period, the bony fishes diverged into two major groups: the **Sarcopterygii** and the **ray-finned fishes,** class **Actinopterygii.** Fossils of the earliest sarcopterygians date back to the Devonian period, about 400 mya. Lungs and fleshy, **lobed fins** characterized these fishes. The flexible fins were not supported by rays of bone except at their tips. Instead, a group of bones with joints between them supported the fins. These fins had muscles that could move them and support the body. Lobed fins may have evolved as an adaptation to life on the bottom of the sea. Fish could use the fins to push against the bottom.

Early sarcopterygians evolved along two separate lines: the **lungfishes** (class **Dipnoi**) and **lobe-finned fishes** (class **Actinistia**). Both lineages have lobed fins. Three genera of lungfishes survive today in the rivers of tropical Africa, Australia, and South America.

The ray-finned fishes underwent two important adaptive radiations. The first gave rise during the Late Paleozoic era to a group of fishes that are now mostly extinct. The second radiation began during the Early Mesozoic era and gave rise to the modern bony fishes.

The common ancestor of the modern bony fishes had primitive lungs that could exchange gases in air. Lungs for gas exchange were retained by the lobe-finned fishes and lungfishes. In the ray-finned fishes, the lungs became modified as a **swim bladder,** an air sac that helps regulate buoyancy (Fig. 31-13). Bones and muscles are heavier than water, and without the swim bladder the fish would sink. By regulating gas exchange between its blood and swim bladder, a fish can control the amount of gas in the swim bladder and thus change the overall density of its body. This ability allows a bony fish, in contrast to a shark, to hover at a given depth of water without much muscular effort.

There are more species of bony fishes than of any other group of vertebrates. Biologists have identified about 49,000 living species of freshwater and saltwater bony fishes, of many shapes and colors (Fig. 31-14). Bony fishes range in size from that of the recently discovered stout infantfish (genus *Paedocypris*), which averages less than about 8 mm (about 0.3 in) long, to that of the ocean sunfish (or *Mola;* see Fig. 20-14c), which may reach 4 m (13 ft) and weigh about 1500 kg (about 3300 lb).

The diversity of bony fishes may have resulted from the action of *Hox* genes. Recall that *Hox* genes are important in determining pattern development in embryos (see Chapter 17). Specifically, *Hox* genes determine the fate of cells in the anterior-posterior axis. These genes occur in clusters on specific chromosomes. All invertebrates and early chordates that have been studied have one *Hox* gene cluster, but tetrapods have four clusters. The zebrafish has seven *Hox* clusters. During the radiation of ray-finned fishes, entire chromosomes duplicated, resulting in one or more additional clusters of *Hox* genes. These genes could have provided the genetic material for the evolution of the diverse species of ray-finned fishes.

Descendants of the lungfishes moved onto the land

Biologists thought the lobe-finned fishes were extinct by the end of the Paleozoic era, so in 1938 the scientific community was very excited when a commercial fisherman caught one off the coast of South Africa. Since that time more than 200 specimens of these giant "living fossils" have been found in the deep waters off the southeastern coast of Africa, the Comores Islands, Madagascar, and Indonesia (Fig. 31-15). These fishes, known as **coelacanths,**

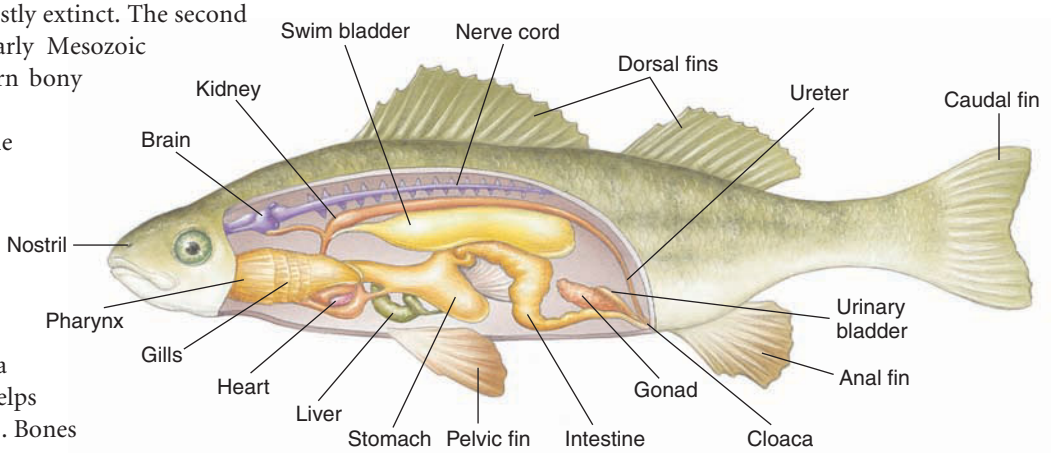


Figure 31-13 ***Animated*** Perch, a representative bony fish

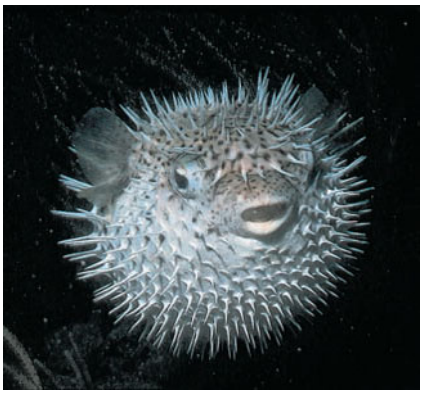
The swim bladder is a hydrostatic organ that enables the fish to change the density of its body and remain stationary at a given depth. Pectoral fins (*not shown*) and pelvic fins are paired.



David Hall/Photo Researchers, Inc.

Figure 31-14 Modern bony fishes

Mark Erdmann

Figure 31-15 Diver swimming with coelacanth

For many years, biologists thought that ancestors of this lobe-finned fish (*Latimeria chalumnae*) gave rise to the amphibians.

measure nearly 2 m (about 6 ft) in length. They are nocturnal predators on other fishes.

Until the 1980s, the prevailing hypothesis was that coelacanths were the living fossil representatives of the group that gave rise to the land vertebrates. Then, a few investigators challenged this hypothesis with structural data. The external nasal openings of fossil and living lungfishes suggested that they, rather than the coelacanths, are the ancestors of the land vertebrates. Other similarities between lungfishes and land vertebrates are tooth enamel and four limbs that have the same structure and position (Fig. 31-16). (Recall that the fins of lungfishes are also lobed.)

During the 1990s, the lungfish hypothesis gained support from comparisons of mitochondrial DNA. More recently, underwater studies of coelacanths have shown that these fish use their muscular fins to slowly swim rather than to "walk" on the ocean bottom. In contrast, living lungfishes do use their fins to "walk" on the river bottom. Biologists now generally agree that ancestors of lungfishes, rather than coelacanths, gave rise to the tetrapods.

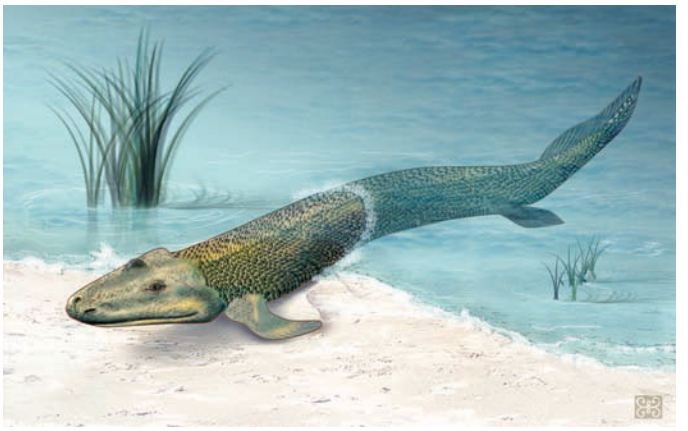
Molecular data support the structural evidence that the limbs of tetrapods evolved from the lobed fins of fishes. Proteins encoded by certain regulatory genes, including *Hox* genes, have been found at the same developmental times and in the same locations in both limbs and fins. These findings indicate that limb and fin development is governed by the same genes.

What drove the evolution of tetrapod limbs? One hypothesis explains that during the frequent seasonal droughts in the Devonian period, swamps became stagnant or dried up completely. Fishes with lobed fins had a tremendous advantage for survival under those conditions. They were strikingly preadapted for moving onto the land. They had lungs for breathing air, and their sturdy, fleshy fins allowed them to "walk" along in shallow water. These fins could support the fish's weight, so it could emerge onto dry land and make its way to another pond or stream.

Perennou Nuridsany/PhotoResearchers, Inc.

Figure 31-16 South American lungfish (*Lepidosiren paradoxus*)

Lungfishes were common in Devonian and Carboniferous times (400 mya to 300 mya). South American lungfish have paired lungs on either side of the throat and can survive for long periods if the river they inhabit dries up.



Zina Deretsky/National Science Foundation

Figure 31-17 ***Animated*** *Tiktaalik*

This fish, which grew to 2.75 m (9 ft), had limblike fins and other tetrapod features.

A more recent hypothesis holds that limbs evolved in a fully aquatic environment. Animals with more developed limbs could move along in shallow water or creep through dense aquatic vegetation more efficiently than their lobe-finned ancestors. ***Tiktaalik*** was a transitional form between fishes and tetrapods (Fig. 31-17). Biologists consider *Tiktaalik,* which lived about 375 mya (during the Devonian period), a fish because it had scales and fins. However, *Tiktaalik* also had tetrapod features such as a movable neck and ribs that supported lungs.

Acanthostega was one of the earliest known tetrapods. Fossils from the Devonian period show that this animal had four legs with well-formed digits. However, its limbs were not sufficiently strong for walking effectively on land. *Acanthostega* was an aquatic animal, not an amphibian. *Ichthyostega* is the earliest amphibian fossil found to date. This animal had strong legs supported by well-developed shoulder and hip bones and muscles. Natural selection favored individuals such as *Ichthyostega* that could explore shallow wetlands and make their way onto dry land. The ability to move about on land, however awkwardly, provided access to new food sources. Terrestrial plants were already established, and terrestrial insects and arachnids were rapidly evolving. A vertebrate that could survive on land had less competition for food. However, success on land required the evolution of several major adaptations in addition to legs.

As already discussed, the lungfishes had lungs for gas exchange. This was important because gills cannot function in air. Life on land also required the evolution of vertebrae and muscles strong enough to support the weight of the body in air. Body coverings and other mechanisms were needed to protect animals against the drying effect of air. Evolution of ears that could hear sound transmitted through air and olfactory mechanisms for detecting airborne odors contributed to the ability to find food and mates and to avoid predators. At first, animals returned to the water to reproduce, but eventually adaptations evolved that allowed animals to reproduce in terrestrial environments. The early vertebrate experience on land was so successful that this lineage gave rise to the amphibians and, later, the reptiles, birds, and mammals.

Amphibians were the first successful land vertebrates

Biologists classify modern amphibians (class **Amphibia**) in three orders. Order **Urodela** ("visible tail") includes salamanders, mud puppies, and newts, all animals with long tails; order **Anura** ("no tail") is made up of frogs and toads, with legs adapted for hopping; and order **Apoda** ("no feet") contains the wormlike caecilians (Fig. 31-18). Although some adult amphibians are quite successful as land animals and live in dry environments, most return to the water to reproduce. Eggs and sperm are typically released in the water.

Amphibians undergo **metamorphosis,** a transition from larva to adult. The embryos of most frogs and toads develop into larvae called **tadpoles.** These larvae have tails and gills, and most feed on aquatic plants. After a time, the tadpole undergoes metamorphosis, a process regulated by hormones secreted by the *thyroid gland.* During metamorphosis, gills and gill slits disappear, the tail is resorbed, and limbs emerge. The digestive tract shortens, and food preference shifts from plant material to a carnivorous diet; the mouth widens; a tongue develops; the tympanic membrane (eardrum) and eyelids appear; and the eye lens changes shape. Many biochemical changes accompany the transformation from a completely aquatic life to an amphibious one.

Several salamanders, such as the mud puppy *Necturus,* do not undergo complete metamorphosis; they retain many larval characteristics even when sexually mature adults. Recall from Chapter 20 that this is an example of **paedomorphosis** (see Fig. 20-15). This type of development permits these salamanders to remain aquatic rather than having to compete on land.

Gerald and Buff Corsi/Tom Stack & Associates

(a) This red dart frog (*Dendrobates pumilio*) is a poison arrow frog.

Lynda Richardson/Corbis

(b) The spotted salamander (*Ambystoma maculatum*) stays underground most of the time. In early spring, these salamanders congregate in woodland ponds to reproduce.

Figure 31-18 ***Animated*** Modern amphibians

The coloration of amphibians may conceal them in their habitat or may be very bright and striking. Many of the brightly colored species are poisonous (see Fig. 31-18a). Their distinctive colors warn predators that they are not encountering an ordinary amphibian. Some frogs camouflage themselves by changing color.

Adult amphibians do not depend solely on their primitive lungs for the exchange of respiratory gases. Their moist, glandular skin, which lacks scales and is plentifully supplied with blood vessels, also serves as a respiratory surface. The numerous mucous glands within the skin help keep the body surface moist, which is important in gas exchange. The mucus also makes the animal slippery, facilitating its escape from predators. Some amphibians have glands in their skin that secrete poisonous substances harmful to predators.

The amphibian heart is divided into three chambers: Two **atria** receive blood, and a single **ventricle** pumps it into the arteries. A double circuit of blood vessels keeps oxygen-rich and oxygen-poor blood partially separate. Blood passes through the **systemic circulation** to the various tissues and organs of the body. Then, after returning to the heart, it is directed through the **pulmonary circulation** to the lungs and skin, where it is recharged with oxygen. The oxygen-rich blood returns to the heart to be pumped out into the systemic circulation again. We discuss the comparative anatomy of the heart and circulation of various vertebrate classes in Chapter 43.

Review

- From an evolutionary perspective, what is the significance of each of the following: (1) placoderms, (2) lungfishes, (3) ray-finned fishes, (4) *Ichthyostega*, and (5) *Tiktaalik?*
- What changes allow amphibians to move from aquatic life as a tadpole to terrestrial life as an adult?

AMNIOTES

Learning Objectives

9 Describe three vertebrate adaptations to terrestrial life.
10 Describe the reptiles and birds, and give an argument for including the birds in the reptile clade.
11 Contrast monotremes, marsupials, and placental mammals; and give examples of animals that belong to each group.

The evolution of reptiles from ancestral amphibians required many adaptations that allowed them to be completely terrestrial. Evolution of the **amniotic egg** was an extremely important event because it allowed terrestrial vertebrates to complete their life cycles on land. This egg contains an **amnion,** a membrane that forms a fluid-filled sac around the embryo. The amnion provides the embryo with its own private "pond," permitting independence from a watery external environment. In addition to keeping the embryo moist, the amniotic fluid serves as a shock absorber to cushion the developing embryo.

The evolution of the amniotic egg is so important to the success of terrestrial vertebrates—reptiles, birds, and mammals—that biologists refer to these animals as **amniotes.** Amniotes are a monophyletic group, because they have a common ancestor that was itself an amniote.

In addition to the amnion, the amniotic egg has three other extraembryonic (not part of the developing body itself) membranes: yolk sac, chorion, and allantois (Fig. 31-19). These membranes protect the developing embryo, store nutrients (*yolk*

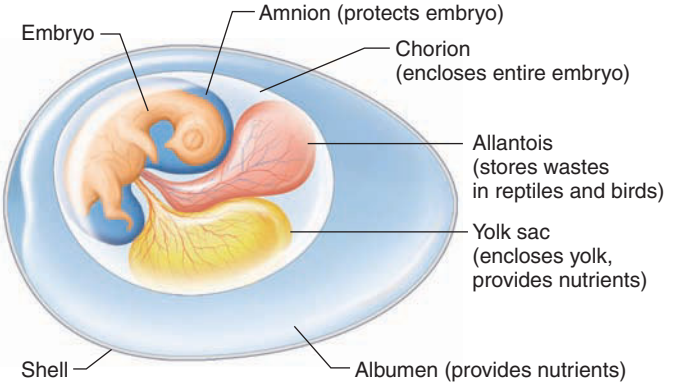


Figure 31-19 ***Animated*** An amniotic egg

The amnion is a protective membrane surrounding the embryo. Other extraembryonic membranes are the yolk sac, allantois, and chorion.

Key Point

The diapsid reptiles gave rise to the birds, and the synapsid reptiles gave rise to the mammals. Note the five (including the birds) main branches of extant diapsids.

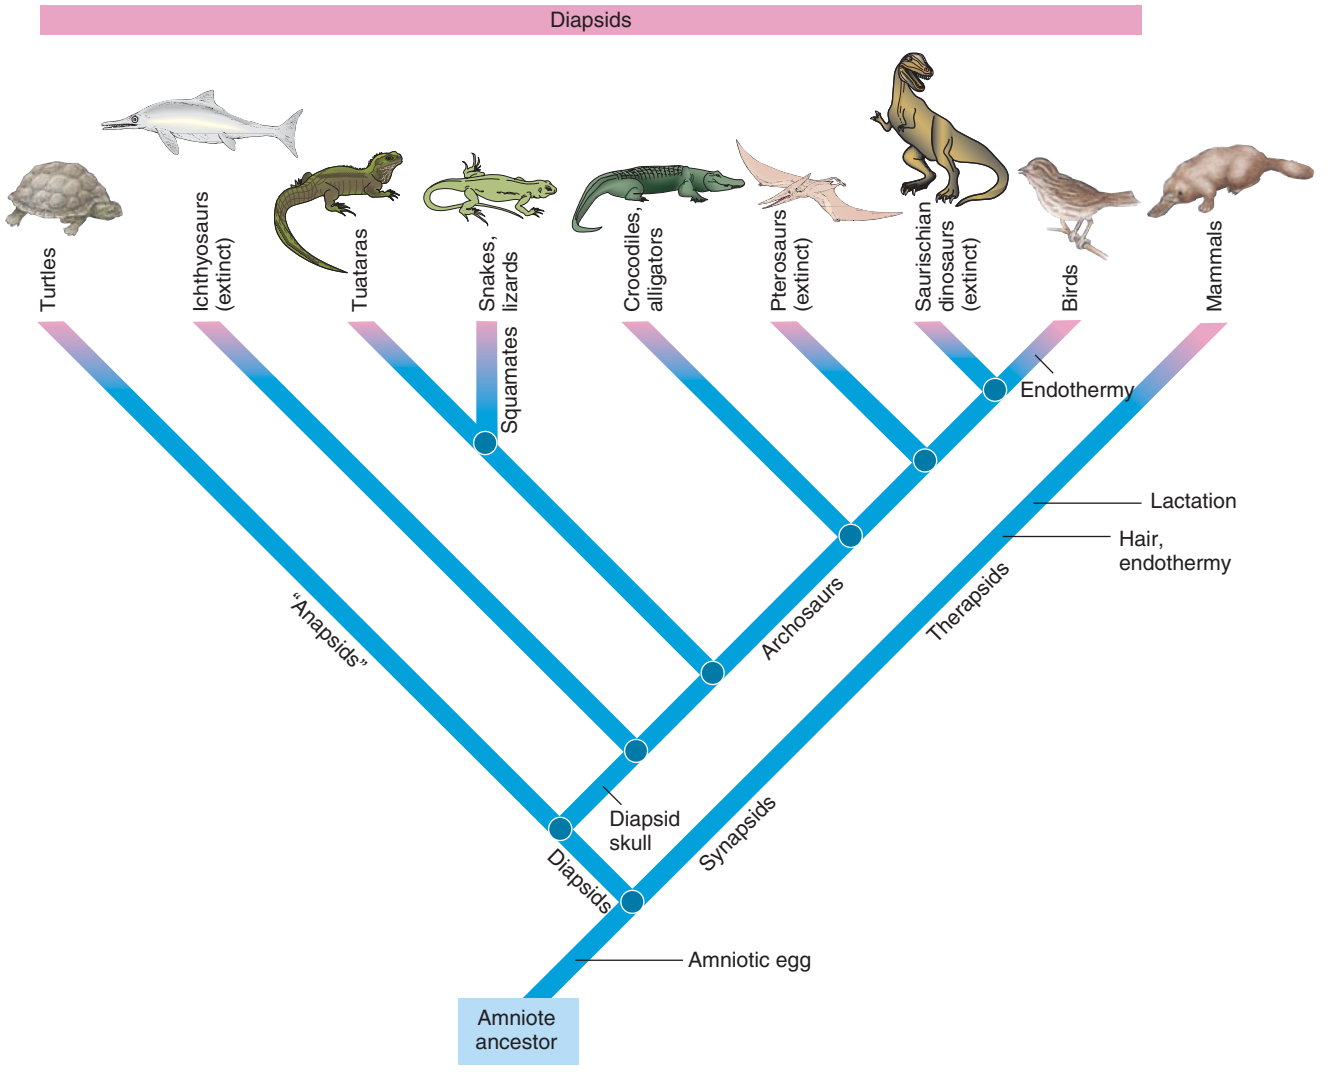

Figure 31-20 Evolutionary relationships of some amniotes

This cladogram shows proposed evolutionary relationships among reptiles, birds, and mammals. Many of these relationships are currently being studied and may be reinterpreted.

sac), carry on gas exchange (*chorion* and *allantois*), and store wastes (*allantois*). We discuss development of the extraembryonic membranes in Chapter 50. Although most extant mammals do not lay eggs, their embryos have an amnion and other extraembryonic membranes.

Another important adaptation to terrestrial life is a body covering that minimizes water loss. Such a covering presents another challenge because it severely decreases gas exchange across the body surface. This challenge has been met by the evolution of efficient lungs and circulatory systems for exchange of oxygen and carbon dioxide. Amniotes also have physiological mechanisms for conserving water. For example, much of the fluid filtered from the blood by the kidneys is reabsorbed in the kidney tubules and urinary bladder to avoid water loss during excretion of metabolic wastes.

Our understanding of amniote phylogeny is changing

Biology instructors once taught that the three classes of amniotes were Reptilia, Aves, and Mammalia. However, cladistic analysis indicates that class Reptilia is not a monophyletic group. Because it includes some, but not all, of its descendants, it is paraphyletic (see Fig. 23-7). Our discussion of amniotes reflects the cladistic view, although we describe modern birds separately for convenience.

TABLE 31-2

Some Major Amniote Groups

Subclass (Superorder/Order)	Important Characters
Subclass Diapsida	Skull with two pairs of temporal openings
Order Testudines (Chelonia) Turtles, terrapins, tortoises Turtles formerly classified as anapsids	Enclosed in bony shell; beak of keratin instead of teeth; some can withdraw head and legs into shell
Superorder Lepidosauria	Overlapping scales; most successful of modern reptiles
Order Squamata Snakes, lizards, amphisbaenians (worm lizards)	Flexible armor of overlapping, horny scales, which are shed
Lizards	Slender body, typically with four limbs; movable eyelids
Snakes	Elongated body with no limbs; flexible, loosely jointed jaw; forked tongue protrusible
Amphisbaenaea (worm lizards)	Elongated body with no limbs (except one genus); eyes hidden under skin
 Order Rhynchocephalia Tuataras	Third eye under skin of forehead; only two extant species
Superorder Ichthyosauria (Extinct) Marine reptiles of Mesozoic	Body somewhat similar to that of modern fishes
Superorder Archosauria	Mainly terrestrial; some specialized for flight
Order Crocodilia Crocodiles, alligators, caimans, gavials 	Four-chambered heart; closest extant relative to birds
Pterosauria (Extinct) Flying reptiles of Mesozoic	Membranous wings
Saurischia (Extinct) Mesozoic dinosaurs (*Tyrannosaurus, Diplodocus*) Birds descended from this lineage	Some were two-legged carnivores; others were four-legged herbivores
Ornithischia (Extinct) Mesozoic dinosaurs (*Triceratops*)	Bipedal and quadrupedal herbivores
Subclass Synapsida	Skull with one pair of temporal openings
Therapsida (Extinct) Mammals descended from this lineage	Many mammal-like characters; became dominant land animals during Middle Permian

Biologists hypothesize that the earliest amniotes resembled lizards. By the Late Carboniferous period, about 290 mya, amniotes had undergone an impressive adaptive radiation and diverged into two main branches: **diapsids** and **synapsids** (▮ Fig. 31-20 and ▮ Table 31-2). The term *diapsid* refers to the two pairs of openings in the temporal bones that characterize the skulls of these animals. Synapsid skulls have one pair of temporal openings. The diapsids comprise all reptilian groups, including most extinct reptiles. Biologists now classify the birds as diapsids, based on cladistic analysis. The synapsids include the extinct therapsid reptiles and the mammals.

Until very recently, systematists included a third branch, the **anapsids.** These animals have no temporal opening in the skull. The turtles were considered the only extant anapsids. However, molecular data suggest that the turtles are actually diapsids.

A second great adaptive radiation of amniotes occurred during the Mesozoic era, which ended about 66 mya. During that time reptiles were the dominant terrestrial animals (see Chapter 21). In fact, the Mesozoic era is known as the "Age of Reptiles." These animals had radiated into an impressive variety of ecological lifestyles (see Figs. 21-12, 21-13, and 21-14). Some could fly, others became marine, and many filled terrestrial habitats. Among the major groups were the **pterosaurs,** the flying reptiles; the **saurischian dinosaurs,** a group that included *Tyrannosaurus* and *Diplodocus;* and the **ornithischian dinosaurs,** including *Triceratops.*

Some of the dinosaurs were among the largest land animals to have ever walked on Earth. Some dinosaurs apparently traveled in social groups and took care of their young. Fossil evidence supports the hypothesis that at least some dinosaurs were **endotherms,** meaning they used metabolic energy to maintain a constant body temperature despite changes in the temperature of the environment. An advantage of endothermy is that it allows animals to be more active. The natural history and evolution of dinosaurs and other early reptiles are discussed in more detail in Chapter 21.

The reptiles were the dominant land animals for almost 200 million years. Then, toward the end of the Mesozoic era, many, including all the dinosaurs and pterosaurs, disappeared from the fossil record. In fact, more than half of all animal species became extinct at that time (see Chapter 21). As a result of this mass extinction, there are many more extinct reptiles than living species.

Reptiles have many terrestrial adaptations

Many reptilian characters are adaptations to terrestrial life. The female reptile secretes a protective leathery shell around the egg, which helps prevent the developing embryo from drying out. However, sperm cannot penetrate this shell. Fertilization must take place within the body of the female before the shell is added. In this process, the male uses a copulatory organ (penis) to transfer sperm into the female reproductive tract. An amnion surrounds the embryo as it develops within the protective shell.

The hard, dry, horny scales that retard drying are another adaptation to life on land. This scaly protective armor, which also protects the reptile from predators, is shed periodically. The dry reptilian skin does not allow effective gas exchange. Reptilian lungs are better developed than the saclike lungs of amphibians. Divided into many chambers, the reptilian lung provides a greatly increased surface area for gas exchange. Most reptiles have a three-chambered heart that is more efficient than the amphibian heart. The single ventricle has a partition, though incomplete, that separates oxygen-rich and oxygen-poor blood, facilitating oxygenation of body tissues. In crocodiles the partition is complete, and the heart has four chambers.

Like fishes and amphibians, extant reptiles generally lack metabolic mechanisms for regulating body temperature. They are **ectothermic,** meaning that their body temperature fluctuates with the temperature of the surrounding environment. Some reptiles have behavioral adaptations that let them maintain a body temperature higher than that of their environment. For example, you may have observed a lizard basking in the sun, which raises its body temperature and so increases its metabolic rate. This permits the lizard to hunt actively for food. When the body of a reptile is cold, its metabolic rate is low and the animal tends to be sluggish. Ectothermy may explain why reptiles are more successful in warm than in cold climates.

Many reptiles are carnivorous (meat eating). Their paired limbs, usually with five toes, are well adapted for running and climbing in search of prey. In addition, their well-developed sense organs enable them to locate prey.

We can assign extant reptiles to four groups

Biologists assign the extant reptiles to four orders (we ignore birds for the moment), though some systematists rank them as classes. Order Testudines includes the turtles, terrapins, and tortoises. Order Squamata includes lizards, snakes, and amphisbaenians (worm lizards). Order Rhynchocephalia includes the **tuataras,** lizardlike animals that live in burrows. Order Crocodilia contains crocodiles, alligators, caimans, and gavials (Fig. 31-21).

Turtles have protective shells

Members of order **Testudines** are enclosed in a protective shell made of bony plates overlaid by horny scales. Some terrestrial species can withdraw their heads and legs completely into their shells. Turtles do not have teeth. Their horny beak covers the jaws. The size of adult turtles ranges in length from about 8 cm (3 in) to more than 2 m (6.5 ft) in the great marine species, which may weigh 450 kg (almost 1000 lb). The forelimbs of marine turtles are modified into flippers. Biologists usually refer to the aquatic forms as *turtles* and to the land species as *tortoises.* Freshwater types are sometimes called *terrapins.*

Lizards and snakes are the most common modern reptiles

Lizards, snakes, and amphisbaenians (worm lizards) are assigned to order **Squamata.** These animals have rows of scales that overlap like shingles on a roof, forming a continuous, flexible armor that is shed periodically. Lizards range in size from certain geckos, which weigh as little as 1 g (less than 0.1 oz), to the Komodo dragon of Indonesia, which may weigh 100 kg (220 lb). Their body sizes and shapes vary greatly. Some lizards, such as the glass snake (which is really a lizard), are legless.

Snakes are characterized by a flexible, loosely jointed jaw structure that lets them swallow animals larger than the diameter of their own jaws. Snakes have elongated bodies with no legs, although pythons have vestigial hindlimb bones (see Fig. 18-14). (Remember that although not all the tetrapods have four limbs, all evolved from four-limbed ancestors.) Their eyes, covered by a transparent scale, do not have movable eyelids. Also absent are an external ear opening, a tympanic membrane (eardrum), and a middle-ear cavity.

The snake uses its forked tongue as an accessory sensory organ for touch and smell. Chemicals from the ground or air adhere to the tongue. The snake rubs the tip of its tongue across the opening of a sense organ in the roof of the mouth that detects odors. Pit vipers and some boas also have a prominent **pit organ** on each side of the head that detects heat from endothermic prey (see Fig. 42-3). These snakes use their pit organs to locate and capture small nocturnal mammals.

Some snakes, such as king snakes, pythons, and boa constrictors, kill their prey by rapidly wrapping themselves around the animal and squeezing so it cannot breathe. Others have fangs, which are hollow teeth connected to venom glands. When the snake bites, it pumps venom through the fangs into the prey. Some snake venoms cause the breakdown of red blood cells; oth-

Representative extant reptiles

ers, such as that of the coral snake, are neurotoxins, which interfere with nerve function. Venomous snakes of the United States include rattlesnakes, copperheads, cottonmouths, and coral snakes. All these except the coral snakes are pit vipers.

Amphisbaenians, or worm lizards, are well adapted for their burrowing lifestyle. They have elongated, legless bodies, and their eyes are hidden under their skin. Most are less than 15 cm (6 in) long. Only one species is known in the United States.

Tuataras superficially resemble lizards

The two extant species of tuataras inhabit small islands off the coast of New Zealand. They originally inhabited the two main islands, but when humans brought rats to New Zealand, the rats decimated the population of tuataras by eating their eggs. Tuataras look somewhat like iguanas but have certain distinct characters. For example, they are the only amniotes with vertebrae that are concave at both ends; such vertebrae are characteristic of fish and some amphibians.

Crocodilians have an elongated skull

The extant members of order **Crocodilia** are the only surviving reptiles (except birds) of the archosaur lineage (see Fig. 20-18). This is the lineage that gave rise to most of the dinosaurs that dominated the Mesozoic era. Modern crocodilians include three groups: (1) the crocodiles of Africa, Asia, and America; (2) the alligators of the southern United States and China, plus the caimans of Central America; and (3) the gavials of South Asia. Most species live in swamps, in rivers, or along seacoasts, feeding on various kinds of animals.

Crocodiles are the largest living reptiles; some exceed 7 m (23 ft) in length. The cranial skeleton is adapted for aquatic life. The crocodile can be distinguished from the alligator or caiman by its long, slender snout and by the large fourth tooth on the bottom jaw that is visible when the mouth is closed.

Are birds really dinosaurs?

Although the bones of birds are fragile and disintegrate quickly, paleobiologists have found a few fossils of early birds. The first birds looked very much like dinosaurs. They had teeth (which modern birds lack), a long tail, and bones with thick walls.

Cladistic analyses indicate that birds evolved from the lineage of saurischian dinosaurs, specifically from the **theropods,** a group of bipedal, mainly carnivorous animals (see Fig. 21-15). In fact, many biologists classify birds as theropods. Many extinct theropods were long-tailed animals that moved about on two feet and had forelimbs with three clawed fingers. Extinct theropods

Figure 31-22 *Archaeopteryx* and *Caudipteryx*

and modern birds have feet with three digits and thin-walled, hollow bones. Both have a **furcula,** or wishbone, which is formed by the two clavicles (collarbones) fusing in the midline. Fossil evidence indicates that some extinct theropods had feathers. Using structural and molecular data, many biologists now view birds as living dinosaurs!

The earliest known bird, *Archaeopteryx* (meaning "ancient wing"), was about the size of a pigeon. Ten specimens of this genus have been found in Bavaria in Jurassic limestone, which was laid down about 150 mya. Unlike those of extant birds, the jawbones of *Archaeopteryx* were armed with teeth, and its long reptilian tail was covered with feathers (Fig. 31-22a). Each of its short, broad wings had three claw-bearing, functional digits. Like modern birds, *Archaeopteryx* had wings, feathers, and a furcula. Its feathers were very similar to those of modern birds. Biologists do not know whether *Archaeopteryx* shared a common ancestor with other birds or whether *Archaeopteryx* itself gave rise to modern birds.

Recently, researchers used computed tomography and computerized three-dimensional reconstruction to see inside the *Archaeopteryx* skull. They found that *Archaeopteryx* had a birdlike brain with comparatively larger cerebral lobes than those of other reptiles. It had enlarged visual centers and highly developed inner ear canals similar to those of modern birds. These structures would support the coordination and agility needed for flight.

Cretaceous rocks have yielded fossils of other early birds. *Hesperornis,* which lived in North America, was a toothed, aquatic diving bird with small wings and broad, lobed feet for swimming. *Ichthyornis* was a toothed, flying bird about the size of a small tern. By the end of the Cretaceous period, fully modern birds had evolved, including early members of several modern bird families.

Some dinosaurs had feathers

Feathers are an amazing example of biological engineering. Until recently, feathers were considered a key derived character of birds. Indeed, birds are the only extant animals with feathers. However, recent molecular and fossil evidence indicates that feathers also evolved in dinosaurs.

Biologists have suggested several hypotheses to explain the early functions of feathers. They may have been important in courtship rituals or in camouflage. They may have been an adaptation that conserved body heat. Insulating feathers could have contributed to the evolution of endothermy (the ability to maintain a constant body temperature), permitting animals to be more active.

Chinese, American, and Canadian paleontologists have discovered a remarkable array of fossils in the Yixian Formation in China. These fossils date back to the Early Cretaceous period (128 mya to 124 mya). These researchers have identified many theropod dinosaur fossils that demonstrate the evolution of feathers from very simple, tubular structures to complex modern

forms. One feathered dinosaur discovered there is *Caudipteryx,* which was about the size of a turkey. It had only a few teeth in the front of its upper jaw, and its bones show many birdlike characteristics (Fig. 31-22b). *Caudipteryx* has well-preserved imprints of complex feathers on its tail and forelimbs. Analyzing fossil evidence and recent molecular data, some biologists hypothesize that feather evolution took place in terrestrial, bipedal dinosaurs before the evolution of birds or flight.

In 2003, paleontologists reported a new species of feathered dinosaur, *Microraptor gui. Microraptor* had asymmetrical feathers on its forelimbs and hind limbs. Modern birds use asymmetrical feathers for flight. These small dinosaurs, which lived about 126 mya, coexisted with early birds. Their small size and body structure support the hypothesis that flying evolved from gliding; that is, bird ancestors climbed trees and used their feathered limbs for gliding. (The evolution of feathers is discussed in *Focus On: The Origin of Flight in Birds,* in Chapter 21).

Modern birds are adapted for flight

Biologists have described about 9000 species of extant birds and classified them into about 23 monophyletic groups. Birds inhabit a variety of habitats and can be found on all continents, most islands, and even the open sea. Birds are a diverse group (Fig. 31-23). The largest living birds are the ostriches of Africa, which may be up to 2 m (6.5 ft) tall and weigh 136 kg (300 lb), and the great condors of the Americas, with wingspans of up to 3 m (10 ft). The smallest known bird is Helena's hummingbird of Cuba, with a length of less than 6 cm (a little over 2 in) and a weight of less than 4 g (0.14 oz).

Like their reptilian ancestors, modern birds lay eggs and have reptilian-type scales on their legs. Birds have evolved remarkable specializations for flight. Their feathers are very light, yet flexible and strong, and present a flat surface to the air. Feathers also protect the body and decrease water and heat loss. The anterior limbs of birds are wings, usually adapted for flight. The posterior limbs are modified for walking, swimming, or perching.

Birds also have other adaptations for flight. Their bodies are compact and streamlined, and the fusion of many bones gives them the rigidity needed for flying. Their bones are strong but very light. Many are hollow, containing large air spaces. The avian jaw is light, and instead of teeth, birds have a light, horny beak. The breastbone is broad and keeled for the attachment of the large flight muscles.

Birds have efficient lungs with **air sacs,** thin-walled extensions that occupy spaces between the internal organs and within certain bones. They have a unique "one-way" flow of air through their respiratory system (discussed in Chapter 45). Birds have a four-chambered heart and a double circuit of blood flow. Blood delivers oxygen to the tissues and then recharges with oxygen in the lungs before the heart pumps it back into the systemic circulation. The very effective respiratory and circulatory systems provide the cells with enough oxygen to permit a high metabolic rate, which is necessary for the tremendous muscular activity that flying requires. Some of the heat a bird generates by metabolic activities helps it maintain a constant body temperature. Because they are endotherms, birds can remain active in cold climates.

Birds excrete nitrogenous wastes mainly as semisolid uric acid. Because birds typically do not have a urinary bladder, these solid wastes are delivered into the cloaca. They leave the body

Figure 31-23 Modern birds

Although they are diverse, most birds are highly adapted for flight, and their basic structure is similar.

with the feces, which are dropped frequently. This adaptive mechanism helps maintain a light body weight.

Birds have become adapted to a variety of environments, and various species have different types of beaks, feet, wings, tails, and behavioral patterns. Not all birds fly. Some, such as penguins, have small, flipperlike wings used in swimming. **Ratites** are a group of mainly large, flightless birds, including the ostriches, cassowaries, and kiwis. These birds have only vestigial wings, but they have well-developed legs used for running.

Bills are specifically adapted for the type of food the bird eats (see Fig. 1-11). Birds must eat frequently because they have a high metabolic rate and typically do not store much fat. Although the choice of food varies widely among species, most birds eat energy-rich foods such as seeds, fruits, worms, mollusks, or arthropods. Warblers and some other species eat mainly insects. Owls and hawks eat rodents, rabbits, and other small mammals. Some hawks catch snakes and lizards. Vultures feed on dead animals. Pelicans, gulls, terns, and kingfishers catch fish.

An interesting feature of the bird digestive system is the **crop,** an expanded, saclike portion of the digestive tract below the esophagus, in which food is temporarily stored. The stomach is divided into a **proventriculus,** which secretes gastric juices; and a thick, muscular **gizzard,** which grinds food. The bird swallows small bits of gravel that act as "teeth" in the gizzard to mechanically break down food.

Birds have a well-developed nervous system, with a brain that is proportionately larger than that of reptiles. Birds rely heavily on vision, and their eyes are relatively larger than those of other vertebrates. Hearing is also well developed.

In striking contrast with the relatively silent reptiles, birds are very vocal. Most have short, simple *calls* that signal danger or influence feeding, flocking, or interaction between parent and young. *Songs* are usually more complex than calls and are performed mainly by males. Birds sing songs to attract and keep a mate and to claim and defend a territory.

One of the most fascinating aspects of bird behavior is the annual migration made by many species. Some birds, such as the golden plover and Arctic tern, fly from Alaska to Patagonia, South America, and back each year, covering perhaps 40,250 km (25,000 mi) en route. Migration and navigation are discussed in Chapter 51.

Many birds have beautiful, striking colors. The color is due partly to pigments deposited during the development of the feathers and partly to reflection and refraction of light of certain wavelengths. Many birds, especially females, are protectively colored by their plumage. During the breeding season the male often assumes brighter colors to help him attract a mate.

Mammals are characterized by hair and mammary glands

Derived characters that distinguish mammals (class Mammalia) include **hair,** which insulates and protects the body; **mammary glands,** which produce milk for the young; **differentiation of teeth** into incisors, canines, premolars, and molars; and three **middle-ear bones** (malleus, incus, and stapes) that conduct vibrations. The evolution of the **cochlea,** an organ of hearing in the inner ear, gives mammals an excellent sense of hearing.

Painting by John C. Germann, Department of Library Services, American Museum of Natural History

Figure 31-24 Therapsid (*Lycaenops*)

The therapsids were synapsid reptiles. *Lycaenops,* a carnivore about the size of a coyote, lived in South Africa during the Late Permian period.

A muscular **diaphragm** helps move air into and out of the lungs. Like birds, mammals are endotherms, but biologists think that mammals evolved endothermy independently of birds. Maintaining a constant body temperature is enhanced by the covering of insulating hair, by the four-chambered heart, and by separate pulmonary and systemic circulations. Red blood cells without nuclei serve as efficient oxygen transporters.

Contributing significantly to the success of the mammals, the nervous system is more highly developed than in any other group of animals. The cerebrum is especially large and complex, with an outer gray region called the **cerebral cortex.** In mammals, the highly specialized cerebral cortex, called the **neocortex,** has six layers of neurons. Specific regions in the neocortex are specialized for functions such as vision, hearing, touch, movement, emotional response, and higher cognitive functions.

Fertilization in mammals is internal, and with the exception of the primitive monotremes that lay eggs, mammals are viviparous. Most mammals develop a **placenta,** an organ of exchange between developing embryo and mother. As the mother's blood passes through blood vessels in the placenta, it delivers nourishment and oxygen to the embryo and carries off wastes. By carrying their developing young internally, mammals avoid the hazards of having their eggs consumed by predators. By nourishing the young and caring for them, the parents offer both protection and an "education" on how to obtain food and avoid being eaten.

The limbs of mammals are variously adapted for walking, running, climbing, swimming, burrowing, or flying. In four-

legged mammals, the limbs are more directly under the body than they are in extant reptiles, which contributes to speed and agility.

New fossil discoveries are changing our understanding of the early evolution of mammals

Mammals descended from **therapsids,** a group of synapsid reptiles, during the Triassic period more than 200 mya. The therapsids were dog-like carnivores with differentiated teeth and legs adapted for running (Fig. 31-24). Until recently, early mammals were thought to be small, about the size of a mouse or shrew. However, recent fossil evidence indicates that early mammals were much more diverse than previously imagined. Some early mammals were fairly large, with limbs adapted for swimming or burrowing. Some had fur, and some may have been endothermic.

How did mammals manage to coexist with reptiles during the approximately 160 million years that reptiles ruled Earth? Many adaptations permitted early mammals to compete for a place on this planet. Perhaps one of the most important was their skill at being inconspicuous. Many were **arboreal** (tree dwelling) and **nocturnal** (active at night), searching for food (mainly insects and plant material, and perhaps reptile eggs) at night while the reptiles were inactive. Although their eyes may have been small, early mammals had well-developed sense organs for hearing and smell.

As many reptiles became extinct, mammals adapted to the niches (lifestyles) that reptiles abandoned. During this time, the flowering plants, including many trees, underwent an adaptive radiation, providing new habitats, sources of food, and protection from predators. Numerous new varieties of mammals evolved. During the Early Cenozoic era (more than 55 mya), the mammals underwent an adaptive radiation; they became widely distributed and adapted to an impressive variety of ecological lifestyles.

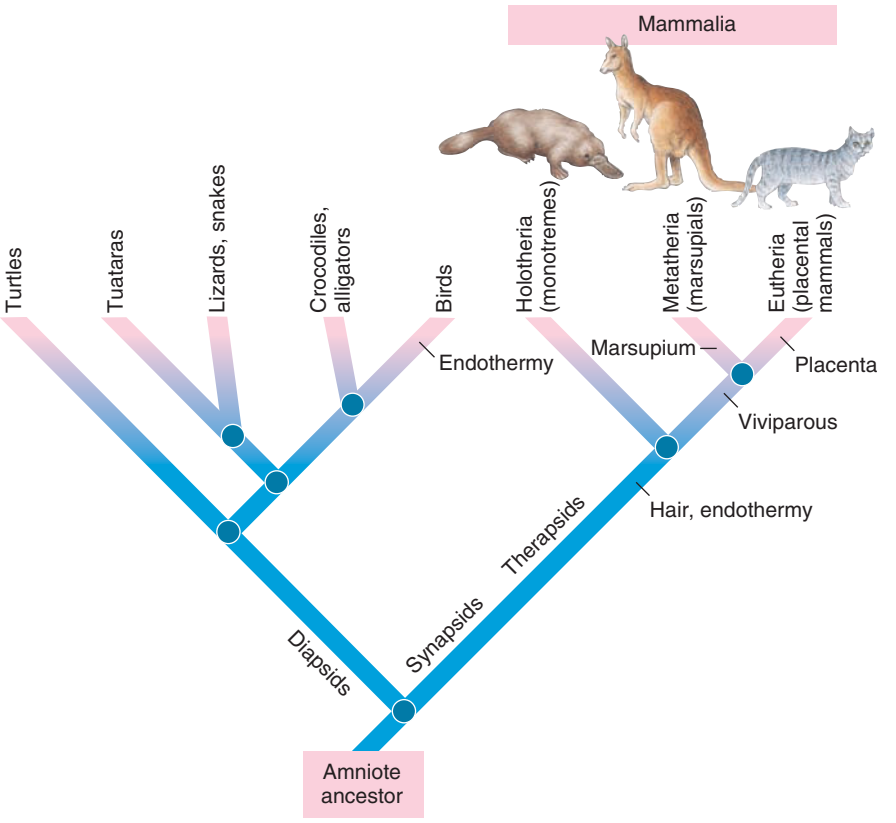

Figure 31-25 Evolution of mammals

This cladogram shows the current interpretation of the evolution of mammals.

Modern mammals are assigned to three subclasses

By the end of the Cretaceous period, three main groups of mammals had evolved (Fig. 31-25). Today, mammals inhabit virtually every corner of Earth; they live on land, in fresh and salt water, and in the air. They range in size from the tiny pigmy shrew, weighing about 2.5 g (less than 0.1 oz), to the blue whale, which may weigh up to 136,000 kg (150 tons) and which is probably one of the largest animals that has ever lived.

Modern mammals are classified in three subclasses: **Holotheria** includes the egg-laying mammals, or monotremes; **Metatheria** includes the marsupials, or pouched mammals; and **Eutheria** includes the placental mammals.

The **monotremes** are the only living order of subclass Holotheria. One genus includes the duck-billed platypus and a second, the spiny anteaters or echidnas (Fig. 31-26; see also

Tom McHugh/Photo Researchers, Inc.

Figure 31-27 Marsupials

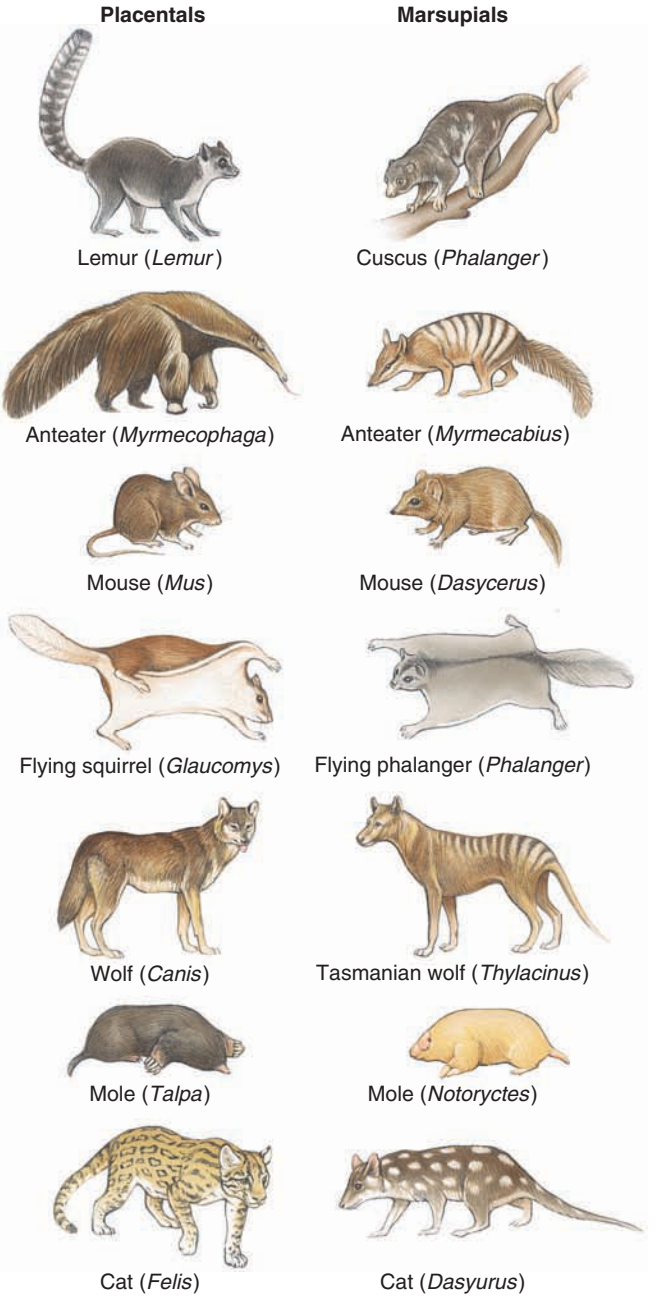

Figure 31-28 Convergent evolution in placental and marsupial mammals

For each mammal in one group, there is a counterpart in the other group. Their similarities include both lifestyles and structural features.

Figs. 1-16 and 23-5). These animals live in Australia and Tasmania; two of the three spiny anteater species also live in New Guinea. The females lay eggs that they carry in a pouch on the abdomen or keep warm in a nest. When the young hatch, they lap up milk secreted by their mother's mammary glands. Unlike other mammals, monotremes do not have nipples. With their long beaks and long, sticky tongues, spiny anteaters capture ants and termites. The duck-billed platypus, which lives in burrows along river banks, preys on freshwater invertebrates. It has webbed feet and a flat, beaverlike tail, which help it swim.

Marsupials include pouched mammals such as kangaroos and opossums (Fig. 31-27a). Embryos begin their development

in the mother's uterus, where they are nourished by fluid and yolk. The young are born after a few weeks in an undeveloped stage. In many species, the young crawl to the **marsupium** (pouch), where they complete their development. The young marsupial attaches its mouth to a mammary gland nipple and is nourished by its mother's milk (Fig. 31-27b).

At one time, marsupials probably inhabited much of the world, but placental mammals largely outcompeted them. Now marsupials live mainly in Australia and in Central and South America. The only marsupial species that ranges into the United States is the Virginia opossum. Australia became geographically isolated from the rest of the world before placental mammals migrated there, and the marsupials remained the dominant mammals (see discussion of continental drift in Chapter 18). Australian marsupials underwent adaptive radiation, paralleling the evolution of placental mammals elsewhere. Thus, marsupials that live in Australia and adjacent islands correspond to North American placental wolves, bears, rats, moles, flying squirrels, and even cats (Fig. 31-28).

Most familiar to us are **placental mammals,** characterized by development of a placenta (Fig. 31-29). The placenta forms from both embryonic membranes and the maternal uterine wall. In it the blood vessels of the embryo come very close to the blood vessels of the mother, so materials can be exchanged by diffusion. (The two circulations do not normally mix.) The placenta allows the young to remain within the mother's body until embryonic development is complete.

Placental mammals are born at a more mature stage than marsupials. Indeed, among some species the young can walk and begin to interact with other members of the group within a few minutes after birth. Biologists assign extant placental mammals to about 19 orders. Table 31-3 gives a brief summary of some of these orders. Remember that aquatic mammals, such as dolphins, whales, and seals, evolved from terrestrial ancestors (see Fig. 18-8).

Review

- What vertebrate adaptations are important for terrestrial life?
- What are some arguments for classifying birds and reptiles in a single clade?
- Which amniotes are endothermic? What are some advantages of endothermy?
- What are the three main clades of mammals? How do they differ?

TABLE 31-3

Some Orders of Living Placental Mammals

Order, Representative Members, and Some Characteristics

Insectivora (moles, hedgehogs, shrews)

Nocturnal; eat insects; considered most primitive placental mammals. Shrew is smallest living mammal; some weigh less than 5 g.

African hedgehog
Atelerix albiventris

Chiroptera (bats)

Adapted for flying; fold of skin extends from elongated fingers to body and legs, forming wing. Guided in flight by type of biological sonar; emit high-frequency squeaks and are guided by echoes from obstructions. Eat insects and fruit or suck blood of other animals.

Bat
Eptesicus fuscus

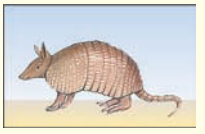
Carnivora (cats, dogs, wolves, foxes, bears, otters, mink, weasels, skunks)

Carnivores with sharp, pointed canine teeth and molars for shearing; keen sense of smell; complex social interactions; among fastest, strongest, and smartest animals. Seals, sea lions, and walruses are large marine carnivores with limbs adapted as flippers for swimming; these mammals, known as pinnipeds, are now classified in order Carnivora.

Wolf
Canis lupus

Xenarthra (sloths, anteaters, armadillos)

Teeth reduced or no teeth. Sloths are sluggish animals that hang upside down from branches; often protectively colored by green algae that grow on their hair. Armadillos are protected by bony plates; eat insects and small invertebrates.



Nine-banded armadillo
Dasypus bellus

Rodentia (squirrels, beavers, rats, mice, hamsters, porcupines, guinea pigs)

Gnawing animals with chisel-like incisors. As they gnaw, teeth are worn down, and so must grow continually.

Flying squirrel
Glaucomys volans

Lagomorpha (rabbits, hares, pikas)

Like rodents, have chisel-like incisors; typically have long hind legs adapted for jumping; many have long ears.

Pika
Ochontona sp.

Primates (lemurs, monkeys, apes, humans)

Highly developed brains and eyes; nails instead of claws; opposable thumb; eyes directed forward; omnivores; most species arboreal. (Primate evolution discussed in Chapter 22.)

Ring-tailed lemur
Lemur catta

Perissodactyla (horses, zebras, tapirs, rhinoceroses)

Herbivores; hoofed with odd number of digits per foot; one or three toes; teeth adapted for chewing; usually large animals with long legs.

Tapir
Tapirus sp.

Artiodactyla (cattle, sheep, pigs, deer, giraffes)

Hoofed with even numbers of digits per foot; most have two toes, some have four. Most have antlers or horns. Herbivores; most are ruminants, chew a cud and have series of stomachs inhabited by bacteria that digest cellulose.

American elk
Cervus elaphus

Proboscidea (elephants)

Largest land animals; weigh up to 7 tons; large head; broad ears; long, muscular, flexible trunk (proboscis); thick loose skin is characteristic; two upper incisors are elongated as tusks. Includes extinct mastodons and woolly mammoths.

African elephant
Loxodonta africana

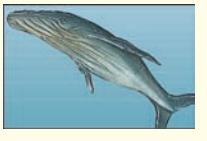
Sirenia (sea cows, manatees)

Herbivorous, aquatic mammals with fin-like forelimbs and no hind limbs. They are probably the basis for most tales about mermaids.

Manatee
Trichechus manatus

Cetacea (whales, dolphins, porpoises)

Adapted for aquatic life with fish-shaped body and broad, paddlelike forelimbs (flippers); posterior limbs absent; many have thick layer of blubber under skin; some are suspension feeders; mate and bear young in the water; very intelligent.



Humpback whale
Megaptera noveangliae

SUMMARY WITH KEY TERMS

Learning Objectives

1 Identify shared derived characters of deuterostomes (page 668).

- **Deuterostomes** include echinoderms, hemichordates, and chordates. **Hemichordates** (acorn worms) are marine deuterostomes with a three-part body, including proboscis, collar, and trunk. Shared derived characters include radial, indeterminate cleavage; the blastopore becomes (or is near the future site of) the anus; basal deuterostomes have a larva with a loop-shaped ciliated band used for locomotion.

2 Identify three shared derived characters of echinoderms, and describe the main classes of echinoderms (page 668).

- Phylum **Echinodermata** includes marine animals with a spiny "skin," **water vascular system, tube feet,** and **endoskeleton.** The larvae exhibit bilateral symmetry; most of the adults exhibit **pentaradial symmetry.**
- Class **Crinoidea** includes sea lilies and feather stars. The **oral surface** of crinoids is turned upward; some crinoids are sessile.
- Class **Asteroidea** consists of the sea stars. They have a central disc with five or more arms. They use tube feet for locomotion.
- Class **Ophiuroidea** includes the brittle stars, which resemble sea stars but have longer, more slender arms that are set off more distinctly from the central disc. They use their arms for locomotion. Their tube feet lack suckers and are not used in locomotion.
- Class **Echinoidea** includes the sea urchins and sand dollars. Echinoids lack arms; they have a solid shell and are covered with spines.
- Class **Holothuroidea** consists of sea cucumbers, animals with elongated flexible bodies. The mouth is surrounded by a circle of modified tube feet that serve as tentacles.

3 Describe five shared derived characters of chordates (page 671).

- Phylum **Chordata** is divided into three subphyla: Urochordata, Cephalochordata, and Vertebrata. At some time in its life cycle, a chordate has a flexible, supporting **notochord;** a **dorsal, tubular nerve cord; pharyngeal (gill) slits;** a muscular **postanal tail;** and an **endostyle,** or thyroid gland.

4 Describe the invertebrate chordate subphyla (page 672).

- The **tunicates,** which belong to subphylum **Urochordata,** are suspension-feeding, marine animals with **tunics.** Larvae have typical chordate characteristics and are free-swimming. Adults of most groups are sessile suspension feeders.
- Subphylum **Cephalochordata** consists of the **lancelets,** small, segmented, fishlike animals that exhibit chordate characteristics.

ThomsonNOW™ Learn more about the body plans of the deuterostomes by clicking on the figures in ThomsonNOW.

5 Discuss the evolution of chordates (page 672).

- The urochordates (tunicates) were probably the first of the extant chordates to evolve.
- Subphyla Cephalochordata and **Vertebrata** are viewed as **sister taxa,** groups that diverged from a recent common ancestor.

ThomsonNOW™ Explore the evolutionary relationships of vertebrates by clicking on the figure in ThomsonNOW.

6 Describe four shared derived characters of vertebrates (page 674).

- The vertebrates have a **vertebral column** that forms the chief skeletal axis of the body and a braincase called a **cranium. Neural crest cells** give rise to or influence the development of many structures, including the cranium and jaws. Vertebrates have pronounced cephalization, a complex brain, and muscles attached to the **endoskeleton** for movement.

7 Distinguish among the major groups of jawless fishes (page 677).

- Some of the earliest known vertebrates, called **ostracoderms,** were jawless fishes that are now extinct.
- The extant jawless fishes, or **agnathans,** are the hagfishes, assigned to class **Myxini,** and the lampreys, to class **Cephalaspidomorphi.** Because hagfishes have no trace of vertebrae, some systematists have argued that they should not be classified as vertebrates. They classify the vertebrates plus the hagfishes as craniates (Craniata). However, molecular data support classifying hagfishes as vertebrates. Jaws and paired fins are absent in both hagfishes and lampreys. Hagfishes are marine scavengers that secrete slime as a defense mechanism. Many lampreys are parasites on other fishes.

8 Trace the evolution of jawed fishes and early tetrapods, and identify major taxa of jawed fishes and amphibians (page 678).

- Class **Chondrichthyes,** the cartilaginous fishes, includes the sharks, rays, and skates. These fishes have jaws, two pairs of fins, and **placoid scales.** Skates and some species of sharks are **oviparous** and lay eggs. Many species of sharks are **ovoviparous;** their young are enclosed by eggs that are incubated in the mother's body. A few shark species are **viviparous;** the young develop in the mother's uterus and are nourished by transfer of nutrients from the mother's blood.
- The bony fishes are assigned to three classes: **Actinopterygii,** ray-finned fishes; **Actinistia,** coelacanths; and **Dipnoi,** lungfishes. During the Devonian, bony fishes gave rise to two evolutionary lines: the Actinopterygii, or **ray-finned fishes,** and the **Sarcopterygii,** or **lobe-finned fishes.**
- The ray-finned fishes gave rise to the modern bony fishes. In these fishes, the lungs have been modified as a **swim bladder,** an air sac for regulating buoyancy.
- The sarcopterygii probably gave rise to the **lungfishes** (class Dipnoi) and **coelacanths** (class Actinistia). Biologists think the lungfishes gave rise to the **tetrapods,** the land vertebrates. ***Tiktaalik*** was a transitional form between fishes and tetrapods.
- Early amphibians were mainly aquatic animals that ventured onto the land to find food or escape predators. These early tetrapods had limbs strong enough to support the weight of their bodies on land.
- Class **Amphibia** includes salamanders, frogs and toads, and caecilians. Most amphibians return to the water to reproduce. Frog embryos develop into **tadpoles,** which undergo **metamorphosis** to become adults. Amphibians use their moist skin as well as lungs for gas exchange.

They have a three-chambered heart and **systemic** and **pulmonary circulations.**

ThomsonNOW™ Learn more about jawless, early jawed, cartilaginous, and bony fishes by clicking on the figures in ThomsonNOW.

9 Describe three vertebrate adaptations to terrestrial life (page 683).

- Terrestrial vertebrates, or **amniotes,** include reptiles, birds, and mammals. The evolution of the **amniotic egg** with its shell and amnion was an important adaptation for life on land. The **amnion** is a membrane that forms a fluid-filled sac around the embryo. Amniotes have a body covering that retards water loss. They also have physiological mechanisms that conserve water.

ThomsonNOW™ Learn more about the amniotic egg by clicking on the figure in ThomsonNOW.

10 Describe the reptiles and birds, and give an argument for including the birds in the reptile clade (page 683).

- Class **Reptilia,** as traditionally defined, is paraphyletic. It includes dinosaurs, turtles, lizards, snakes, and alligators. Biologists classify amniotes in two main groups: diapsids and synapsids. **Diapsids** include the turtles, ichthyosaurs, tuataras, squamates (snakes and lizards), crocodiles, pterosaurs, saurischian dinosaurs, and birds. The **synapsids** gave rise to the **therapsids,** which gave rise to the mammals.
- Many biologists consider the birds as feathered dinosaurs; they classify the birds along with most of the reptiles as diapsids.
- Extant reptiles (excluding birds) are classified in four groups: turtles, terrapins, and tortoises; lizards, snakes, and amphisbaenians; tuataras; and crocodiles, alligators, caimans, and gavials.
- In reptiles, fertilization is internal, and most reptiles secrete a leathery protective shell around the egg. The embryo develops protective membranes, including an amnion that keeps it moist. Reptiles have dry skin with horny scales, lungs with many chambers, and a three-chambered heart with some separation of oxygen-rich and oxygen-poor blood.
- Birds have many adaptations for powered flight, including feathers; wings; and light, hollow bones containing air spaces. Birds have a four-chambered heart and very efficient lungs, and they excrete solid metabolic wastes (uric acid). They are **endotherms,** that is, they maintain a constant body temperature. Birds have a well-developed nervous system and excellent vision and hearing.

11 Contrast monotremes, marsupials, and placental mammals; and give examples of animals that belong to each group (page 683).

- **Mammals** have **hair, mammary glands, differentiated teeth,** and three **middle-ear bones.** They are endotherms and have a highly developed nervous system and a muscular **diaphragm.**
- **Monotremes** (subclass **Holotheria**) include the duck-billed platypus and spiny anteaters. Monotremes lay eggs.
- **Marsupials** (subclass **Metatheria**) include pouched mammals, such as kangaroos and opossums. The young are born in an embryonic stage. They complete their development in their mother's **marsupium,** where they are nourished with milk from the mammary glands.
- **Placental mammals** (subclass **Eutheria**) are characterized by the **placenta,** an organ of exchange that develops between the embryo and the mother.

TEST YOUR UNDERSTANDING

1. Which of the following is *not* a deuterostome? (a) echinoderm (b) chordate (c) hemichordate (d) arthropod (e) hagfish
2. Which of the following belongs to subphylum Vertebrata? (a) lophophorate (b) lamprey (c) lancelet (d) tunicate (e) crinoid
3. Which of the following is/are found in tunicates? (a) notochord (b) tube feet (c) anal gill slits (d) two pairs of appendages (e) vertebral column
4. Which of the following was an early jawed fish? (a) placoderm (b) crinoid (c) therapsid (d) saurischian (e) ostracoderm
5. Arrange the following animals to reflect an accepted sequence of evolution.

   1. lungfish 2. dinosaur 3. amphibian 4. bird

   (a) 3, 1, 2, 4 (b) 1, 3, 2, 4 (c) 2, 1, 3, 4 (d) 1, 2, 3, 4
6. Which of the following characteristics is *not* associated with sea stars? (a) tube feet (b) water vascular system (c) central disc with five or more arms (d) spiny skeleton (e) notochord
7. Which of the following characteristics is associated with amphibians? (a) mantle (b) placoid scales (c) three-chambered heart (d) swim bladder (e) amnion
8. Which of the following is *not* characteristic of birds? (a) hollow bones (b) ectothermy (c) amnion (d) high metabolic rate (e) reptilian-like scales on legs
9. Which of the following is *not* true of the duck-billed platypus? (a) is classified as a marsupial (b) lays eggs (c) has a notochord at embryo stage (d) has pharyngeal slits at embryo stage (e) is a predator
10. Which of the following is *not* a placental mammal? (a) shrew (b) human (c) dolphin (d) spiny anteater (e) bat
11. Which of the following is a shared derived character of mammals? (a) placenta (b) amnion (c) three middle-ear bones (d) endostyle (e) notochord
12. The vertebral column (a) is a shared derived character of chordates (b) forms the skeletal axis of the chordate body (c) may consist of cartilaginous or bony segments (d) is well developed in lancelets (e) three of the preceding are correct

13. A shark is characterized by (a) placoid scales (b) bony skeleton (c) water vascular system (d) amnion (e) muscular diaphragm
14. Reptiles (a) have dry, scaly skin (b) are amniotes (c) gave rise to the birds and mammals (d) a, b, and c (e) a and c
15. Amniotes (a) include amphibians, reptiles, birds, and mammals (b) are especially well adapted for fresh water (c) have physiological mechanisms for conserving water (d) typically excrete ammonia (e) gave rise to the amphibians
16. Which of the following is *not* true? (a) feathers evolved in dinosaurs (b) birds are endothermic (c) birds excrete uric acid (d) birds have an amniotic egg (e) *Archaeopteryx* was the ancestor of feathered dinosaurs

CRITICAL THINKING

1. Sea urchins have radial symmetry. Explain why they are not classified as Radiata along with the cnidarians.
2. Which are more specialized, birds or mammals? Argue for each case.
3. Imagine that you discover an interesting new animal. You find it has a dorsal, tubular nerve cord; a cranium; moist skin; and a heart with two atria and a single ventricle. How would you classify the animal? Explain each step in your decision.
4. **Evolution Link.** Discuss the relationships among the echinoderms and chordates, describing shared derived characters that support grouping them as deuterostomes.
5. **Evolution Link.** Support the hypothesis that lungfishes gave rise to tetrapods.
6. **Evolution Link.** Many biologists now consider birds as living dinosaurs. Justify this position.
7. **Evolution Link.** Some biologists consider monotremes to be therapsid reptiles rather than mammals. Give arguments for and against this position.

Plant Structure, Growth, and Differentiation

Runk/Schoenberger from Grant Heilman

Oak seedling. A massive oak tree may grow from this young basket oak (*Quercus prinus*) seedling.

KEY CONCEPTS

Plants exhibit a variety of patterns of growth, reproduction, and longevity.

The structure of plant cells, tissues, and organs matches their functions.

The vascular plant body is differentiated into three tissue systems: the ground tissue system, the vascular tissue system, and the dermal tissue system.

Primary growth lengthens roots and shoots throughout the life span of most plants.

Woody plants have both primary growth and secondary growth, in which they increase in thickness.

About 90% of the approximately 330,000 species of plants are *flowering plants*, vascular plants characterized by flowers, double fertilization, endosperm, and seeds enclosed within fruits (see Chapter 28). Because flowering plants are the largest, most successful group of plants, they are the focus of much of this chapter and of Chapters 33 to 37.

Let us begin our study of the structure and functions of plants by examining a familiar species, the oak, and its fruit, the acorn. A new oak often begins its life after a squirrel has buried an acorn in the soil. The seed within first absorbs water from the surrounding soil. *Germination* occurs as a root emerges and works its way into the soil, absorbing additional water and anchoring the young plant. A shoot grows upward and breaks through the soil. At this point the young oak (see photograph) is a *seedling* that still depends on the food supply within the seed.

The stem continues to elongate, and small leaves develop, expand, and begin to photosynthesize. The young tree grows taller by growth at the tips of its branches. The roots likewise elongate at their tips. As it ages, the tree also forms wood and bark, increasing in girth (thickness) along the sides of the more mature stems and roots. Growth and expansion of both the root and shoot systems continue throughout the oak's life.

After several years, the oak tree becomes reproductively mature. Oaks reproduce by forming separate male and female flowers. The minute male flowers are found together on slender, drooping, caterpillar-shaped *catkins* (clusters); in contrast, the tiny female flowers are often solitary. After wind carries pollen from a male flower to a female flower, a sperm cell fertilizes the egg and

an acorn develops, partially enclosed by a scaly cup. Within the acorn is a seed containing an embryo of a miniature oak, along with a supply of stored food. Thus, the cycle of life repeats itself.

In this chapter we examine the external structure of the flowering plant body; the organization of its cells, tissues, and tissue systems; and its basic growth patterns. ■

PLANT STRUCTURE AND LIFE SPAN

Learning Objectives

1 Distinguish between herbaceous and woody plants.
2 Discuss the differences among annuals, biennials, and perennials, and give an example of each.
3 Contrast two different life history strategies in plants.

Plants range in size from the minute floating water-meal (*Wolffia microscopica*), the smallest flowering plant known, to Australian gum trees (*Eucalyptus*), some of Earth's tallest trees (Fig. 32-1). The more than 300,000 species of flowering plants that live in and are adapted to the many environments on Earth represent remarkable variety. Yet all of these—from desert cacti with enormously swollen stems, to cattails partly submerged in marshes, to orchids growing in the uppermost tree branches of lush tropical rain forests—are recognizable as plants. Almost all plants have the same basic body plan, which consists of roots, stems, and leaves.

Plants are either herbaceous or woody. *Herbaceous* plants are nonwoody. In temperate climates, the aerial parts (stems and leaves) of herbaceous plants die back to the ground at the end of the growing season. In contrast, the aerial parts of *woody* plants (trees and shrubs) persist. Botanically speaking, woody plants produce hard, lignified secondary tissues (the cell walls of secondary tissues contain *lignin*), and herbaceous plants do not. Lignin and the production of secondary tissues are discussed later in the chapter.

Annuals are herbaceous plants (such as corn, geranium, and marigold) that grow, reproduce, and die in 1 year or less. Other herbaceous plants (such as carrot, Queen Anne's lace, cabbage, and foxglove) are **biennials;** they take 2 years to complete their life cycles before dying. During their first season, biennials produce extra carbohydrates, which they store and use during their second year, when they typically form flowers and reproduce. **Perennials** are herbaceous and woody plants that have the potential to live for more than 2 years. In temperate climates, the aerial (aboveground) stems of herbaceous perennials such as iris, rhubarb, onion, and asparagus die back each winter. Their underground parts (roots and underground stems) become dormant during the winter and send out new growth each spring. (In **dormancy,** an organism reduces its metabolic state to a minimum level to survive unfavorable conditions.) Similarly, in certain tropical climates with pronounced wet and dry seasons, the aerial parts of herbaceous perennials die back and the underground parts become dormant during the unfavorable dry season. Other tropical plants, such as orchids, are herbaceous perennials that grow year-round.

All woody plants are perennials, and some of them live for hundreds or even thousands of years. In temperate climates, the

Carlyn Iverson

(a) Duckweed (*Spirodela*), the larger green plants in the photograph, are tiny floating aquatic plants about 1 cm (0.4 in) across. If you look closely at the frog's body, you will see minute green dots. Each is a water-meal (*Wolffia*) plant. These tiny floating herbs, about 1.5 mm (0.06 in) wide, are the smallest known flowering plants.

Gunter Ziesler/Peter Arnold, Inc.

(b) This red tingle tree (*Eucalyptus jacksonii*) was photographed in Walpole Noralup National Park, Australia. Red tingles, which are rare and endemic to Western Australia, have massive bases, with girths up to 26 m (85 ft), and heights of 75 m (244 ft).

Figure 32-1 Size variation in plants

aboveground stems of woody plants become dormant during the winter. Many temperate woody perennials are **deciduous;** that is, they shed their leaves before winter and produce new stems with new leaves the following spring. Other woody perennials are **evergreen** and shed their leaves over a long period, so some leaves are always present. Because they have permanent woody stems that are the starting points for new growth the following season, many trees attain massive sizes.

Plants have different life history strategies

Woody perennials often live for hundreds of years, whereas some herbaceous annuals may live for only a few weeks or months. Such characteristic features of an organism's life cycle, particularly as they relate to its survival and successful reproduction, are known as **life history strategies.** Biologists try to understand the relative advantages of each life history strategy, including any trade-offs involved in the allocation of various resources. It appears that in some environments a longer life span is advantageous, whereas in other environments a shorter life span increases a species' chances for reproductive success—that is, for long-term survival.

When an environment is relatively favorable, it is filled with plants competing for available space. Because such an environment is so crowded, it has few open spots in which new plants can become established. When a plant dies, the empty area is quickly filled by another plant, but not necessarily by the same species as before. Thus, an adult perennial survives well, but young plants, whether perennials or annuals, do not. A plant with a long life span thrives in this type of environment because it can occupy a piece of soil and continue to produce seeds for many years. In a tropical rain forest, for example, competition prevents most young plants from becoming established, and woody perennials predominate. These perennials expend considerable energy in making woody tissues, but this energy investment allows them to thrive and reproduce for a long period.

In a relatively unfavorable environment, many possible sites are usually available. This type of environment is not crowded, and young plants usually do not have to compete against large, fully established plants. Here, smaller, short-lived plants have the reproductive advantage. These plants are opportunists; that is, they grow and mature quickly during the brief periods when environmental conditions are most favorable. As a result, all their resources are directed into producing as many seeds as possible before dying. In deserts following a rainy period, for example, annuals are more prevalent than woody perennials.

Thus, each species has a characteristic life history strategy, with some plants adapted to variable environments and others adapted to stable environments. The longer life span characteristic of woody perennials is just one of several successful life history plans. We return to life history strategies in our discussion of population ecology (see Chapter 52).

Review

- Consider a common plant such as a marigold. Is it herbaceous or woody? An annual, biennial, or perennial? Explain.
- Consider a common plant such as a carrot. Is it herbaceous or woody? An annual, biennial, or perennial? Explain.
- Consider a common plant such as an oak. Is it herbaceous or woody? An annual, biennial, or perennial? Explain.

THE PLANT BODY

Learning Objectives

4 Discuss the functions of various parts of the vascular plant body, including the nutrient- and water-absorbing root system and the photosynthesizing shoot system.
5 Describe the structure and functions of the ground tissue system (parenchyma tissue, collenchyma tissue, and sclerenchyma tissue).
6 Describe the structure and functions of the vascular tissue system (xylem and phloem).
7 Describe the structure and functions of the dermal tissue system (epidermis and periderm).

The plant body of flowering plants (and other vascular plants) is usually organized into a root system and a shoot system (Fig. 32-2). The **root system** is generally underground. The aboveground portion, the **shoot system,** usually consists of a vertical stem that bears leaves and, in flowering plants, flowers and fruits that contain seeds.

Each plant typically grows in two different environments: the dark, moist soil and the illuminated, relatively dry air. Plants usually have both roots and shoots because they require resources from both environments. Thus, roots branch extensively through the soil, forming a network that anchors the plant firmly in place and absorbs water and dissolved minerals (inorganic nutrients) from the soil. Leaves, the flattened organs of photosynthesis, are attached more or less regularly on the stem, where they absorb the sun's light and atmospheric carbon dioxide (CO_2) used in photosynthesis.

The plant body consists of cells and tissues

As in other organisms, the basic structural and functional unit of plants is the cell. Plants have evolved a variety of cell types, each specialized for particular functions.

Like animal cells, plant cells are organized into tissues. A **tissue** is a group of cells that forms a structural and functional unit. *Simple tissues* are composed of only one kind of cell, whereas *complex tissues* have two or more kinds of cells.

In vascular plants, tissues are organized into three tissue systems, each of which extends throughout the plant body (Fig. 32-3). Each tissue system contains two or more kinds of tissues (Table 32-1 on page 703). Most of the plant body is composed of the **ground tissue system,** which has a variety of functions, including photosynthesis, storage, and support. The **vascular tissue system,** an intricate conducting system that extends throughout the plant body, is responsible for conduction of various substances, including water, dissolved minerals, and

Key Point

During the evolution of plants, the root and shoot systems specialized to obtain resources from the soil and air, respectively.

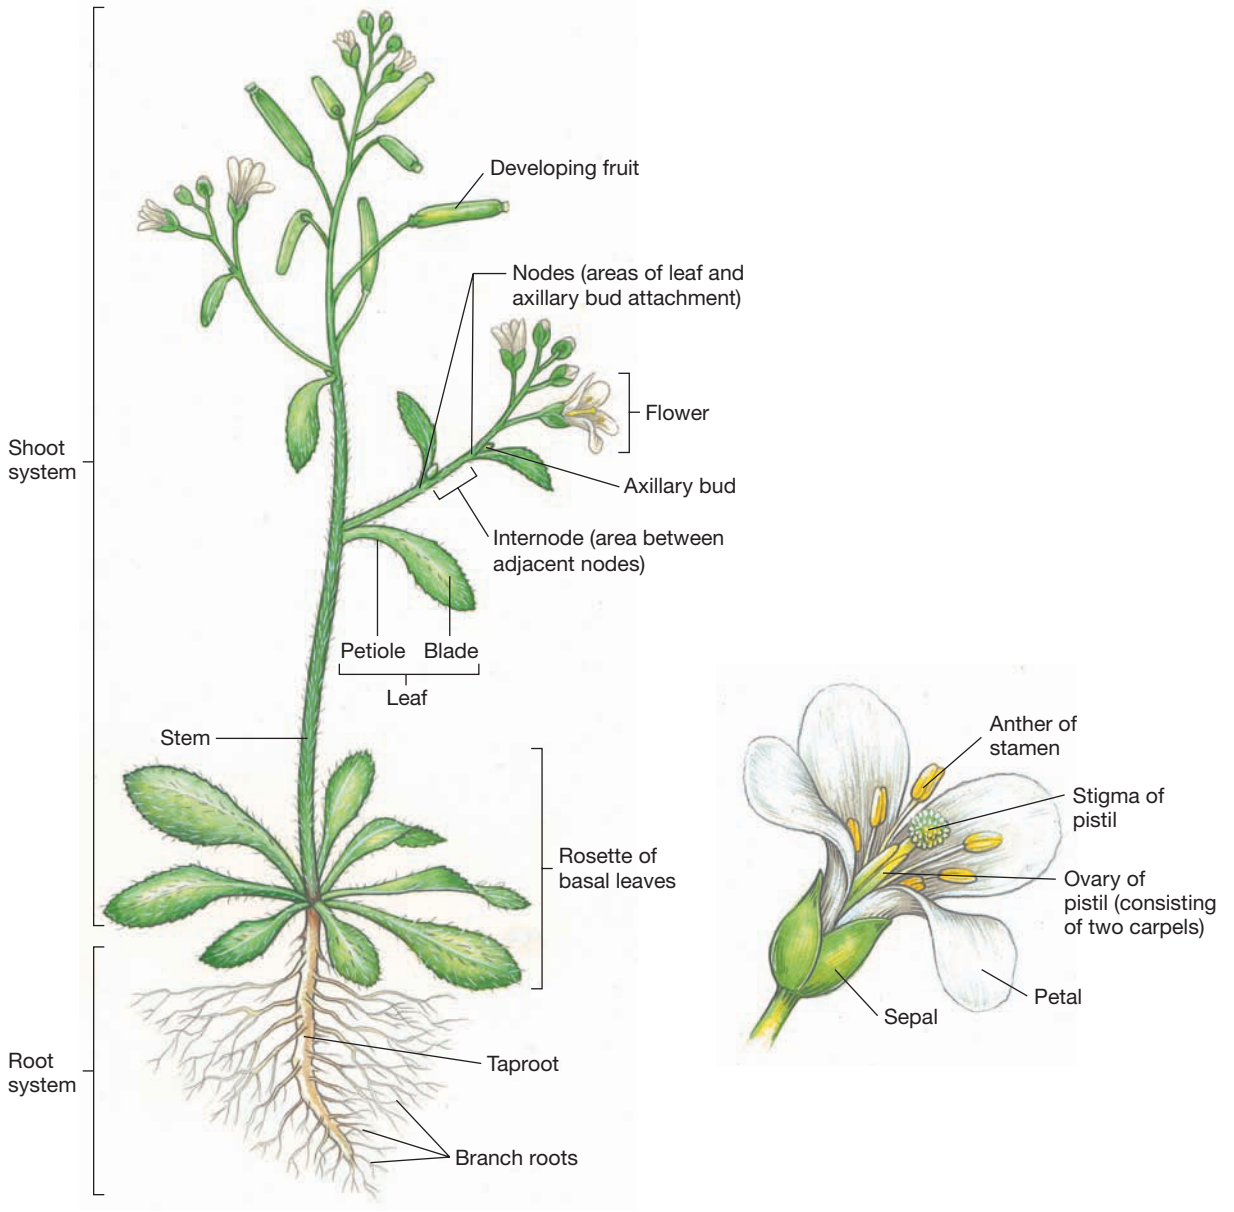

Figure 32-2 The plant body

A plant body consists of a root system, usually underground, and a shoot system, usually aboveground. Shown is mouse-ear cress (*Arabidopsis thaliana*), a small plant in the mustard family that is a model plant for biological research. *Arabidopsis* is native to North Africa and Eurasia and has been naturalized (was introduced and is now growing in the wild) in California and the eastern half of the United States.

food (dissolved sugar). The vascular tissue system also functions in strengthening and supporting the plant. The **dermal tissue system** provides a covering for the plant body.

Roots, stems, leaves, flower parts, and fruits are **organs,** because each is composed of all three tissue systems. The tissue systems of different plant organs form an interconnected network throughout the plant. For example, the vascular tissue system of a leaf is continuous with the vascular tissue system of the stem to which it is attached, and the vascular tissue system of the stem is continuous with the vascular tissue system of the root.

Key Point

The tissue systems are continuous throughout the plant. For example, the vascular tissue system in a leaf is continuous with the vascular tissue system in the stem to which it is attached.

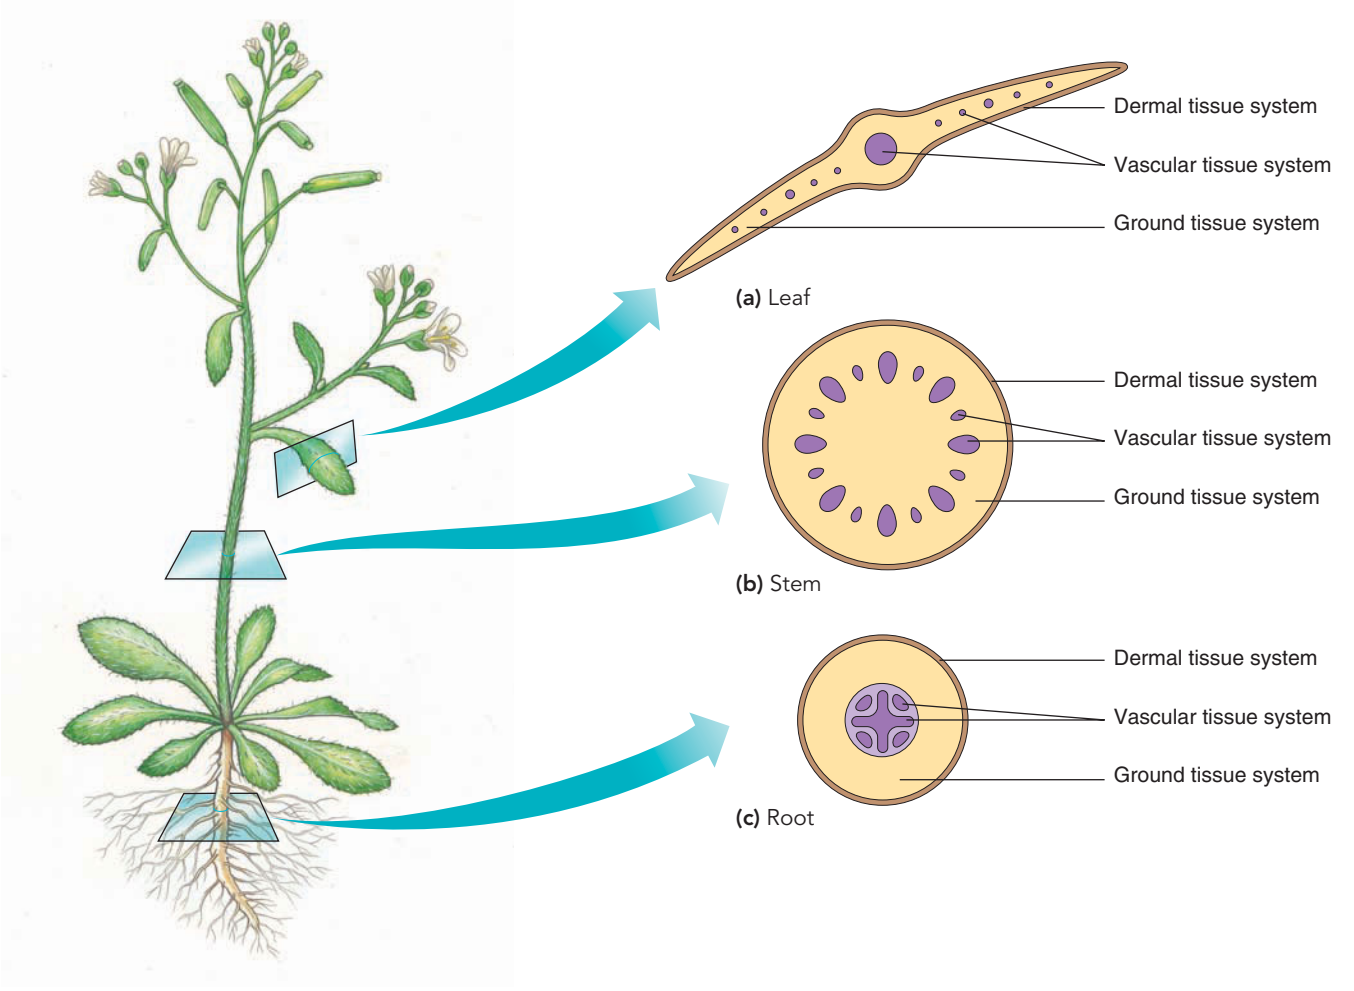

Figure 32-3 ***Animated*** The three tissue systems in the plant body

This figure shows the distribution of the ground tissue system, vascular tissue system, and dermal tissue system in the **(a)** leaves, **(b)** stems, and **(c)** roots of a herbaceous eudicot such as *Arabidopsis*.

The ground tissue system is composed of three simple tissues

The bulk of a herbaceous plant is its ground tissue system, which is composed of three tissues: parenchyma, collenchyma, and sclerenchyma (Table 32-2). These tissues can be distinguished by their cell wall structures. Recall that plant cells are surrounded by a cell wall that provides structural support (see Chapter 4). A growing plant cell secretes a thin **primary cell wall,** which stretches and expands as the cell increases in size. After the cell stops growing, it sometimes secretes a thick, strong **secondary cell wall,** which is deposited *inside* the primary cell wall—that is, between the primary cell wall and the plasma membrane (see Fig. 4-29).

Plant cell walls have several important roles. They are involved in growth; the ability of primary cell walls to expand allows cells to increase in size. Scientists are increasingly aware that **signal transduction** takes place in plant cell walls, because many carbohydrate and protein molecules in plant cell walls communicate with other molecules both inside and outside the cell. The cell wall is also the first line of defense against disease-causing organisms.

TABLE 32-1

Tissue Systems, Tissues, and Cell Types of Flowering Plants

Tissue System	Tissue	Cell Types	Main Functions of Tissue
Ground tissue system	Parenchyma tissue	Parenchyma cells	Storage, secretion, photosynthesis
	Collenchyma tissue	Collenchyma cells	Support
	Sclerenchyma tissue	Sclerenchyma cells (sclereids or fibers)	Support, strength
Vascular tissue system	Xylem	Tracheids	Conduction of water and nutrient minerals, support
		Vessel elements	Conduction of water and nutrient minerals, support
		Xylem parenchyma cells	Storage
		Fibers (sclerenchyma cells)	Support, strength
	Phloem	Sieve tube elements	Conduction of sugar in solution, support
		Companion cells	May control functioning of sieve tube elements, loading sugar into sieve tube elements
		Phloem parenchyma cells	Storage
		Fibers (sclerenchyma cells)	Support, strength
Dermal tissue system	Epidermis	Epidermal cells	Protective covering over surface of plant body
		Guard cells	Regulate stomata
		Trichomes	Variable functions
	Periderm	Cork cells	Protective covering over surface of plant body
		Cork cambium cells	Meristematic (form new cells)
		Cork parenchyma cells	Storage

Parenchyma cells have thin primary walls

Parenchyma tissue, a simple tissue composed of parenchyma cells, is found throughout the plant body and is the most common type of cell and tissue (Fig. 32-4a). The soft parts of a plant, such as the edible part of an apple or a potato, consist largely of parenchyma.

Parenchyma cells perform several important functions, such as photosynthesis, storage, and secretion. Parenchyma cells that function in photosynthesis contain green chloroplasts, whereas nonphotosynthetic parenchyma cells lack chloroplasts and are often colorless. Materials stored in parenchyma cells include starch grains, oil droplets, water, and salts, which are sometimes visible as crystals. Resins, tannins, hormones, enzymes, and sugary nectar are examples of substances that may be secreted by parenchyma cells. The various functions of parenchyma require that parenchyma cells be alive and metabolically active.

Parenchyma cells have the ability to *differentiate* into other kinds of cells, particularly when a plant has been injured. If xylem (water-conducting) cells are severed, for example, adjacent parenchyma cells may divide and differentiate into new xylem cells within a few days. (Recall from Chapter 17 that it is possible to induce certain plant cells to become the equivalent of embryonic cells that can then differentiate into specialized cells.)

Collenchyma cells have unevenly thickened primary walls

Collenchyma tissue, a simple plant tissue composed of collenchyma cells, is an extremely flexible structural tissue that provides much of the support in soft, nonwoody plant organs (Fig. 32-4b). Support is crucial for plants, in part because it lets them grow upward to compete with other plants for available sunlight in a plant-crowded area. Plants lack the bony skeletal system typical of many animals; instead, individual cells, including collenchyma cells, support the plant body.

Collenchyma cells, which are usually elongated, are alive at maturity. Their primary cell walls are unevenly thickened and are especially thick in the corners. Collenchyma is not found uniformly throughout the plant and often occurs as long strands near stem surfaces and along leaf veins. The "strings" in a celery stalk, for example, consist of collenchyma tissue.

Sclerenchyma cells have both primary walls and thick secondary walls

Another simple plant tissue specialized for structural support is **sclerenchyma** tissue, whose cells have both primary and secondary cell walls. The root of the word *sclerenchyma* is derived from the Greek word *sclero,* meaning "hard." The secondary cell walls of sclerenchyma cells become strong and hard because of extreme thickening. Thus, sclerenchyma cells are unable to stretch or elongate. At functional maturity, when sclerenchyma tissue is providing support for the plant body, its cells are often dead.

Sclerenchyma tissue may be located in several areas of the plant body. Two types of sclerenchyma cells are sclereids and fibers. **Sclereids** are cells of variable shape common in the shells of nuts and in the stones of fruits such as cherries and peaches. The slightly gritty texture of pears results from the presence of clusters of sclereids. **Fibers,** which are long, tapered cells that often occur in patches or clumps, are particularly abundant in

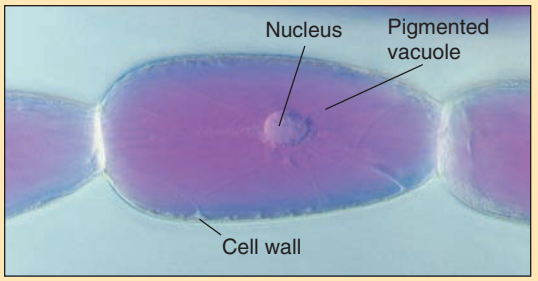
Cell Types in the Ground Tissue System



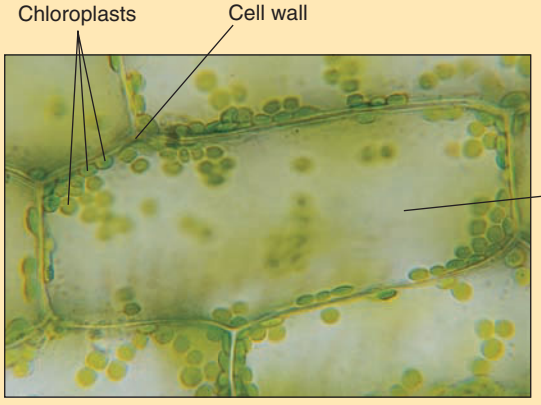
Phil Gates/Biological Photo Service

Parenchyma cell

Description
Living, actively metabolizing; thin primary cell walls

Functions
Storage; secretion, and/or photosynthesis

Location and comments
Throughout the plant body; shown is an LM of a stamen hair of a spiderwort (*Tradescantia virginiana*) flower; note the large pigmented vacuole; the nucleus is not inside the vacuole but is lying on *top* of the vacuole



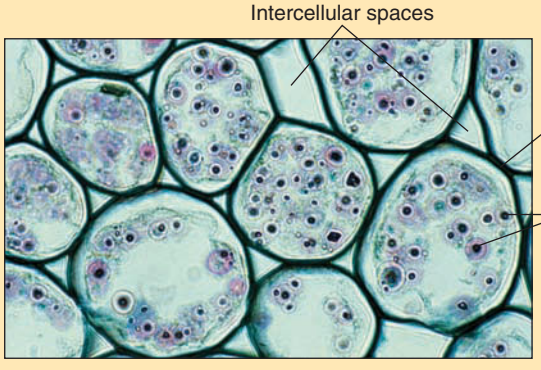
Dennis Drenner

Parenchyma cell

Description
Living, actively metabolizing; thin primary cell walls

Functions
Storage; secretion; photosynthesis

Location and comments
Throughout the plant body; shown is an LM of leaf cells from an aquatic plant (*Elodea*); note the many chloroplasts in the thin layer of cytoplasm surrounding the large, transparent vacuole



Dennis Drenner

Parenchyma cell

Description
Living, actively metabolizing; thin primary cell walls

Functions
Storage; secretion; photosynthesis

Location and comments
Throughout the plant body; shown is an LM of a cross section of part of a buttercup (*Ranunculus*) root; note the starch grains filling the cells

Ed Reschke

Collenchyma cell

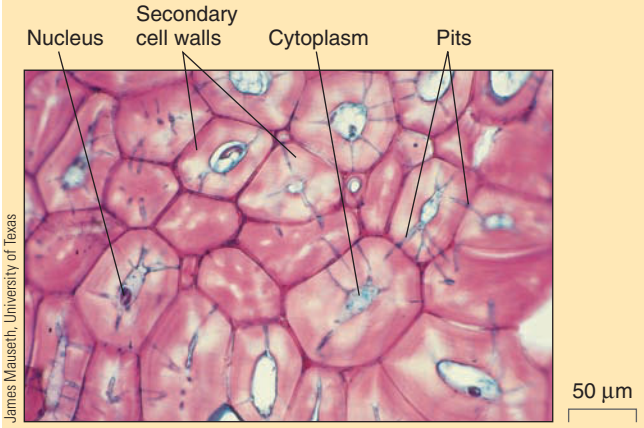
Description
Living; unevenly thickened primary cell walls

Function
Elastic support

Location and comments
Just under stem epidermis; shown is an LM of a cross section of an elderberry (*Sambucus*) stem; note the unevenly thickened cell walls that are especially thick in the corners, making the cell contents assume a rounded shape in cross section

TABLE 32-2

Continued



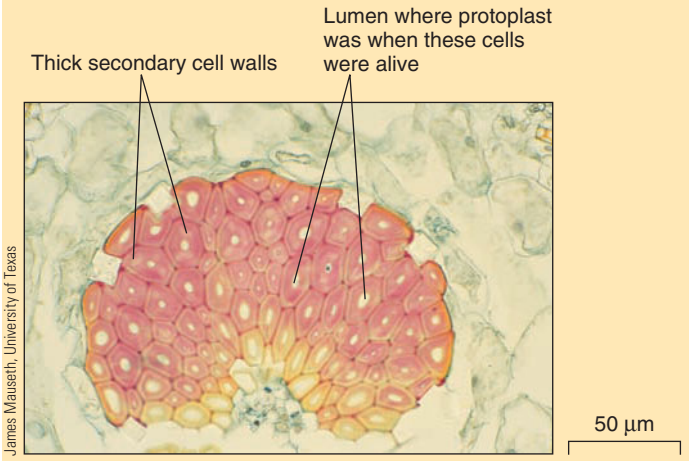
James Mauseth, University of Texas

Sclereid (sclerenchyma cell)

Description
May be living or dead at maturity; thick secondary cell walls; lacks secondary wall at pits

Functions
Strength; sclereid-rich tissue is hard and inflexible

Location and comments
Shells of walnuts and coconuts; pits of cherries and peaches; shown is an LM of living sclereids in a section through a cherry (*Prunus avium*) pit



James Mauseth, University of Texas

Fiber (sclerenchyma cell)

Description
Often dead at maturity; thick secondary cell walls; fewer pits than in sclereids

Functions
Support; provides strength

Location and comments
Throughout the plant body; common in stems and certain leaves; shown is an LM of a cross section through a clump of fibers from a century plant (*Agave*) leaf

the wood, inner bark, and leaf ribs (veins) of flowering plants (Fig. 32-4c).

Cells of the three simple tissues vary in their cell wall chemistry

Parenchyma, collenchyma, and sclerenchyma cells can be distinguished by the chemistry of their cell walls. Cell walls may contain cellulose, hemicelluloses, pectin, and lignin. **Cellulose,** the most abundant polymer in the world, accounts for about 40% to 60% of the dry weight of plant cell walls. As discussed in Chapter 3, cellulose is a **polysaccharide** composed of glucose units joined by β-1,4 bonds. Each cellulose molecule consists of thousands of glucose subunits joined to form a flat, ribbonlike chain. From 40 to 70 of these chains lie parallel to one another and connect by hydrogen bonding to form a **cellulose microfibril,** a strong, tiny strand visible under the electron microscope (see Fig. 3-10a).

Cellulose microfibrils are cemented together by a matrix of hemicelluloses and pectins. **Hemicelluloses** are a group of polysaccharides that are more soluble than cellulose. Hemicelluloses vary in their chemical composition from one species to another. Some hemicelluloses are composed of *xyloglucan,* which consists of a backbone of β-1,4-glucose molecules to which side chains of *xylose,* a five-carbon sugar, are attached. Despite their name, the chemical structure of the hemicelluloses is significantly different from that of cellulose. **Pectin,** another cementing polysaccharide, is less variable in its monomer composition than are the hemicelluloses. Pectin monomer units are *α-galacturonic acid,* a six-carbon molecule that is a derivative of glucose.

An important component of secondary plant cell walls, particularly those of wood, is **lignin.** Composing as much as 35% of the dry weight of the secondary cell wall, lignin is an extremely complex strengthening polymer made up of monomers derived from certain amino acids. Scientists have not yet determined the exact chemical structure of lignin because it is hard to remove

from cellulose and other cell wall materials to which it is covalently bound.

Having discussed the four main components in plant cell walls, we can now generalize about the cell chemistry of parenchyma, collenchyma, and sclerenchyma cells. The thin primary cell walls of parenchyma cells contain predominantly cellulose, although they also contain hemicelluloses and pectin. Both parenchyma and collenchyma cells have primary cell walls, but their walls are chemically distinct because the thickened areas of collenchyma walls contain large quantities of pectin in addition to cellulose and hemicelluloses. The thick secondary walls of sclerenchyma cells are chemically different because they are rich in lignin, in addition to cellulose, hemicelluloses, and pectin.

The vascular tissue system consists of two complex tissues

The vascular tissue system, which is embedded in the ground tissue, transports needed materials throughout the plant via two complex tissues: xylem and phloem (▮ Table 32-3). Both xylem and phloem are continuous throughout the plant body. (Chapter 34 discusses the mechanisms of transport in xylem and phloem.)

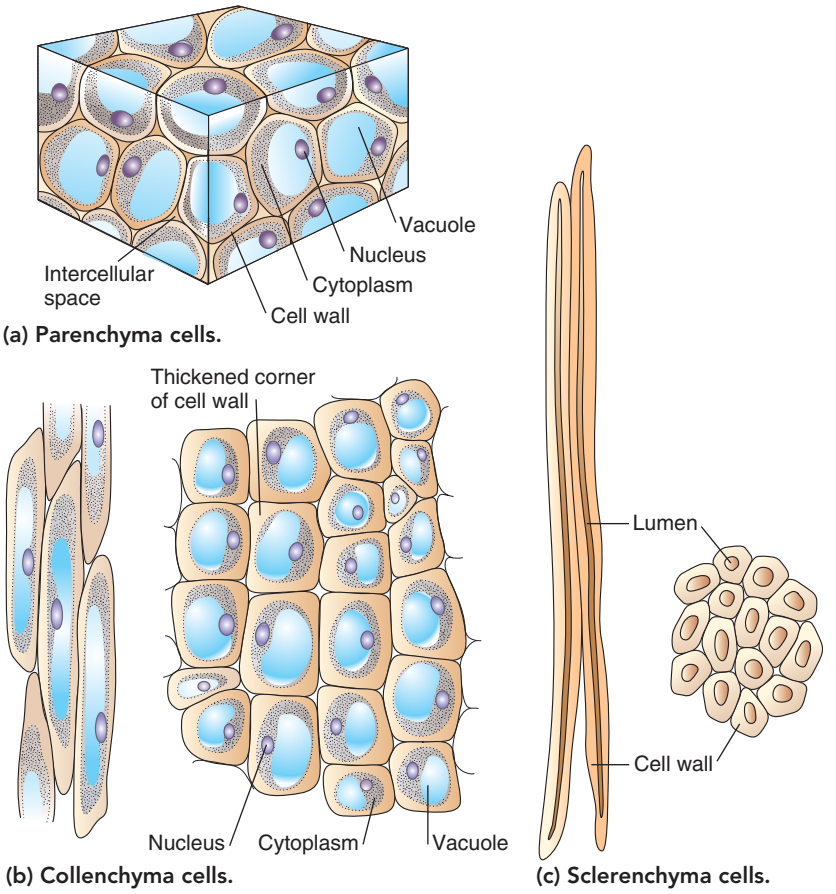


Figure 32-4 ***Animated*** Cell types: parenchyma, collenchyma, and sclerenchyma

(a) A 3-D view of parenchyma cells. Parenchyma cells vary in size and structure, depending on their various functions within the plant body. **(b)** Collenchyma cells in longitudinal section (*left*) and cross section. Note the elongated cells, evident in longitudinal section, and the unevenly thickened cell walls, evident in cross section. **(c)** Sclerenchyma cells (fibers) in longitudinal section (*left*) and cross section. Mature fibers are often dead at functional maturity and therefore lack nuclei and cytoplasm; the lumen is the space formerly occupied by the living cell.

The conducting cells in xylem are tracheids and vessel elements

Xylem conducts water and dissolved minerals from the roots to the stems and leaves and provides structural support. In flowering plants, xylem is a complex tissue composed of four cell types: tracheids, vessel elements, parenchyma cells, and fibers. Two of the four cell types found in xylem, the **tracheids** and **vessel elements,** conduct water and dissolved minerals. Xylem also contains fibers that provide support, and parenchyma cells, known as *xylem parenchyma,* that perform storage functions.

Tracheids and vessel elements are highly specialized for conduction. As they develop, both types of cells undergo apoptosis, or programmed cell death. As a result, mature tracheids and vessel elements are dead and therefore hollow; only their cell walls remain. Tracheids, the chief water-conducting cells in gymnosperms (such as pine) and seedless vascular plants (such as ferns), are long, tapering cells located in patches or clumps (▮ Fig. 32-5a). Water is conducted upward, from roots to shoots, passing from one tracheid into another through *pits,* thin areas in the tracheids' cell walls where a secondary wall did not form.

In addition to tracheids, flowering plants possess extremely efficient vessel elements (▮ Fig. 32-5b). The cell diameters of vessel elements are usually greater than those of tracheids. Vessel elements are hollow, but unlike tracheids, the end walls have holes, known as *perforations,* or are absent. Vessel elements are stacked one on top of the other, and water is conducted readily from one vessel element into the next. A stack of vessel elements, called a **vessel,** resembles a miniature water pipe. Vessel elements also have pits in their side walls that permit the lateral transport (sideways movement) of water from one vessel to another.

Sieve tube elements are the conducting cells of phloem

Phloem conducts food materials, that is, carbohydrates formed in photosynthesis, throughout the plant and provides structural support. In flowering plants, phloem is a complex tissue composed of four cell types: sieve tube elements, companion cells, fibers, and phloem parenchyma cells (▮ Fig. 32-5c and d). Fibers, which are usually extensive in the phloem of herbaceous plants, provide additional structural support for the plant body.

Food materials are conducted in solution—that is, dissolved in water—through the **sieve tube elements,** which are among

TABLE 32-3

Selected Cell Types in the Vascular Tissue System

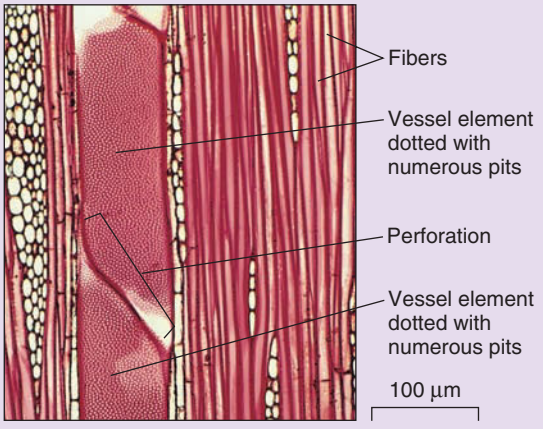
Tracheid

Description
Dead at maturity; lacks secondary wall at pits

Functions
Conduction of water and nutrient minerals; support

Location and comments
Occurs in clumps in xylem throughout plant body; shown is an LM of a longitudinal section of tracheids from white pine (*Pinus strobus*) wood



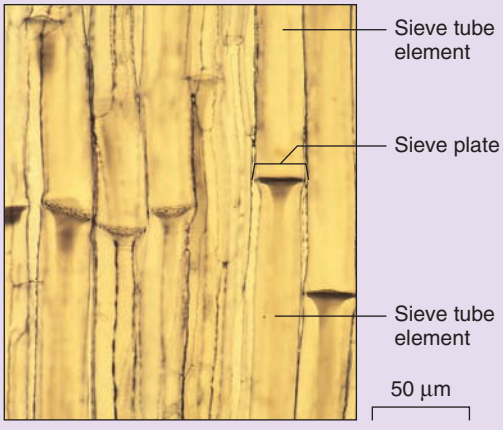
James Mauseth, University of Texas

Vessel element

Description
Dead at maturity; end walls have perforations; lacks secondary wall at pits

Functions
Conduction of water and nutrient minerals; support

Location and comments
Xylem throughout plant body; vessel elements are more efficient than tracheids in conduction; shown is an LM of a longitudinal section of two vessel elements from an unknown woody eudicot



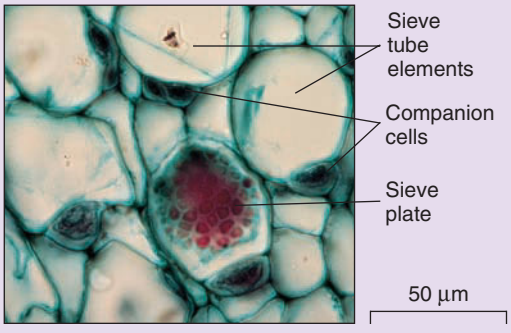
James Mauseth, University of Texas

Sieve tube element

Description
Living but lacks nucleus and other organelles at maturity; end walls are sieve plates

Function
Conduction of sugar in solution

Location and comments
Phloem throughout plant body; shown is an LM of a longitudinal section through a clump of sieve tube elements in a squash (*Cucurbita*) petiole (leaf stalk)



J. Robert Waaland/Biological Photo Service

Companion cell

Description
Living; has cytoplasmic connections with sieve tube element

Function
Assists in moving sugars into and out of sieve tube element

Location and comments
Phloem throughout plant body; shown is an LM of phloem from a squash (*Cucurbita*) petiole (leaf stalk) in cross section

the most specialized plant cells. Sieve tube elements are joined end to end to form long **sieve tubes.** The cells' end walls, called *sieve plates,* have a series of holes through which cytoplasm extends from one sieve tube element into the next. Sieve tube elements are living at maturity, but many of their organelles, including the nucleus, vacuole, mitochondria, and ribosomes, disintegrate or shrink as they mature.

Sieve tube elements are among the few eukaryotic cells that can function without nuclei. These cells typically live for less than a year. There are, however, notable exceptions. Certain palms have sieve tube elements that remain alive for approximately 100 years!

Adjacent to each sieve tube element is a **companion cell** that assists in the functioning of the sieve tube element. The companion cell is a living cell, complete with a nucleus. This nucleus is thought to direct the activities of both the companion cell and sieve tube element. Numerous **plasmodesmata**—cytoplasmic connections through which cytoplasm extends from one cell to another (see Chapter 5)—occur between a companion cell and its adjoining sieve tube element. The companion cells play an essential role in moving sugar into the sieve tube elements for transport to other parts of the plant.

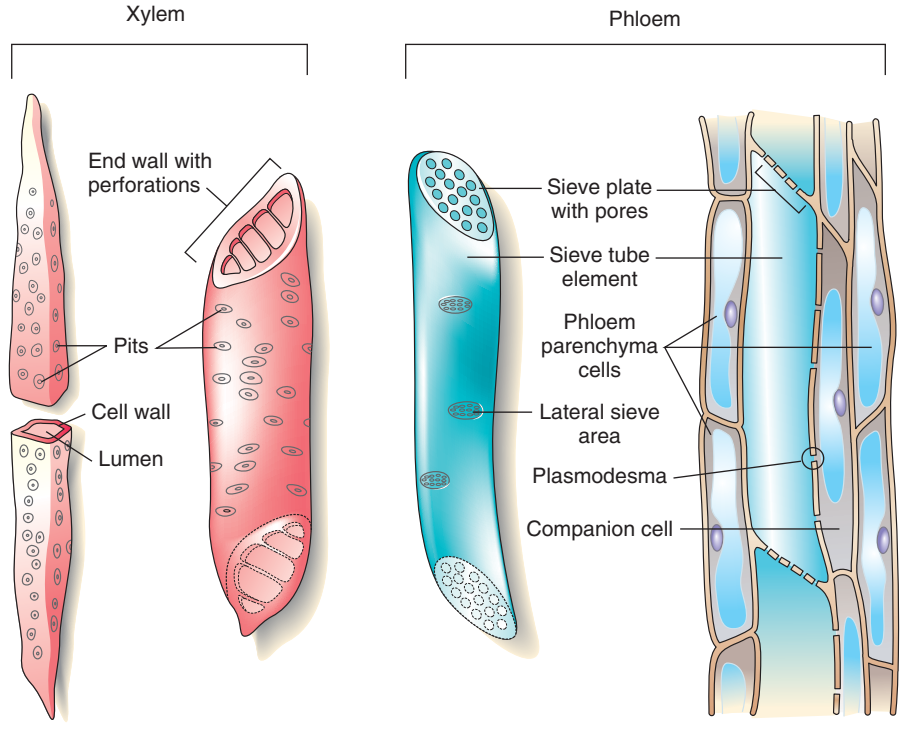


Figure 32-5 ***Animated*** Longitudinal views of cell types in xylem and phloem tissues

(a) A 3-D view of a tracheid (xylem cell). The tracheid is opened to reveal the cell's appearance in cross section. At maturity, tracheids are usually dead. **(b)** A 3-D view of a vessel element (xylem cell). The end walls of vessel elements have a variety of openings, or perforations, depending on the species. Vessel elements are joined end to end to produce minute "water pipes" that run the length of the plant, from roots to leaves and other shoot parts. **(c)** A 3-D view of a sieve tube element, showing the sieve plate. **(d)** Longitudinal section of phloem tissue, showing sieve tube elements, companion cells, and phloem parenchyma cells. Fiber cells are not shown.

The dermal tissue system consists of two complex tissues

The dermal tissue system, the epidermis and periderm, provides a protective covering over plant parts (Table 32-4). In herbaceous plants, the dermal tissue system is a single layer of cells called the epidermis. Woody plants initially produce an epidermis, but it splits apart as a result of the production of additional woody tissues inside the epidermis as the plant increases in girth. Periderm, a tissue several to many cell layers thick, forms under the epidermis to provide a new protective covering as the epidermis is destroyed. Periderm, which replaces the epidermis in the stems and roots of older woody plants, composes the outer bark.

Epidermis is the outermost layer of a herbaceous plant

The **epidermis** is a complex tissue composed primarily of relatively unspecialized living cells. Dispersed among these cells are more specialized guard cells and outgrowths called trichomes (discussed later). In most plants, the epidermis consists of a single layer of flattened cells (Fig. 32-6). Epidermal cells generally contain no chloroplasts and are therefore transparent, so light can penetrate the interior tissues of stems and leaves. In both stems and leaves, photosynthetic tissues lie *beneath* the epidermis.

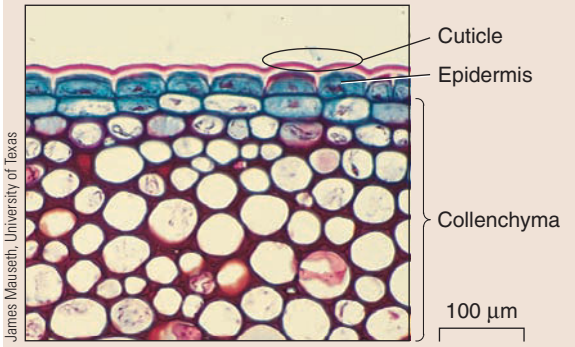
An important requirement of the aerial parts (stems, leaves, flowers, and fruits) of a plant is the ability to control water loss. Epidermal cells of aerial parts secrete a waxy **cuticle** over the surface of their exterior walls; this waxy layer greatly restricts water loss from plant surfaces.

Although the cuticle is extremely efficient at preventing most water loss through epidermal cells, it also slows the diffusion of CO_2, needed for photosynthesis, from the atmosphere into the leaf or stem. The diffusion of CO_2 is facilitated by **stomata** (sing., *stoma*). Stomata are minute pores in the epidermis that are surrounded by two cells called **guard cells** (see Figure 33-4). Many gases, including CO_2, oxygen, and water vapor, pass through the stomata by diffusion. Stomata are generally open during the day when photosynthesis is occurring, and the water loss that also takes place when stomata are open provides some evaporative cooling. At night, stomata usually close. In drought conditions, the need to conserve water overrides the need to cool the leaves and exchange gases. Thus, during a drought, the stomata close in the daytime. Stomata are discussed in greater detail in Chapter 33.

The epidermis also contains special outgrowths, or hairs, called **trichomes,** which occur in many sizes and shapes and

TABLE 32-4

Selected Cell Types in the Dermal Tissue System



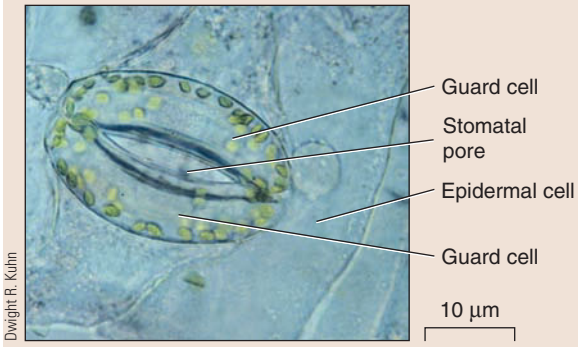
James Mauseth, University of Texas

Epidermal cell

Description
Relatively unspecialized cell with thin primary wall; outer wall often thicker and covered by a noncellular waxy layer (cuticle)

Functions
Protective covering over surface of plant body; helps reduce water loss

Location and comments
Epidermis is usually one cell thick; shown is an LM of a cross section through epidermis of an ivy (*Hedera helix*) stem



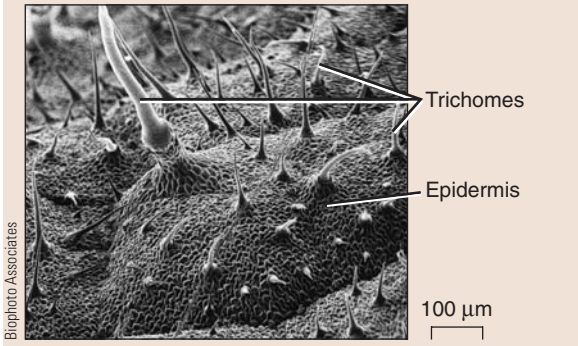
Dwight R. Kuhn

Guard cell

Description
Chloroplast-containing cell that occurs in pairs; pair changes shape to open and close stomatal pore

Function
Opens and closes stomatal pore

Location and comments
Epidermis of stems and leaves; shown is an LM of the epidermis of a spiderwort (*Tradescantia virginiana*) leaf



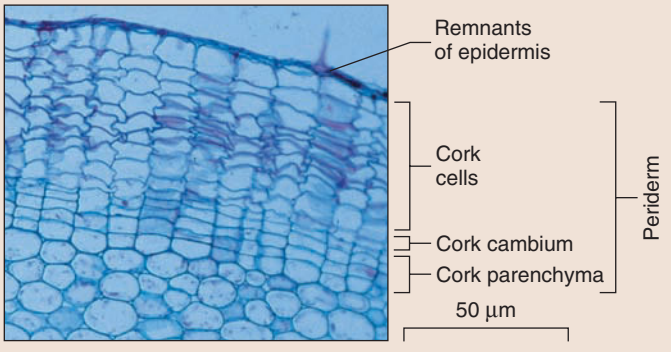
Biophoto Associates

Trichome

Description
Hair or other epidermal outgrowth; may be unicellular or multicellular; occurs in variety of sizes and shapes

Functions
Varied; absorption; secretion; excretion; protection; reduction of water loss

Location and comments
Epidermis; shown is an SEM of a nettle (*Solanum carolinense*) leaf, which has trichomes that break off inside the skin of animals and inject irritating substances that cause a stinging sensation



Dennis Drenner

Cork cell

Description
Dead at maturity; cell walls impregnated with waterproof material (suberin)

Functions
Reduces water loss and prevents disease-causing organisms from penetrating

Location and comments
Produced in large numbers; cork often forms just under the epidermis; replaces epidermis in older stems and roots; shown is an LM of a cross section through periderm of a geranium (*Pelargonium*) stem

have a variety of functions. Plants that tolerate salty environments such as the seashore often have specialized trichomes on their leaves to remove excess salt that accumulates in the plant. The presence of trichomes on the aerial parts of desert plants may increase the reflection of light off the plants, thereby cooling the internal tissues and decreasing water loss. Other trichomes have a protective function. For example, the trichomes on stinging nettle leaves and stems contain irritating substances that may discourage herbivorous animals from eating the plant. **Root hairs** are simple, unbranched trichomes that increase the surface area

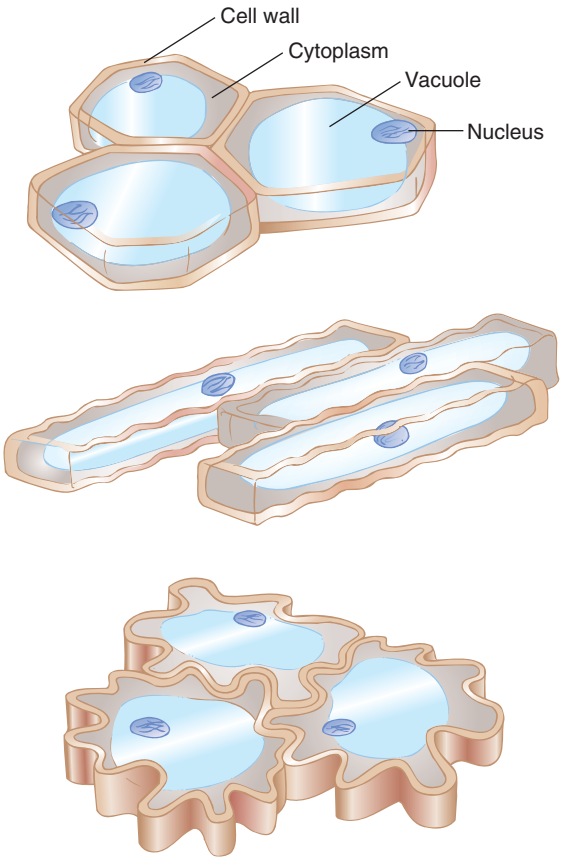


Figure 32-6 Cell types: epidermal cells

Diagrams of 3-D views of epidermal cells from three different plants. Note that regardless of the cell shape, epidermal cells fit tightly together.

of the root epidermis (which comes into contact with the soil) for more effective water and mineral absorption.

Periderm replaces epidermis in woody plants

As a woody plant begins to increase in girth, its epidermis is sloughed off and replaced by **periderm.** Periderm forms the outer bark of older stems and roots. It is a complex tissue composed mainly of cork cells and cork parenchyma cells. **Cork cells** are dead at maturity, and their walls are heavily coated with a waterproof substance called *suberin,* which helps reduce water loss. **Cork parenchyma** cells function primarily in storage.

Review

- What are some of the functions of roots? Of shoots?
- What are the three tissue systems in plants? Describe the functions of each.
- How do parenchyma, collenchyma, and sclerenchyma tissues differ in cell structure and function?
- What are the functions of xylem and phloem? Describe the conducting cells that occur in each of these complex tissues.
- How are epidermis and periderm alike? How are they different?

PLANT MERISTEMS

Learning Objectives

8 Discuss what is meant by growth in plants, and state how it differs from growth in animals.
9 Distinguish between primary and secondary growth.
10 Distinguish between apical meristems and lateral meristems.

Plant growth involves three processes: cell division, cell elongation (the lengthening of a cell), and cell differentiation. Cell division is an essential part of plant growth that results in an increase in the number of cells. These new cells elongate as the cytoplasm grows and the vacuole fills with water, which exerts pressure on the cell wall and causes it to expand. In an onion root cell, the vacuole increases in size by some 30 to 150 times during elongation. Plant cells also differentiate, or specialize, into the various cell types just discussed. These cell types constitute the mature plant body and perform the various functions required in a multicellular organism. Although differentiation does not contribute to an increase in size, it is an important aspect of growth and development because it is essential for tissue formation.

One difference between plants and animals is the *location* of growth. When a young animal is growing, all parts of its body

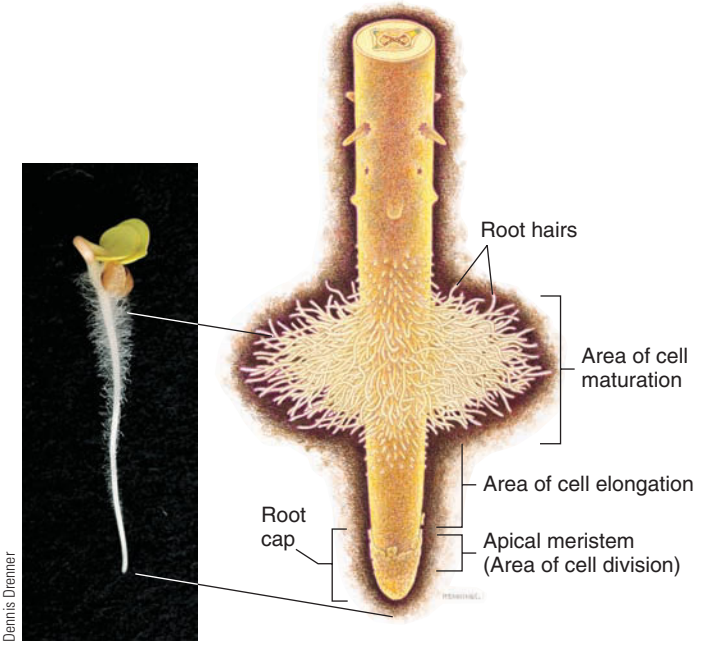

Figure 32-7 ***Animated*** A root tip

The root apical meristem (where cells divide and thus increase in number) is protected by a root cap. Farther from the tip is an area of cell elongation where cells enlarge and begin to differentiate. The area of cell maturation has fully mature, differentiated cells. Note the young root hairs in this area and on the root of a young radish (*Raphanus sativus*) seedling, which is approximately 5 cm (2 in) long (*left*).

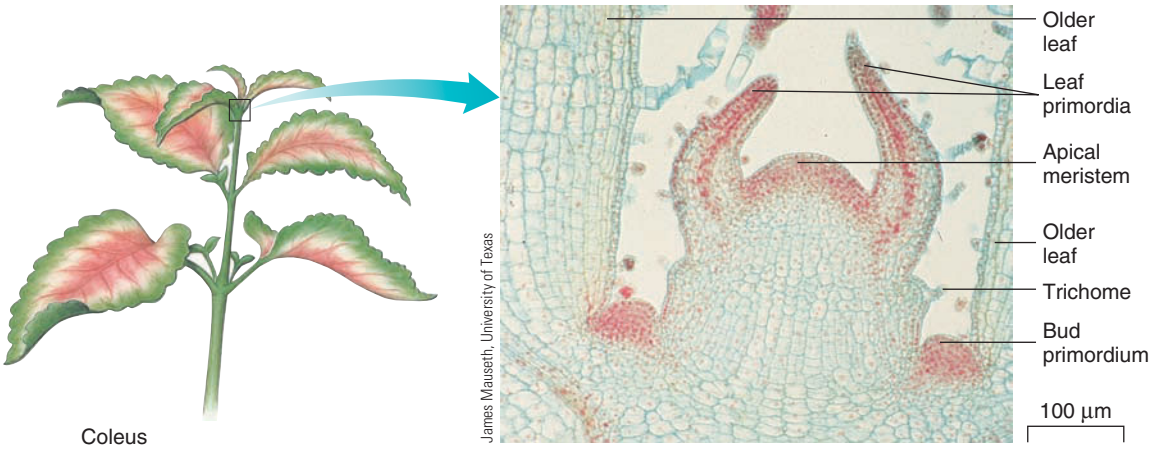

Figure 32-8 ***Animated*** A shoot apex

LM of a longitudinal section through a shoot apex of *Coleus*, showing the shoot apical meristem, leaf primordia, and bud primordia.

grow, although not necessarily at the same rate. However, when plants grow, their cells divide only in specific areas, called **meristems,** which are composed of cells whose primary function is to form new cells by mitotic division. Meristematic cells do not differentiate. Instead, they retain the ability to divide by mitosis, a trait that many differentiated cells lose. The persistence of mitotically active meristems means that plants, unlike most animals, can grow throughout their entire life span.

This ability of roots and stems to grow throughout a plant's life is known as **indeterminate growth.** In contrast, many leaves and flowers have **determinate growth;** that is, they stop growing after reaching a certain size. The size of leaves and flowers with determinate growth varies from species to species and from individual to individual, depending on the plant's genetic programming and on environmental conditions, such as availability of sunlight, water, and essential minerals.

Two kinds of meristematic growth may occur in plants. **Primary growth** is an increase in stem and root length. All plants have primary growth, which produces the entire plant body in herbaceous plants and the young, soft shoots and roots in woody trees and shrubs. **Secondary growth** is an increase in the girth of a plant. For the most part, only gymnosperms and woody eudicots have secondary growth.[1] Tissues produced by secondary growth comprise the wood and bark, which make up most of the bulk of trees and shrubs. A few annuals—geranium and sunflower, for example—undergo limited secondary growth despite the fact that they lack obvious wood and bark tissues.

[1]Recall from Chapter 28 that on the basis of structural features and molecular data, flowering plants are divided into two main groups, informally called *eudicots* and *monocots.* Oak, sycamore, ash, cherry, apple, and maple are examples of woody eudicots; whereas bean, daisy, and snapdragon are herbaceous eudicots. Palm, corn, bluegrass, lily, and tulip are monocots.

Primary growth takes place at apical meristems

Primary growth occurs as a result of the activity of **apical meristems,** areas located at the tips of roots and shoots, including within the buds of stems. (**Buds** are dormant embryonic shoots that eventually develop into branches.)

Primary growth is evident when a root tip is examined (Fig. 32-7). A protective layer of cells called a **root cap** covers the root tip. Directly behind the root cap is the root apical meristem, which consists of meristematic cells. Meristematic cells, which are cube shaped, remain small because they are continually dividing. (In meristems, as daughter cells begin to enlarge, one or both will divide again.)

Farther from the root tip, just behind the area of cell division, is an area of cell elongation where the cells have been displaced from the meristem. Here the cells are no longer dividing but instead are growing longer, pushing the root tip ahead of them, deeper into the soil. Some differentiation also begins to occur in the area of cell elongation, and immature tissues such as differentiating xylem and phloem become evident. The tissue systems continue to develop and differentiate into primary tissues (epidermis, xylem, phloem, and ground tissues) of the adult plant. Farther from the tip, behind the area of cell elongation, most cells have completely differentiated and are fully mature. Root hairs are evident in this area.

A shoot apex (such as the terminal bud) is quite different in appearance from a root tip (Fig. 32-8). A dome of minute, regularly arranged meristematic cells—the shoot apical meristem—is located in each shoot apex. **Leaf primordia** (developing leaves) and **bud primordia** (developing buds) arise from the shoot apical meristem. The tiny leaf primordia cover and protect the shoot apical meristem. As the cells formed by the shoot apical meristem elongate, the shoot apical meristem is pushed upward. Subsequent cell divisions produce additional stem tissue

and cause new leaf and bud primordia to appear. Farther from the stem tip, the immature cells differentiate into the three tissue systems of the mature plant body.

Secondary growth takes place at lateral meristems

Trees and shrubs undergo both primary and secondary growth. These plants increase in length by primary growth and increase in girth by secondary growth. The increase in girth, which occurs in areas that are no longer elongating, is due to cell divisions that take place in **lateral meristems,** areas extending along the entire length of the stems and roots except at the tips. Two lateral meristems, the vascular cambium and the cork cambium, are responsible for secondary growth, which is the formation of secondary tissues: secondary xylem, secondary phloem, and periderm (Fig. 32-9).

The **vascular cambium** is a layer of meristematic cells that forms a long, thin, continuous cylinder within the stem and root. It is located between the wood and bark of a woody plant. Division of cells of the vascular cambium adds more cells to the wood (secondary xylem) and inner bark (secondary phloem).

The **cork cambium,** located in the outer bark, is composed of a thin cylinder or irregular arrangement of meristematic cells. Cells of the cork cambium divide and form **cork cells** toward the outside and one or more underlying layers of **cork parenchyma** cells that function in storage. Collectively, cork cells, cork cambium, and cork parenchyma make up the periderm.

We are now ready to give a more precise definition of bark. **Bark,** the outermost covering over woody stems and roots, consists of all plant tissues located outside the vascular cambium. Bark has two regions, a living inner bark composed of secondary phloem and a mostly dead outer bark composed of periderm. Chapters 34 and 35 present a more comprehensive discussion of secondary growth.

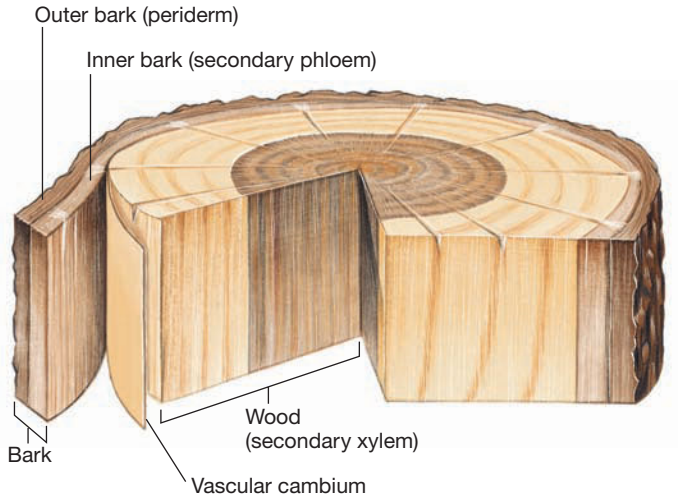

Figure 32-9 ***Animated*** Secondary growth

The vascular cambium, a thin layer of cells sandwiched between the wood and bark, produces the secondary vascular tissues: the wood, which is secondary xylem, and the inner bark, which is secondary phloem. The cork cambium produces the periderm, the outer bark tissue that replaces the epidermis in a plant with secondary growth.

Review

- What is the role of plant meristems? Does animal growth involve meristems?
- What is primary growth? Secondary growth?
- What are apical meristems? Lateral meristems?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Distinguish between herbaceous and woody plants (page 699).
- Plants are either herbaceous (nonwoody) or woody. In temperate climates, the aerial parts of herbaceous plants die back, whereas the aerial parts of woody plants persist.

2 Discuss the differences among annuals, biennials, and perennials, and give an example of each (page 699).
- **Annuals,** such as corn, geranium, and marigold, are herbaceous plants that grow, reproduce, and die in 1 year or less. **Biennials,** such as carrot and Queen Anne's lace, take 2 years to complete their life cycles before dying. **Perennials,** such as asparagus and oak trees, are herbaceous and woody plants that have the potential to live for more than 2 years.

3 Contrast two different life history strategies in plants (page 699).
- Plants have a variety of **life history strategies** to ensure their successful reproduction and survival.
- Long-lived trees thrive in a tropical rain forest, where competition prevents most small, short-lived plants from becoming established. Small, short-lived plants thrive in a relatively unfavorable environment, such as a desert following a rainy period.

4 Discuss the functions of various parts of the vascular plant body, including the nutrient- and water-absorbing root system and the photosynthesizing shoot system (page 700).
- The vascular plant body typically consists of a root system and a shoot system. The **root system** is generally underground and obtains water and dissolved minerals for the plant. Roots also anchor the plant firmly in place.
- The **shoot system** is generally aerial and obtains sunlight and exchanges gases such as CO_2, oxygen, and water vapor. The shoot system consists of a vertical stem that bears leaves (the main organs of photosynthesis) and reproductive structures (flowers and fruits in flowering plants). **Buds,** undeveloped embryonic shoots, develop on stems.

- Although separate **organs** (roots, stems, leaves, flower parts, and fruits) exist in the plant, tissue systems are integrated throughout the plant body, providing continuity from organ to organ. The plant body is composed of three tissue systems: ground, vascular, and dermal.

ThomsonNOW™ Learn more about the plant body by clicking on the figure in ThomsonNOW.

5 Describe the structure and functions of the ground tissue system (parenchyma tissue, collenchyma tissue, and sclerenchyma tissue) (page 700).
- The **ground tissue system** consists of three tissues with a variety of functions. **Parenchyma** tissue is composed of living parenchyma cells that have thin **primary cell walls.** Functions of parenchyma tissue include photosynthesis, storage, and secretion.
- **Collenchyma** tissue consists of collenchyma cells with unevenly thickened primary cell walls. This tissue provides flexible structural support.
- **Sclerenchyma** tissue is composed of sclerenchyma cells—**sclereids** or **fibers**—that have both primary cell walls and **secondary cell walls.** Sclerenchyma cells are often dead at maturity but provide structural support.

ThomsonNOW™ Learn more about parenchyma, collenchyma, and sclerenchyma cells by clicking on the figure in ThomsonNOW.

6 Describe the structure and functions of the vascular tissue system (xylem and phloem) (page 700).
- The **vascular tissue system** conducts materials throughout the plant body and provides strength and support.
- **Xylem** is a complex tissue that conducts water and dissolved minerals. The actual conducting cells of xylem are **tracheids** and **vessel elements.**
- **Phloem** is a complex tissue that conducts sugar in solution. **Sieve tube elements** are the conducting cells of phloem; they are assisted by **companion cells.**

ThomsonNOW™ Learn more about xylem and phloem by clicking on the figure in ThomsonNOW.

7 Describe the structure and functions of the dermal tissue system (epidermis and periderm) (page 700).
- The **dermal tissue system** is the outer protective covering of the plant body.
- The **epidermis** is a complex tissue that covers the herbaceous plant body. The epidermis that covers aerial parts secretes a waxy **cuticle** that reduces water loss. **Stomata** permit gas exchange between the interior of the shoot system and the surrounding atmosphere. **Trichomes** are outgrowths, or hairs, that occur in many sizes and shapes and have a variety of functions.
- The **periderm** is a complex tissue that covers the woody parts of the plant body in woody plants.

8 Discuss what is meant by growth in plants, and state how it differs from growth in animals (page 710).
- Growth in plants, unlike that in animals, is localized in specific regions called **meristems.** Growth involves three processes: cell division, cell elongation, and cell differentiation.

9 Distinguish between primary and secondary growth (page 710).
- **Primary growth** is an increase in stem or root length. Primary growth occurs in all plants.

ThomsonNOW™ See root and shoot development by clicking on the figures in ThomsonNOW.

- **Secondary growth** is an increase in stem or root girth (thickness). Secondary growth typically occurs in long cylinders of meristematic cells throughout the length of older stems and roots.

ThomsonNOW™ Learn more about secondary growth by clicking on the figures in ThomsonNOW.

10 Distinguish between apical meristems and lateral meristems (page 710).
- Primary growth results from the activity of **apical meristems** that are localized at the tips of roots and shoots and within the buds of stems.
- The two **lateral meristems** responsible for secondary growth are the **vascular cambium** and the **cork cambium.**

TEST YOUR UNDERSTANDING

1. Plants that complete their life cycles in 1 year are called _____; those that complete them in 2 years are _____; and those that live year after year are _____. (a) annuals; perennials; biennials (b) biennials; annuals; perennials (c) annuals; biennials; perennials (d) perennials; annuals; biennials (e) perennials; biennials; annuals

2. Which of the following plant life history strategies would be successful in a relatively favorable environment such as a tropical rain forest? (a) long life span with flowers and seeds produced each year (b) long life span with flowers and seeds produced only when the plant is very young (c) short life span with flowers and seeds produced each year (d) short life span with flowers and seeds produced only when the plant is very young (e) very short life span with flowering at end of life

3. Most of the plant body consists of the _____ tissue system. (a) ground (b) vascular (c) periderm (d) dermal (e) cortex

4. The cell walls of parenchyma cells (a) contain large quantities of pectin in the thickened corners (b) are rich in lignin but do not contain hemicelluloses and pectin (c) are predominantly cellulose, although they also contain hemicelluloses and pectin (d) contain cellulose, hemicelluloses, and lignin in approximately equal amounts (e) contain hemicelluloses, pectin, and lignin but no cellulose

5. Which tissue system provides a covering for the plant body? (a) ground (b) vascular (c) periderm (d) dermal (e) cortex

6. Storage, secretion, and photosynthesis are the functions of (a) collenchyma (b) vessel elements (c) lateral meristems (d) sclerenchyma (e) parenchyma

7. The two simple tissues that are specialized for support are (a) parenchyma and collenchyma (b) collenchyma and sclerenchyma (c) sclerenchyma and parenchyma (d) parenchyma and xylem (e) xylem and phloem
8. Sclereids and fibers are examples of which plant tissue? (a) parenchyma (b) collenchyma (c) sclerenchyma (d) xylem (e) epidermis
9. Which of the following statements about the vascular tissue system is *not* true? (a) xylem and phloem are continuous throughout the plant body (b) xylem not only conducts water and dissolved minerals but also provides support (c) four cell types occur in phloem: sieve tube elements, companion cells, tracheids, and vessel elements (d) sieve tube elements lack nuclei (e) vessel elements are hollow, and their end walls have perforations or are entirely dissolved away
10. Conduction of water and minerals in xylem occurs in vessel elements and (a) sieve tube elements (b) tracheids (c) collenchyma (d) cork cells (e) phloem
11. Conduction of sugar in solution in the sieve tube elements is aided by (a) cork cells (b) sclerenchyma (c) parenchyma (d) guard cells (e) companion cells
12. The outer tissue that covers plants with primary growth is _____, whereas _____ covers plants with secondary growth. (a) cuticle; cork parenchyma (b) periderm; phloem (c) epidermis; periderm (d) epidermis; collenchyma (e) cellulose; lignin
13. The noncellular waxy layer secreted by the epidermis over its aerial surface is called (a) lignin (b) cuticle (c) periderm (d) cellulose (e) trichome
14. Minute pores known as _____ dot the surface of the epidermis of leaves and stems; each pore is bordered by two _____. (a) stomata; guard cells (b) stomata; fibers (c) sieve tube elements; companion cells (d) sclereids; guard cells (e) cuticle; guard cells
15. Localized areas within the plant body where cell divisions occur are known as (a) organs (b) fibers (c) meristems (d) cork parenchyma (e) stomata
16. Primary growth, an increase in the length of a plant, occurs at the (a) cork cambium (b) apical meristem (c) vascular cambium (d) lateral meristem (e) periderm
17. The two lateral meristems responsible for secondary growth are the (a) cork cambium and apical meristem (b) apical meristem and cork parenchyma (c) vascular cambium and apical meristem (d) vascular cambium and cork cambium (e) cork cambium and cork parenchyma

CRITICAL THINKING

1. Grasses have a special meristem situated at the base of the leaves. Relate this information to what you know about the growth of grass after you mow the lawn.
2. A couple carved a heart with their initials into a tree trunk 4 ft above ground level; the tree was 25 ft tall at the time. Twenty years later the tree was 50 ft tall. How far above the ground were the initials? Explain your answer.
3. Sclerenchyma in plants is the functional equivalent of bone in humans (both sclerenchyma and bone provide support). However, sclerenchyma is dead, whereas bone is living tissue. What are some of the advantages of a plant having dead support cells? Can you think of any disadvantages?
4. **Evolution Link.** Flowering plants have both tracheids and vessel elements in their xylem. Conifers, which evolved earlier than flowering plants, have tracheids only. How do these differences in xylem structure help explain the difference in the success of these two plant groups?

Leaf Structure and Function

David Sieren/Visuals Unlimited

Red maple leaves. Note how the leaves of red maple (*Acer rubrum*) are arranged to efficiently capture light.

KEY CONCEPTS

Leaf structure reflects its primary function of photosynthesis.

Opening and closing of stomata affect carbon dioxide availability in the daily cycle of photosynthesis.

Transpiration keeps leaves from getting overheated and promotes water transport in the plant.

Leaf abscission is the seasonal removal of deciduous leaves.

Some leaves are modified for special functions in addition to photosynthesis and transpiration.

Imagine that you are taking a course in engineering and are asked to design an efficient solar collector that can convert the radiant energy it collects into chemical energy. Where would you start? It might be helpful to check in the library to see how solar collectors have been designed in the past. In this instance, it would also be wise to ask a biology student if anything comparable exists in nature. The answer, of course, is yes. Plants have organs that are effective solar collectors and energy converters: *leaves.*

Plants allocate many resources to the production of leaves. Each year, a large maple tree (see photograph) may produce 47 m^2 (500 ft^2) of leaves, which may weigh more than 113 kg (250 lb). The metabolic cost of producing so many leaves is high, but leaves are essential to the tree's survival. Leaves gather the sunlight necessary for **photosynthesis,** the biological process that converts radiant energy into the chemical energy of carbohydrate molecules. Plants use these molecules as starting materials to synthesize all other organic compounds and as fuel to provide energy for metabolism. During a single summer, the leaves of a maple tree will fix about 454 kg (1000 lb) of carbon dioxide (CO_2) into organic compounds.

The structure of a leaf is superbly adapted for its primary function of photosynthesis. Most leaves are thin and flat, a shape that allows optimal absorption of light energy and the efficient internal diffusion of gases such as CO_2 and O_2. As a result of their ordered arrangement on the stem, leaves efficiently catch the sun's rays. The leaves form an intricate green mosaic, bathed in sunlight and atmospheric gases.

To control water loss, a thin, transparent layer of wax covers the leaf surface. Such structural adaptations are compromises between competing needs, and some features that optimize photosynthesis *promote* water loss. For example, plants have minute pores that allow gas exchange for photosynthesis, but these openings also let water vapor escape into the atmosphere. Thus, leaf structure represents a trade-off between photosynthesis and water conservation. ■

LEAF FORM AND STRUCTURE

Learning Objectives

1 Discuss variation in leaf form, including simple versus compound leaves, leaf arrangement on the stem, and venation patterns.
2 Describe the major tissues of the leaf (epidermis, photosynthetic ground tissue, xylem, and phloem), and label them on a diagram of a leaf cross section.
3 Compare leaf anatomy in eudicots and monocots.
4 Relate leaf structure to its function of photosynthesis.

Foliage leaves are the most variable of plant organs, so much so that plant biologists developed specific terminology to describe their shapes, margins (edges), vein patterns, and the way they attach to stems. Because each leaf is characteristic of the species on which it grows, many plants can be identified by their leaves alone. Leaves may be round, needlelike, scalelike, cylindrical, heart shaped, fan shaped, or thin and narrow. They vary in size from those of the raffia palm (*Raphia ruffia*), whose leaves often grow more than 20 m (65 ft) long, to those of water-meal (*Wolffia*), whose leaves are so small that 16 of them laid end to end measure only 2.5 cm (1 in) (see Fig. 32-1a).

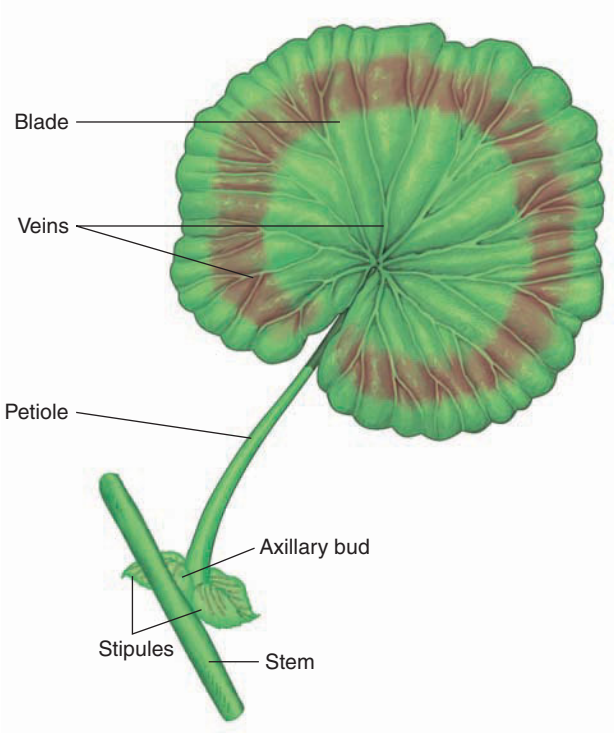

Figure 33-1 Parts of a leaf
A geranium leaf consists of a blade, a petiole, and two stipules at the base of the leaf. Note the axillary bud in the leaf axil.

The broad, flat portion of a leaf is the **blade;** the stalk that attaches the blade to the stem is the **petiole.** Some leaves also have **stipules,** which are leaflike outgrowths usually present in pairs at the base of the petiole (Fig. 33-1). Some leaves do not have petioles or stipules.

Leaves may be *simple* (having a single blade) or *compound* (having a blade divided into two or more leaflets) (Fig. 33-2a). Sometimes it is difficult to tell whether a plant has formed one compound leaf or a small stem bearing several simple leaves. One easy way to determine if a plant has simple or compound leaves is to look for axillary buds, so called because each develops in a leaf *axil* (the angle between the stem and petiole). Axillary buds form at the base of a leaf, whether it is simple or compound. However, axillary buds never develop at the base of leaflets. Also, the leaflets of a compound leaf lie in a single plane (you can lay a compound leaf flat on a table), whereas simple leaves usually are not arranged in one plane on a stem.

Leaves are arranged on a stem in one of three possible ways (Fig. 33-2b). Plants such as beeches and walnuts have an *alternate leaf arrangement,* with one leaf at each **node,** the area of the stem where one or more leaves are attached. In an *opposite leaf arrangement,* as occurs in maples and ashes, two leaves grow at each node. In a *whorled leaf arrangement,* as in catalpa trees, three or more leaves grow at each node.

Leaf blades may possess *parallel venation,* in which the primary **veins**—strands of vascular tissue—run approximately parallel to one another (generally characteristic of monocots), or *netted venation,* in which veins are branched in such a way that they resemble a net (generally characteristic of eudicots; Fig. 33-2c).[1] Netted veins can be *pinnately netted,* with major veins branching off in succession along the entire length of the **midvein** (main or central vein of a leaf), or *palmately netted,* with several major veins radiating out from one point.

Leaf structure consists of an epidermis, photosynthetic ground tissue, and vascular tissue

The leaf is a complex organ composed of several tissues organized to optimize photosynthesis (Fig. 33-3). The leaf blade has upper and lower surfaces consisting of an epidermal layer. The **upper**

[1]Recall that flowering plants, the focus of this chapter, are divided into two main groups, informally called *eudicots* and *monocots* (see Chapter 28). Examples of eudicots include beans, petunias, oaks, cherry trees, roses, and snapdragons; monocots include corn, lilies, grasses, palms, tulips, orchids, and bananas.

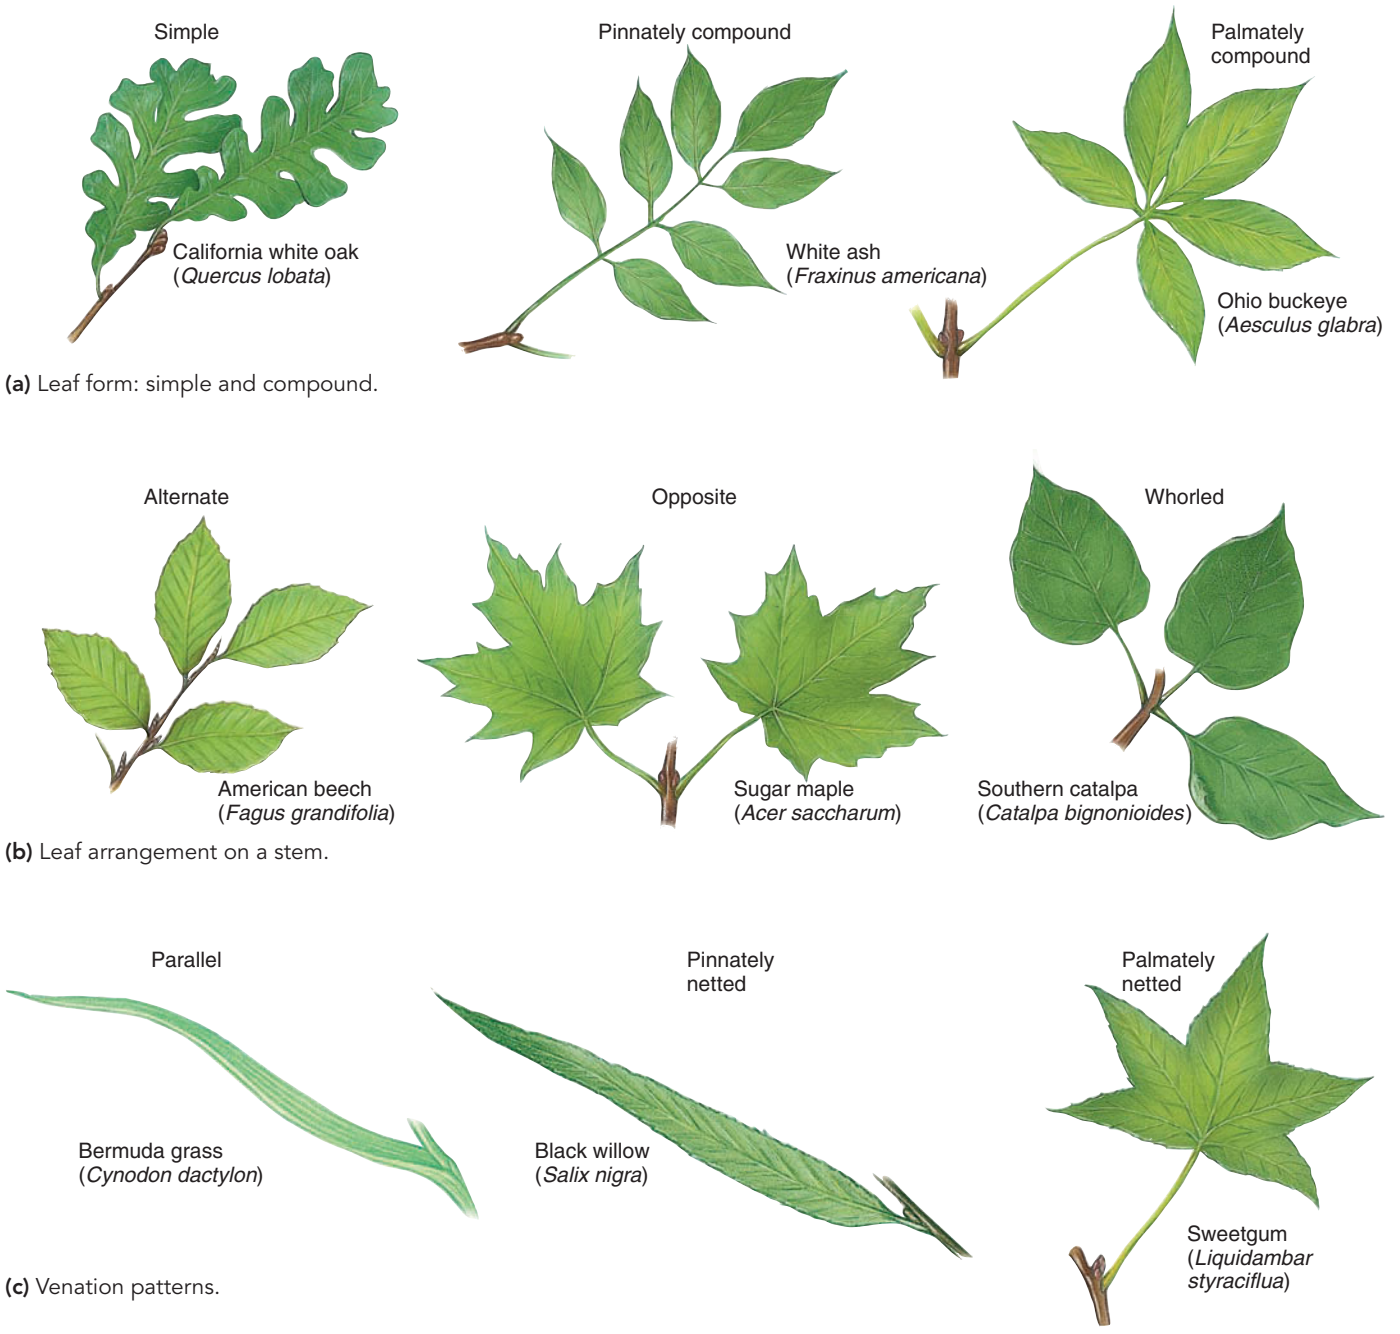

Figure 33-2 Leaf morphology

All leaves shown are woody eudicot trees from North America, except Bermuda grass, which is a herbaceous monocot native to Europe and Asia.

epidermis covers the upper surface, and the **lower epidermis** covers the lower surface. Most cells in these layers lack chloroplasts and are relatively transparent. One interesting feature of leaf epidermal cells is that the cell wall facing toward the outside environment is somewhat thicker than the cell wall facing inward. This extra thickness may provide the plant with additional protection against injury or water loss.

Because leaves have such a large surface area exposed to the atmosphere, water loss by evaporation from the leaf's surface is unavoidable. However, epidermal cells secrete a waxy layer, the **cuticle,** that reduces water loss from their exterior walls (see Table 32-4). The cuticle, which consists primarily of a waxy substance called **cutin,** varies in thickness in different plants, in part as a result of environmental conditions. As one might expect, the leaves of plants adapted to hot, dry climates have extremely thick cuticles. Furthermore, a leaf's exposed (and warmer) upper epidermis generally has a thicker cuticle than its shaded (and cooler) lower epidermis.

Key Point

Leaves contain all three tissue systems found in plants: the dermal tissue system, represented by the upper and lower epidermis; the ground tissue system, represented by the mesophyll; and the vascular tissue system, represented by the xylem and phloem in the veins.

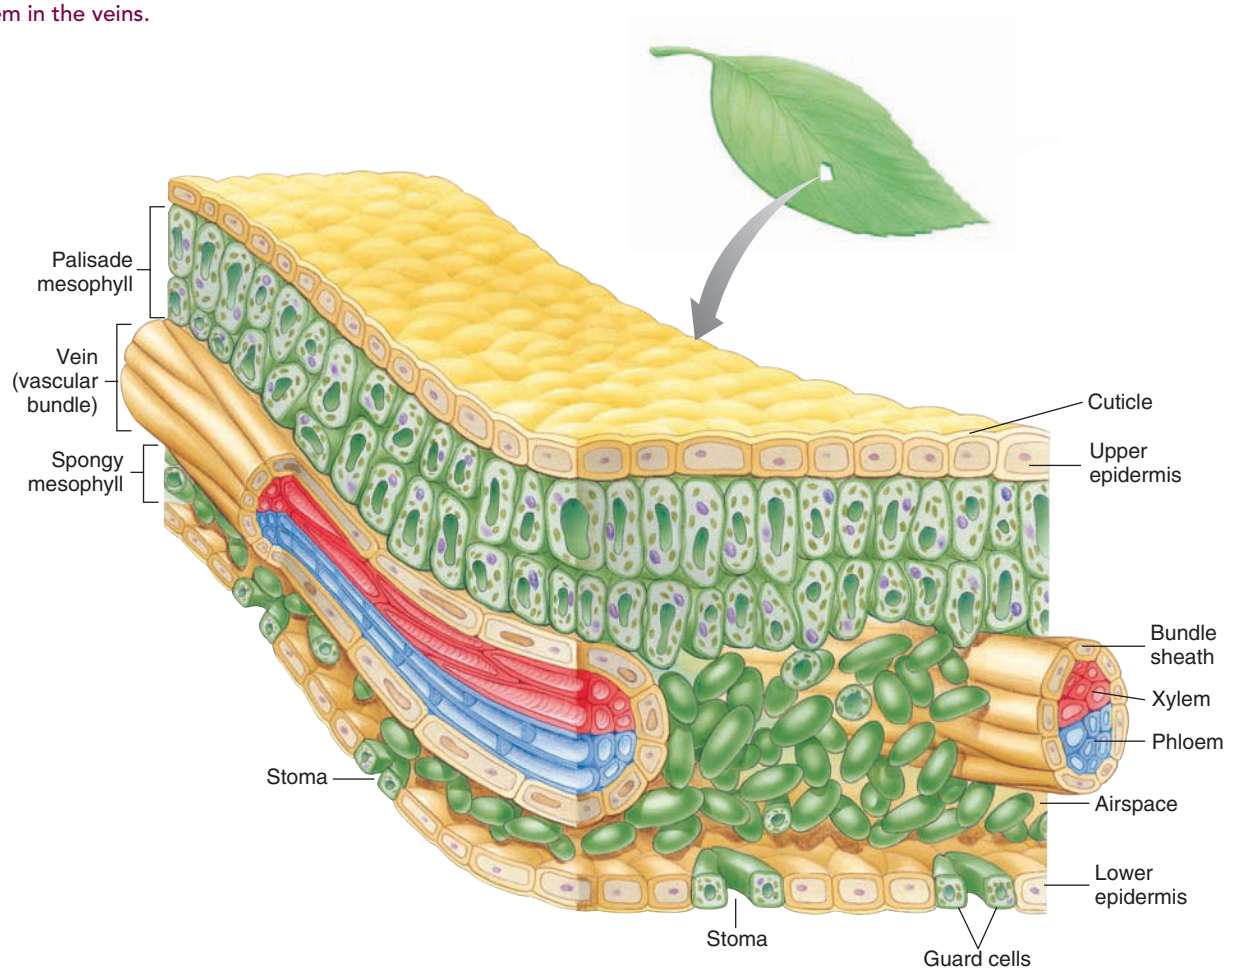

Figure 33-3 ***Animated*** Tissues in a typical leaf blade

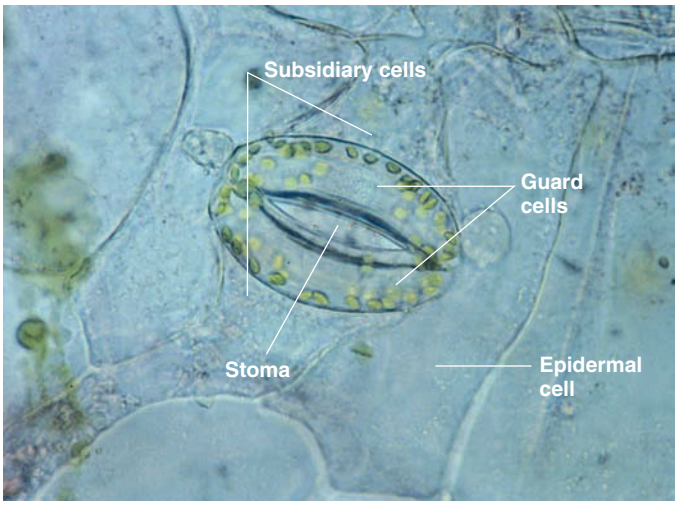
An upper epidermis and lower epidermis cover the blade. The photosynthetic ground tissue, called *mesophyll,* is often arranged into palisade and spongy layers. Veins branch throughout the mesophyll.

The epidermis of many leaves is covered with various hair-like structures called **trichomes,** which have several functions (see Table 32-4). Trichomes of some plants help reduce water loss from the leaf surface by retaining a layer of moist air next to the leaf and by reflecting sunlight, thereby protecting the plant from overheating. Some trichomes secrete stinging irritants for deterring *herbivores,* animals that feed on plants. In addition, a leaf covered with trichomes is difficult for an insect to walk over or eat. Other trichomes excrete excess salts absorbed from a salty soil.

The leaf epidermis contains minute openings, or **stomata** (sing., *stoma*), for gas exchange between leaf cells and the environment; the stomata are evenly spaced to optimize this gas exchange. Each stoma is flanked by two specialized epidermal **guard cells** (Fig. 33-4) responsible for opening and closing the stoma. Guard cells are usually the only epidermal cells with chloroplasts.

Stomata are especially numerous on the lower epidermis of horizontally oriented leaves (an average of about 100 stomata per square millimeter) and in many species are located *only* on the lower surface. The lower epidermis of apple (*Malus sylvestris*) leaves, for example, has almost 400 stomata per square millimeter, whereas the upper epidermis has none. This adaptation reduces water loss because stomata on the lower epidermis are shielded from direct sunlight and are therefore cooler than those on the upper epidermis. In contrast, floating leaves of aquatic plants, such as water lilies, have stomata only on the upper epidermis.

Guard cells are associated with special epidermal cells called **subsidiary cells** that are often structurally different from other epidermal cells. Subsidiary cells provide a reservoir of water and ions that move into and out of the guard cells as they change shape during stomatal opening and closing (discussed later in the chapter).



Dwight R. Kuhn

Figure 33-4 Stoma

LM of an open stoma from the leaf epidermis of inch plant (*Zebrina pendula*). Note the chloroplasts present in the guard cells and the thicker inner wall of each guard cell.

The photosynthetic ground tissue of the leaf, called the **mesophyll** (from the Greek *meso,* "the middle of"; and *phyll,* "leaf"), is sandwiched between the upper epidermis and the lower epidermis. Mesophyll cells, which are parenchyma cells (see Chapter 32) packed with chloroplasts, are loosely arranged, with many air spaces between them that facilitate gas exchange. These intercellular air spaces account for as much as 70% of the leaf's volume.

In many plants, the mesophyll is divided into two sublayers. Toward the upper epidermis, the columnar cells are stacked closely together in a layer called **palisade mesophyll.** In the lower portion, the cells are more loosely and irregularly arranged in a layer called **spongy mesophyll.** The two layers have different functions. Palisade mesophyll is the main site of photosynthesis in the leaf. Photosynthesis also occurs in the spongy mesophyll, but the primary function of the spongy mesophyll is to allow diffusion of gases, particularly CO_2, within the leaf.

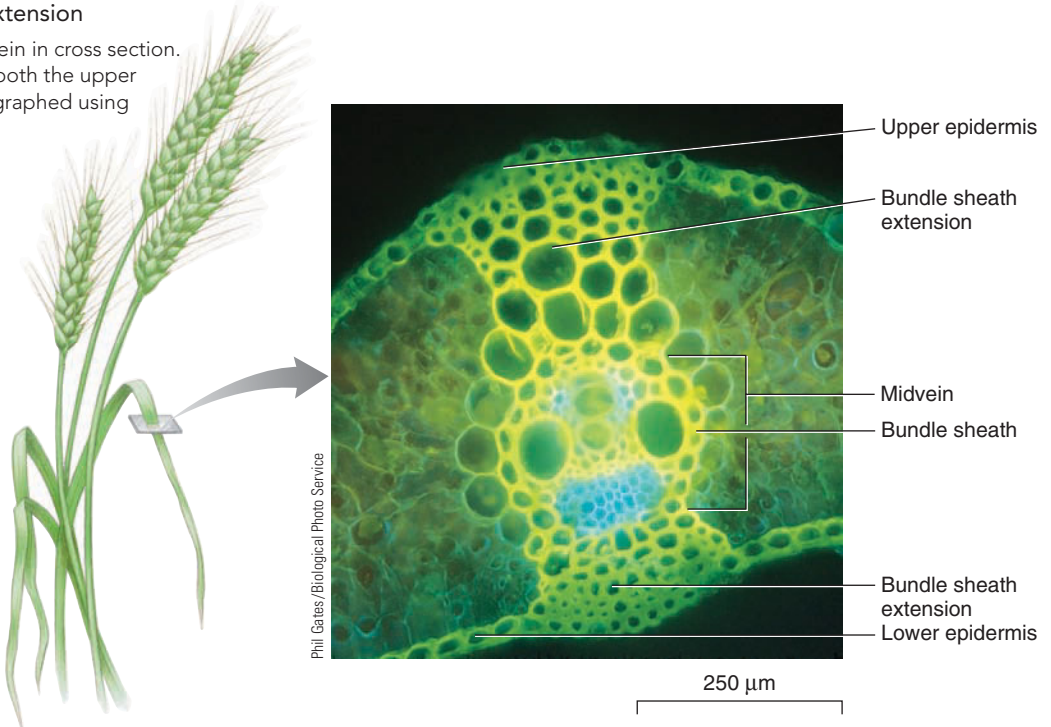
Palisade mesophyll may be further organized into one, two, three, or even more layers of cells. The presence of additional layers is at least partly an adaptation to environmental conditions. Leaves exposed to direct sunlight contain more layers of palisade mesophyll than do shaded leaves on the same plant. In direct sunlight, the light is strong enough to effectively penetrate multiple layers of palisade mesophyll, allowing all layers to photosynthesize efficiently.

The veins, or **vascular bundles,** of a leaf extend through the mesophyll. Branching is extensive, and no mesophyll cell is more than two or three cells away from a vein. Therefore, the slow process of diffusion does not limit the movement of needed resources between mesophyll cells and veins. Each vein contains two types of vascular tissue: xylem and phloem. **Xylem,** which conducts water and dissolved minerals (inorganic nutrients), is usually located in the upper part of a vein, toward the upper epidermis. **Phloem,** which conducts dissolved sugars, is usually confined to the lower part of a vein.

One or more layers of nonvascular cells surround the larger veins and make up the **bundle sheath.** Bundle sheaths are composed of parenchyma or sclerenchyma cells (see Chapter 32). Frequently the bundle sheath has support columns, called **bundle sheath extensions,** that extend through the mesophyll from the upper epidermis to the lower epidermis (Fig. 33-5). Bundle

Figure 33-5 Bundle sheath extension

LM of a wheat (*Triticum aestivum*) midvein in cross section. Note the bundle sheath extensions to both the upper epidermis and lower epidermis. Photographed using fluorescence microscopy.



Phil Gates/Biological Photo Service

sheath extensions may be composed of parenchyma, collenchyma, or sclerenchyma cells.

Leaf structure differs in eudicots and monocots

Each eudicot leaf is usually composed of a broad, flattened blade and a petiole. As mentioned previously, eudicot leaves typically have netted venation. In contrast, many monocot leaves lack a petiole; they are narrow, and the base of the leaf often wraps around the stem to form a sheath. Parallel venation is characteristic of monocot leaves.

Eudicots and certain monocots also differ in internal leaf anatomy (Fig. 33-6). Although most eudicots and monocots have both palisade and spongy layers, some monocots (corn and other grasses) do not have mesophyll differentiated into distinct palisade and spongy layers. Because eudicots have netted veins, a cross section of a eudicot blade often shows veins in both cross-sectional and lengthwise views. In a cross section of a monocot leaf, in contrast, the parallel venation pattern produces evenly spaced veins, all of which appear in cross section.

Differences between the guard cells in eudicot and certain monocot leaves also occur (Fig. 33-7). The guard cells of eudicots and many monocots are shaped like kidney beans. Other monocot leaves (those of grasses, reeds, and sedges) have guard cells shaped like dumbbells. These structural differences affect how the cells swell or shrink to open or close the stoma.

(b) Monocot leaf. LM of part of a leaf cross section of corn (*Zea mays*). Corn leaves lack distinct regions of palisade and spongy mesophyll.

Figure 33-6 Eudicot and monocot leaf cross sections

Leaf structure is related to function

How is leaf structure related to its primary function of photosynthesis? The epidermis of a leaf is relatively transparent and allows light to penetrate to the interior of the leaf where the photosynthetic ground tissue, the mesophyll, is located. Stomata, which dot the leaf surfaces, permit the exchange of gases between the atmosphere and the leaf's internal tissues. CO_2, a raw material of photosynthesis, diffuses into the leaf through stomata, and the oxygen produced during photosynthesis diffuses rapidly out of the leaf through stomata. Stomata also permit other gases, including air pollutants, to enter the leaf (see *Focus On: Air Pollution and Leaves*).

Water required for photosynthesis is obtained from the soil and transported in the xylem to the leaf, where it diffuses into the mesophyll and moistens the surfaces of mesophyll cells. The loose arrangement of the mesophyll cells, with air spaces between cells, allows for rapid diffusion of CO_2 to the mesophyll cell surfaces; there it dissolves in a film of water before diffusing into the cells.

The veins not only supply the photosynthetic ground tissue with water and minerals (from the roots, by way of the xylem) but also carry (in the phloem) dissolved sugar produced during photosynthesis to all parts of the plant. Bundle sheaths and bundle sheath extensions associated with the veins provide additional support to prevent the leaf, which is structurally weak because of the large amount of air space in the mesophyll, from collapsing under its own weight.

focus on

AIR POLLUTION AND LEAVES

The air we breathe is often dirty and contaminated with many pollutants, particularly in urban areas. Air pollution consists of gases, liquids, or solids present in the atmosphere in levels high enough to harm humans and other organisms as well as nonliving materials. Although air pollutants can come from natural sources, for example, from a lightning-caused fire or a volcanic eruption, human activities are a major cause of global air pollution. Motor vehicles and industry are the two main human sources of air pollution.

Air pollution can damage all parts of a plant, but leaves are particularly susceptible because of their structure and function. The thin blade provides a large surface area that comes into contact with the surrounding air. The thousands of stomatal pores that dot the epidermis and allow gas exchange with the atmosphere also permit pollutants to diffuse into the leaf. Just as lungs, the organs of gas exchange in humans and other terrestrial vertebrates, are affected by air pollution, so too the leaves of a plant are affected.

Many studies have shown that high levels of most forms of air pollution reduce the overall productivity of crop plants. The worst pollutant in terms of yield loss is ozone, a toxic gas produced when sunlight catalyzes a reaction between pollutants emitted by motor vehicles and industries. Ozone has been observed to reduce soybean yields by as much as 35%, and the average yield reduction from exposure to ozone is 15%. Ozone inhibits photosynthesis because it damages the mesophyll cells, probably by altering the permeability of their cell membranes. Exposure to low levels of air pollution often causes a decline in photosynthesis without other symptoms of injury. Lesions on leaves and other obvious symptoms appear at much higher levels of air pollution.

Air pollution combined with other environmental stressors (such as low winter temperatures; prolonged droughts; insects; and bacterial, fungal, and viral diseases) causes plants to decline and die. More than half of the red spruce trees in the mountains of the northeastern United States have died since the mid-1970s, and sugar maples in eastern Canada and the United States are also dying. Many still-living trees are exhibiting symptoms of **forest decline**, characterized by gradual deterioration and eventual death of trees. The general symptoms of forest decline are reduced vigor and growth, but some plants exhibit specific symptoms, such as yellowing of needles in conifers. Forest decline is more pronounced at higher elevations, possibly because most trees growing at high elevations are at the limit of their normal range and are therefore more susceptible to wind and low temperatures.

Many factors interact to decrease the health of trees, and no single factor accounts for the recent instances of forest decline. Several air pollutants have been implicated, including acid precipitation, ozone, and toxic heavy metals such as lead, cadmium, and copper. Power plants, ore smelters, refineries, and motor vehicles produce these pollutants. Insects and weather factors such as drought and severe winters may also be important. To complicate matters further, the actual causes of forest decline may vary from one tree species to another and from one location to another. Thus, forest decline appears to result from the combination of multiple stressors. When one or more stressors weaken a tree, then an additional stressor may be enough to cause its death.

Leaves are adapted to help a plant survive in its environment

Leaf structure reflects the environment to which a particular plant is adapted. Although both aquatic plants and those adapted to dry conditions perform photosynthesis and have the same basic leaf anatomy, their leaves are modified to enable them to survive different environmental conditions. The leaves of water lilies have petioles long enough to allow the blade to float on the water's surface. Large air spaces in the mesophyll make the floating blade buoyant. The petioles and other submerged parts have an internal system of air ducts; oxygen moves through these ducts from the floating leaves to the underwater roots and stems, which live in a poorly aerated environment.

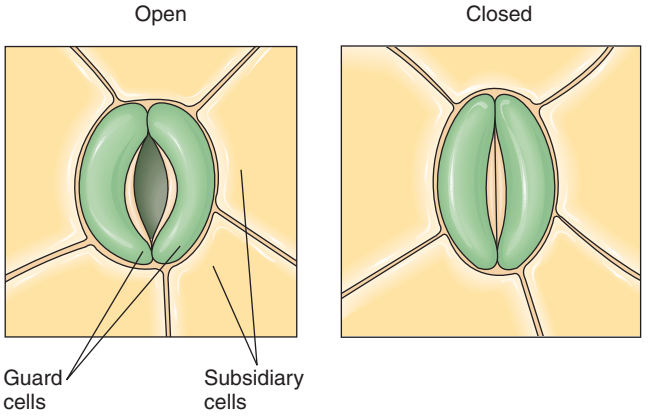
Conifers are an important group of woody trees and shrubs that includes pine, spruce, fir, redwood, and cedar.[2] Most conifers are evergreen, which means they lose leaves throughout the year rather than during certain seasons. Conifers dominate a large portion of Earth's land area, particularly in northern forests and mountains. The leaves of most conifers are waxy needles. Their needles have structural adaptations that help them survive winter, the driest part of the year. (Winter is arid even in areas of heavy snows because roots cannot absorb water from soil when the soil temperature is very low.) Indeed, many of the structural features of needles are also found in many desert plants.

Figure 33-8 shows a cross section of a pine needle. Note that the needle is somewhat thickened rather than thin and bladelike. The needle's relative thickness, which results in less surface area exposed to the air, reduces water loss. Other features that help conserve water include the thick, waxy cuticle and sunken stomata; these permit gas exchange while minimizing water loss. Thus, needles help conifers tolerate the dry winds that occur during winter (*dry* refers here to low relative humidity). With the warming of spring, soil water again becomes available, and the needles quickly resume photosynthesis.

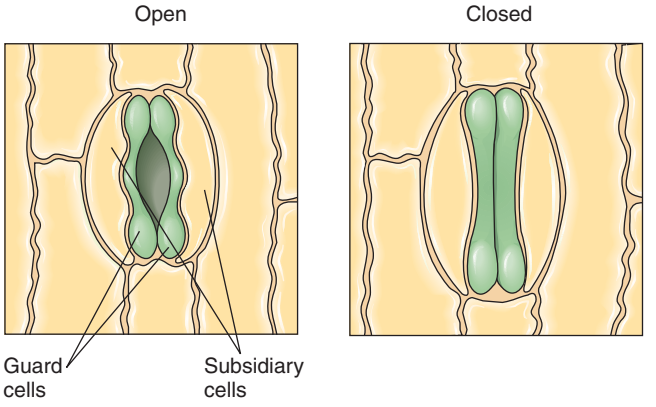
Review

- How are leaves adapted to conserve water?
- What is the photosynthetic ground tissue of a leaf called? What are its two sublayers?
- What are the two types of vascular tissue in a vascular bundle? Which vascular tissue is usually located on the upper part of the vascular bundle?
- How is the leaf organized to deliver the raw materials and remove the products of photosynthesis?

[2] As discussed in Chapter 28, conifers are gymnosperms, one of the two groups of seed plants (the other group is the flowering plants, or angiosperms). Unlike flowering plants, whose seeds are enclosed in fruits, conifers bear "naked" seeds on the scales of female cones.



(a) Guard cells of eudicots and many monocots are bean shaped.



(b) Some monocot guard cells are narrow in the center and thicker at each end.

Figure 33-7 Variation in guard cells

Guard cells are associated with epidermal cells called *subsidiary cells*.

STOMATAL OPENING AND CLOSING

Learning Objectives

5 Explain the role of blue light in the opening of stomata.

6 Outline the physiological changes that accompany stomatal opening and closing.

Stomata are adjustable pores that are usually open during the day when CO_2 is required for photosynthesis and closed at night when photosynthesis is shut down (see the section on CAM photosynthesis in Chapter 9 for an interesting exception). The opening and closing of stomata are controlled by changes in the shape of the two guard cells that surround each pore. The guard cells' shape is determined by their rigidity. When water moves into guard cells from surrounding nonguard cells, the guard cells become turgid (swollen) and bend, producing a pore. When water leaves the guard cells, they become flaccid (limp) and collapse against one another, closing the pore. What causes water to move into and out of guard cells?

Blue light triggers stomatal opening

Data from numerous experiments and observations are beginning to explain the complexities of stomatal movements. Let us begin with stomatal opening, which occurs when the plant detects light from the rising sun. You already know that light is a form of energy; plants absorb light and convert it to chemical energy in the process of photosynthesis. However, light is also an important *environmental signal* for plants—that is, light provides plants with information about their environment that they use to modify various activities at the molecular and cellular levels.

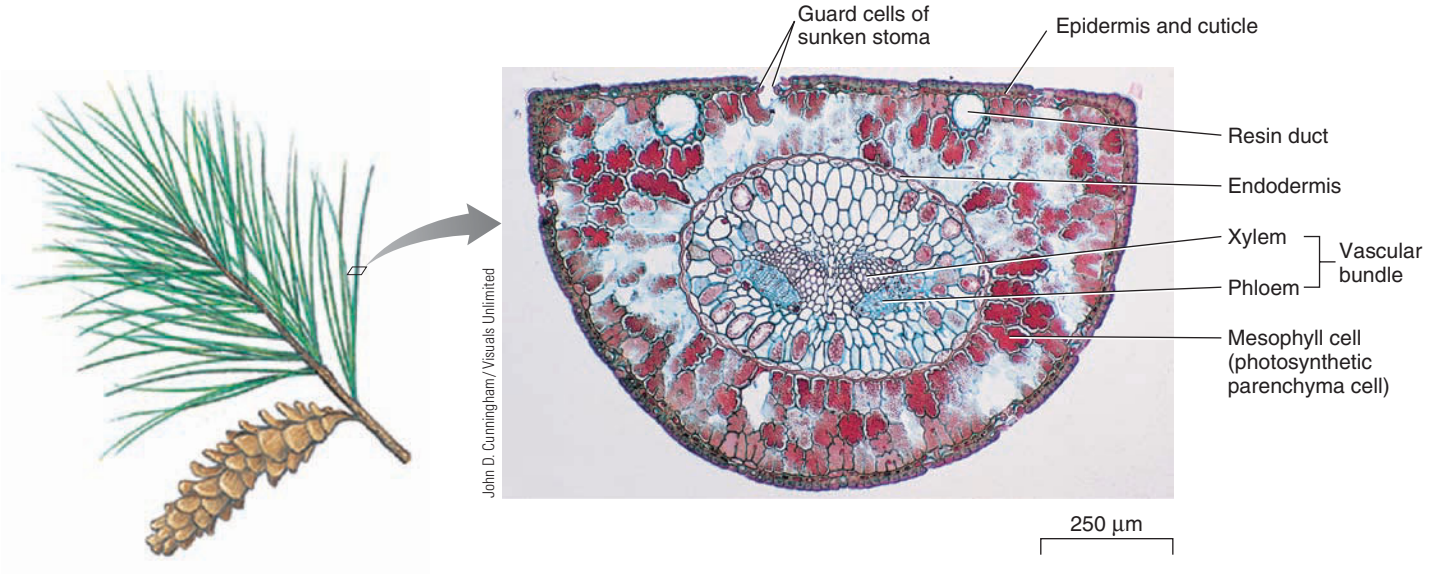


Figure 33-8 LM of a pine needle in cross section

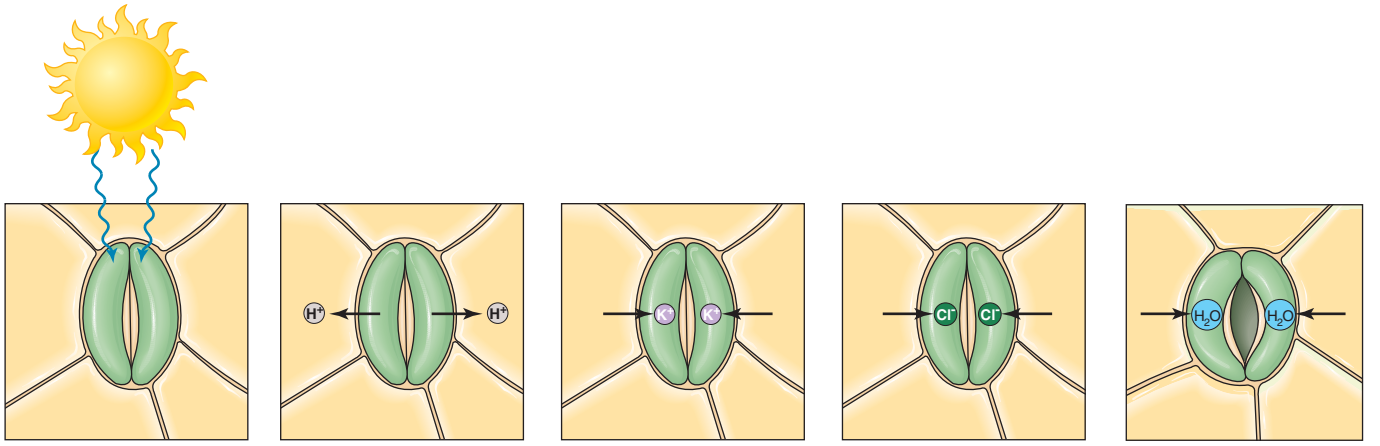
The thick, waxy cuticle and sunken stomata are two structural adaptations that enable pine (*Pinus*) to retain its needles throughout the winter.

Key Point

The accumulation of osmotically active ions (K^+ and Cl^-) in the guard cells is driven by a proton (H^+) gradient.



1 Blue light activates proton pumps.

2 Protons are pumped out of guard cells, forming electrochemical gradient.

3 Potassium ions enter guard cells through voltage-activated ion channels.

4 Chloride ions also enter guard cells through ion channels.

5 Water enters guard cells by osmosis, and stoma opens.

Figure 33-9 ***Animated*** Mechanism of stomatal opening

In stomatal opening and several other plant responses, **blue light,** which has wavelengths from 400 to 500 nm, is an environmental signal. Any plant response to light must involve a **pigment,** a molecule that absorbs the light before the induction of a particular biological response. Data such as the responses of stomata to different colors of light suggest that the pigment involved in stomatal opening and closing is yellow (yellow pigments strongly absorb blue light). The yellow pigment is thought to be located in the guard cells, probably in their plasma membranes.

In step 1 of Figure 33-9, blue light, which is a component of sunlight, triggers the activation of proton pumps, located in the guard cell plasma membrane. Blue light also triggers the synthesis of malic acid and the **hydrolysis** (splitting) of starch (discussed later).

In step 2, the proton pumps use ATP energy to actively transport protons (H^+) out of the guard cells. The H^+ that are pumped are formed when malic acid produced in the guard cells ionizes to form H^+ and negatively charged malate ions. As the proton pumps in the plasma membranes of guard cells transport protons out of the guard cells, an **electrochemical gradient**—that is, a charge and concentration difference—forms on the two sides of the guard cell plasma membrane.

In step 3, the resulting electrochemical gradient of H^+ drives the facilitated diffusion of large numbers of potassium ions *into* guard cells. This movement occurs through **voltage-activated potassium channels,** which open when a certain voltage (difference in charge between the two sides of the guard cell plasma membrane) is attained. This movement of potassium ions has been experimentally measured by the **patch clamp technique,** in which researchers seal the tip of a micropipette to a tiny patch of membrane that contains a single ion channel. They measure the flow of ions through that channel between the cytoplasm and the solution in the micropipette. (Interestingly, in animals, voltage-activated ion channels are found in the plasma membranes of nerve cells and are involved in transmitting neural impulses.)

As shown in step 4, chloride ions are also taken into the guard cells through ion channels in the guard cell plasma membrane. The negatively charged chloride and malate ions help to electrically balance the positively charged potassium ions.

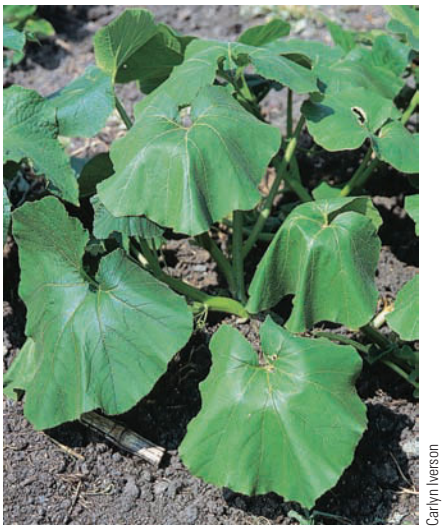
The potassium, chloride, and malate ions accumulate in the vacuoles of the guard cells, thus increasing the solute concentration in the vacuoles. You may recall from the discussion of osmosis in Chapter 5 that when a cell has a solute concentration greater than that of surrounding cells, water flows *into* the cell. Thus, in step 5, water enters the guard cells from surrounding epidermal cells by osmosis. The increased turgidity of the guard cells changes their shape, because the thickened inner cell walls do not expand as much as the outer walls, so the stoma opens.

Blue light activates proton pumps ⟶ proton pump moves H^+ out of guard cells ⟶ K^+ and Cl^- diffuse into guard cells through voltage-activated ion channels ⟶ water diffuses by osmosis into guard cells ⟶ guard cells change shape and stoma opens

Stomata close in the late afternoon or early evening, but not by an exact reversal of the opening process. Recent studies have demonstrated that the concentration of potassium ions in guard cells slowly decreases during the day. However, the concentration of sucrose, another osmotically active substance, increases dur-

ing the day—maintaining the open pore—and then slowly decreases as evening approaches. This sucrose comes from the hydrolysis of the polysaccharide starch, which is stored in the guard cell chloroplasts. As evening approaches, the sucrose concentration in the guard cells declines as sucrose is converted back to starch (which is osmotically inactive), water leaves by osmosis, the guard cells lose their turgidity, and the pore closes.

To summarize, different mechanisms appear to regulate the opening and closing of stomata. The uptake of potassium and chloride ions is mainly associated with stomatal opening, and the declining concentration of sucrose is mainly associated with stomatal closing. In Chapter 37, we discuss other blue-light responses in plants.



Carlyn Iverson

(a) In the late afternoon of a hot day, the leaves have wilted because of water loss. Note that wilting helps reduce the surface area from which transpiration occurs.

Carlyn Iverson

(b) The next morning, water in the leaves has been replenished. Transpiration is negligible during the night, and the plants recover by absorbing water from the soil.

Figure 33-10 Temporary wilting in squash (*Cucurbita pepo*) leaves

Additional factors affect stomatal opening and closing

Although light and darkness trigger the opening and closing of stomata, other environmental factors are also involved, including CO_2 concentration. A low concentration of CO_2 in the leaf induces stomata to open, even in the dark. The effects of light and CO_2 concentration on stomatal opening are interrelated. Photosynthesis, which occurs in the presence of light, reduces the internal concentration of CO_2 in the leaf, triggering stomatal opening. Another environmental factor that affects stomatal opening and closing is dehydration (water stress). During a prolonged drought, stomata remain closed, even during the day. Stomatal opening and closing are under hormonal control, particularly by the plant hormone *abscisic acid* (see Table 37-1).

The opening and closing of stomata are also regulated by an internal biological clock that in some way measures time. For example, after plants are placed in continual darkness, their stomata continue to open and close at more or less the same time each day. Such biological rhythms that follow an approximate 24-hour cycle are known as **circadian rhythms.** Other examples of circadian rhythms are provided in Chapter 37.

Review

- How does blue light trigger stomatal opening?
- What physiological changes occur in guard cells during stomatal opening? During stomatal closing?

TRANSPIRATION AND GUTTATION

Learning Objectives

7 Discuss transpiration and its effects on plants.
8 Distinguish between transpiration and guttation.

Despite leaf adaptations such as the cuticle, approximately 99% of the water that a plant absorbs from the soil is lost by evaporation from the leaves and, to a lesser extent, the stems. Loss of water vapor by evaporation from aerial plant parts is called **transpiration.**

The cuticle is extremely effective in reducing water loss by transpiration. It is estimated that only 1% to 3% of the water lost from a plant passes directly through the cuticle. Most transpiration occurs through open stomata. The numerous stomatal pores that are so effective in gas exchange for photosynthesis also provide openings through which water vapor escapes. In addition, the loose arrangement of the spongy mesophyll cells provides a large surface area within the leaf from which water can evaporate.

Several environmental factors influence the rate of transpiration. More water is lost from plant surfaces at higher temperatures. Light increases the transpiration rate, in part because it triggers stomatal opening and in part because it increases the leaf's temperature. Wind and dry air increase transpiration, but humid air *decreases* transpiration because the air is already saturated, or nearly so, with water vapor.

Although transpiration may seem wasteful, particularly to farmers in arid lands, it is an essential process that has adaptive value. Transpiration is responsible for water movement in plants, and without it water would not reach the leaves from the soil (see discussion of the tension–cohesion model in Chapter 34). The large amount of water that plants lose by transpiration may provide some additional benefits. Transpiration, like sweating in humans, cools the leaves and stems. When water passes from a liquid state to a vapor, it absorbs a great deal of heat. When the water molecules leave the plant as water vapor, they carry this heat with them. Thus, the cooling effect of transpiration may prevent leaves from overheating, particularly in direct sunlight.

Another benefit of transpiration is that it distributes essential minerals throughout the plant. The water that a plant transpires is initially absorbed from the soil, where it is present not as pure water but as a dilute solution of dissolved mineral salts. The water and dissolved minerals are then transported in the xylem throughout the plant, including its leaves. Water moves from the plant to the atmosphere during transpiration, but minerals remain in plant tissues. Many of these minerals are required for the plant's growth. It has been suggested that transpiration enables a plant to take in sufficient water to provide enough essential minerals and that plants cannot satisfy their mineral requirements if the transpiration rate is not high enough.

There is no doubt, however, that under certain circumstances excessive transpiration can be harmful to a plant. On hot summer days, plants frequently lose more water by transpiration than they can take in from the soil. Their cells experience a loss of turgor, and the plants wilt (Fig. 33-10). If a plant is able to recover overnight, because of the combination of negligible transpiration (recall that stomata are closed) and absorption of water from the soil, the plant is said to have experienced *temporary wilting.* Most plants recover from temporary wilting with no ill effects. In cases of prolonged drought, however, the soil may not contain sufficient moisture to permit recovery from wilting. A plant that cannot recover is said to be *permanently wilted* and will die.

Transpiration is an important part of the **hydrologic cycle,** in which water cycles from the ocean and land to the atmosphere and then back to the ocean and land (see Fig. 54-11). As a result of transpiration, water evaporates from leaves and stems to form clouds in the atmosphere. Thus, transpiration eventually results in precipitation. As you may expect, forest trees release substantial amounts of moisture into the air by transpiration. Researchers have determined that at least half the rain that falls in the Amazon rainforest basin is recycled again and again by transpiration and precipitation.

Some plants exude liquid water

Many leaves have special structures through which liquid water is literally forced out. This loss of liquid water, known as **guttation,** occurs when transpiration is negligible and available soil moisture is high. Guttation typically occurs at night because the stomata are closed, but water continues to move into the roots by osmosis. People sometimes mistake the early-morning water droplets formed on leaf margins by guttation for dew (Fig. 33-11). Unlike dew, which condenses from cool night air, guttation droplets come from within the plant. (The mechanism for guttation is discussed in Chapter 34.)

Review

- What is transpiration? How is leaf structure related to transpiration?
- How do environmental factors (sunlight, temperature, humidity, and wind) influence the rate of transpiration?
- How does guttation differ from transpiration?

Ed Reschke/Peter Arnold, Inc.

Figure 33-11 Guttation

Shown is a compound leaf of strawberry (*Fragaria*). Many people mistake guttation for early-morning dew.

LEAF ABSCISSION

Learning Objective

9 Define leaf *abscission,* explain why it occurs, and describe the physiological and anatomical changes that precede it.

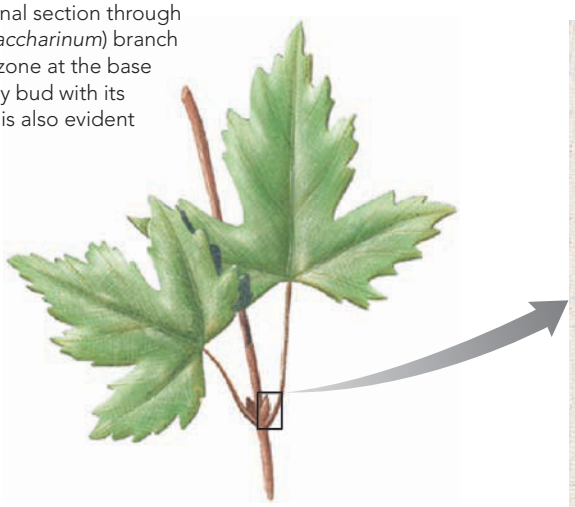
All trees shed leaves, a process known as **abscission.** Many conifers shed their needles in small numbers year-round. The leaves of deciduous plants turn color and abscise, or fall off, once a year—as winter approaches in temperate climates or at the beginning of the dry period in tropical climates with pronounced wet and dry seasons. In temperate forests, most woody plants with broad leaves shed their leaves to survive the low temperatures of winter. During winter, the plant's metabolism, including its photosynthetic machinery, slows down or halts temporarily.

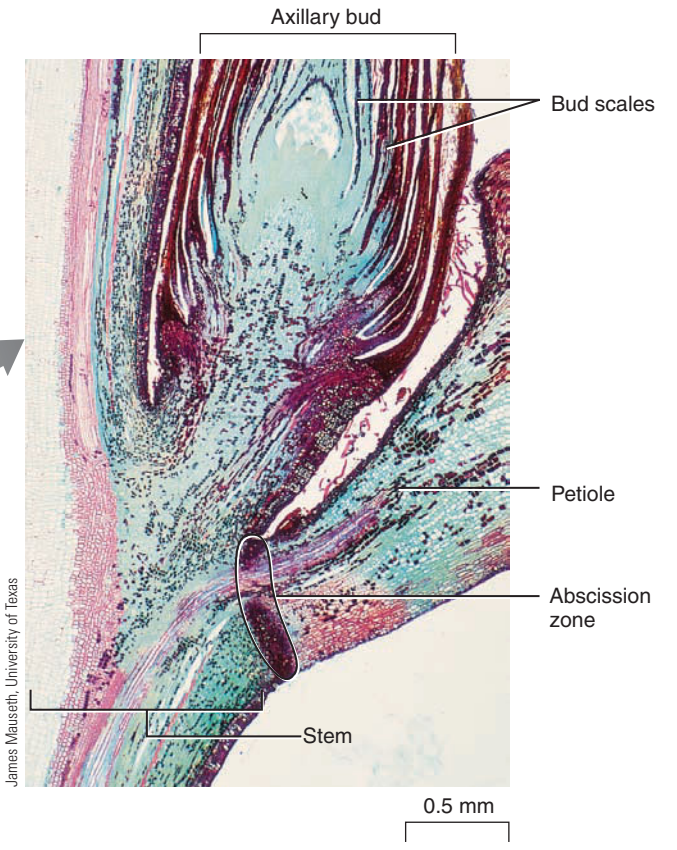
Another reason for abscission is related to a plant's water requirements, which become critical during the physiological drought of winter. As mentioned previously, as the ground chills, absorption of water by the roots is inhibited. When the ground freezes, *no* absorption occurs. If the broad leaves were to stay on the plant during the winter, the plant would continue to lose water by transpiration but would be unable to replace it with water absorbed from the soil.

Leaf abscission is a complex process that involves many physiological changes, all initiated and orchestrated by changing levels of plant hormones, particularly *ethylene.* Briefly, the process is this: As autumn approaches, sugars, amino acids, and many es-

Figure 33-12 Abscission zone

This LM of a longitudinal section through a silver maple (*Acer saccharinum*) branch shows the abscission zone at the base of a petiole. An axillary bud with its protective bud scales is also evident above the petiole.





sential minerals (such as nitrogen, phosphorus, and possibly potassium) are mobilized and transported from the leaves to other plant parts; these minerals will be reused during the following spring. Chlorophyll breaks down, allowing the **carotenoids** (orange carotenes and yellow xanthophylls), some of the accessory pigments in the chloroplasts of leaf cells, to become evident (see Fig. 3-14b). Accessory pigments are always present in the chloroplasts but are masked by the green of the chlorophyll. In addition, red water-soluble pigments called **anthocyanins** may accumulate in the vacuoles of epidermal leaf cells in some species; anthocyanins may protect leaves against damage by ultraviolet radiation. The various combinations of carotenoids and anthocyanins are responsible for the brilliant colors found in autumn landscapes in temperate climates.

In many leaves, abscission occurs at an abscission zone near the base of the petiole

The area where a petiole detaches from the stem is a structurally distinct area called the **abscission zone.** Composed primarily of thin-walled parenchyma cells, it is anatomically weak because it contains few fibers (Fig. 33-12). A protective layer of cork cells develops on the stem side of the abscission zone. These cells have a waxy, waterproof material impregnated in their walls. Enzymes then dissolve the **middle lamella** (the "cement" that holds the primary cell walls of adjacent cells together) in the abscission zone (see Fig. 4-29). Once this process is completed, nothing holds the leaf to the stem but a few xylem cells. A sudden breeze is enough to make the final break, and the leaf detaches. The protective layer of cork remains, sealing off the area and forming a leaf scar.

Although the structure of abscission zones and the physiological changes associated with abscission are well known, only recently have botanists investigated the genes responsible for the development of an abscission zone and the physiological changes of leaf abscission. Using **DNA microarrays,** for example, botanists have identified about 35 genes that are expressed in leaves only as winter approaches. (As shown in Figure 15-13, a DNA microarray contains hundreds of different DNA molecules placed on a glass slide or chip). Some of these genes code for degradative enzymes involved in breaking down proteins and other molecules; others have functions not yet identified.

Review

- Why do many woody plants living in temperate zones lose their leaves in autumn?
- What physiological changes occur during leaf abscission?
- What is the abscission zone?

MODIFIED LEAVES

Learning Objective

10 List at least four examples of modified leaves, and give the function of each.

Although photosynthesis is the main function of leaves, certain leaves have special modifications for other functions. Some plants have leaves specialized for deterring herbivores. **Spines,** modified leaves that are hard and pointed, are found on many desert plants, such as cacti (Fig. 33-13a). In the cactus, the main organ of photosynthesis is the stem rather than the leaf. Spines discourage animals from eating the succulent stem tissue.

Barbara Gerlach/Dembinsky Photo Associates

(a) The leaves of this pincushion cactus (*Mammilaria*) are spines for deterring herbivores.

(b) Tendrils of bur cucumber (*Echinocystis lobata*) are modified leaves that wind around objects and aid in climbing.

Dennis Drenner

(c) A terminal bud and two axillary buds of a maple (*Acer*) twig have overlapping bud scales to protect buds.

Dennis Drenner

(d) The leaves of bulbs such as the onion (*Allium cepa*) are fleshy for storage of food materials and water.

James Mauseth, University of Texas

(e) The succulent leaves of the string-of-beads plant (*Senecio rowleyanus*) are spherical to minimize surface area, thereby conserving water.

Figure 33-13 Leaf modifications

Vines are climbing plants whose stems cannot support their own weight, so they often possess **tendrils** that help keep the vine attached to the structure on which it is growing. The tendrils of many vines, such as peas, cucumbers, and squash, are specialized leaves (Fig. 33-13b). However, some tendrils, such as those of ivy, Virginia creeper, and grape, are specialized stems.

The winter buds of a dormant woody plant are covered by **bud scales,** modified leaves that protect the delicate meristematic tissue of the bud from injury, freezing, or drying out (Fig. 33-13c).

Leaves may also be modified for storage of water or food. For example, a **bulb** is a short, underground stem to which large, fleshy leaves are attached (Fig. 33-13d). Onions and tulips form bulbs. Many plants adapted to arid conditions, such as jade plant, medicinal aloe, and string-of-beads, have succulent leaves for water storage (Fig. 33-13e). These leaves are usually green and also function in photosynthesis.

Some leaves are modified for sexual reproduction (see discussion of flower evolution in Chapter 28, including Fig. 28-15) or asexual reproduction (see Fig. 36-22).

Modified leaves of carnivorous plants capture insects

Carnivorous plants are plants that capture insects. Most carnivorous plants grow in poor soil that is deficient in certain essential minerals, particularly nitrogen. These plants meet some of their mineral requirements by digesting insects and other small animals. The leaves of carnivorous plants are adapted to attract, capture, and digest their animal prey.

Some carnivorous plants have passive traps. The leaves of a pitcher plant, for example, are shaped so that rainwater collects and forms a reservoir that also contains acid secreted by the plant (Fig. 33-14). Some pitchers are quite large; in the tropics, pitcher plants may be large enough to hold 1 L (approximately 1 qt) or more of liquid. An insect attracted by the odor or nectar of the pitcher may lean over the edge and fall in. Although it may make repeated attempts to escape, the insect is prevented from crawling out by the slippery sides and the rows of stiff hairs that point downward around the lip of the pitcher. The insect eventually drowns, and part of its body disintegrates and is absorbed.

Most insects are killed in pitcher plants. However, the larvae of several insects (certain flies, midges, and mosquitoes) and a large community of microorganisms live inside the pitchers. These insect species obtain their food from the insect carcasses, and the pitcher plant digests what remains. It is not known how these insects survive the acidic environment inside the pitcher.

The Venus flytrap is a carnivorous plant with active traps. Its leaf blades resemble tiny bear traps (see Fig. 1-3). Each side of the leaf blade contains three small, stiff hairs. If an insect alights and brushes against two of the hairs, or against the same hair twice in quick succession, the trap springs shut with amazing rapidity—about 100 milliseconds. The spines along the margins of the blades fit closely together to prevent the insect from escaping. After the leaf initially traps the insect, the leaf continues to slowly close for the next several hours. Digestive glands on the surface of the trap secrete enzymes in response to the insect pressing against them. Days later, after the insect has died and been digested, the trap reopens and the indigestible remains fall out.

Figure 33-14 A common pitcher plant

This species (*Sarracenia purpurea*), whose pitchers grow to 30.5 cm (12 in), is widely distributed in acidic bogs and marshes in eastern North America. Young pitchers are green but turn red as they age. Note the dead beetle in the "pitcher."

Review

- What are the primary functions of each of the following modified leaves: spines, tendrils, and bud scales?
- What are the functions of bulbs? Of succulent leaves?
- What are some of the specialized features of the leaves of carnivorous plants?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Discuss variation in leaf form, including simple versus compound leaves, leaf arrangement on the stem, and venation patterns (page 716).

- Leaves typically consist of a broad, flat **blade** and a stalklike **petiole.** Some leaves also have small, leaflike outgrowths from the base called **stipules.**
- Leaves may be simple (having a single blade) or compound (having a blade divided into two or more leaflets).
- Leaf arrangement on a stem may be alternate (one leaf at each **node**), opposite (two leaves at each node), or whorled (three or more leaves at each node).
- Leaves may have parallel or netted venation. Netted venation may be palmately netted, with several major **veins** radiating from one point, or pinnately netted, with veins branching along the entire length of the midvein.

2 Describe the major tissues of the leaf (epidermis, photosynthetic ground tissue, xylem, and phloem), and label them on a diagram of a leaf cross section (page 716).

- Upper and lower surfaces of the leaf blade are covered by an **epidermis.** A waxy **cuticle** coats the epidermis, enabling the plant to survive the dry conditions of a terrestrial existence.
- **Stomata** are small pores in the epidermis that permit gas exchange needed for photosynthesis. Each pore is surrounded by two **guard cells** that are often associated with special epidermal cells called **subsidiary cells.** Subsidiary

cells provide a reservoir of water and ions that move into and out of the guard cells as they change shape during stomatal opening and closing.

- **Mesophyll** consists of photosynthetic parenchyma cells. Mesophyll is divided into **palisade mesophyll,** which functions primarily for photosynthesis, and **spongy mesophyll,** which functions primarily for gas exchange.
- Leaf veins have **xylem** to conduct water and essential minerals to the leaf and **phloem** to conduct sugar produced by photosynthesis to the rest of the plant.

ThomsonNOW™ Learn more about leaf tissues by clicking on the figure in ThomsonNOW.

3 Compare leaf anatomy in eudicots and monocots (page 716).
- Monocot leaves have parallel venation, whereas eudicot leaves have netted venation.
- Some monocots (corn and other grasses) do not have mesophyll differentiated into distinct palisade and spongy layers.
- Some monocots (grasses, reeds, and sedges) have guard cells shaped like dumbbells, unlike the more common bean-shaped guard cells.

4 Relate leaf structure to its function of photosynthesis (page 716).
- Leaf structure is adapted for its primary function of **photosynthesis.** Most leaves have a broad, flattened blade that is quite efficient in collecting the sun's radiant energy.
- Stomata generally open during the day for gas exchange needed during photosynthesis and close at night to conserve water when photosynthesis is not occurring.
- The transparent epidermis allows light to penetrate into the middle of the leaf, where photosynthesis occurs.
- Air spaces in mesophyll tissue permit the rapid diffusion of CO_2 and water into, and oxygen out of, mesophyll cells.

5 Explain the role of blue light in the opening of stomata (page 722).
- **Blue light,** which is a component of sunlight, triggers the activation of proton pumps located in the guard cell plasma membrane. Blue light also triggers the synthesis of malic acid and the **hydrolysis** of starch.

6 Outline the physiological changes that accompany stomatal opening and closing (page 722).
- Protons (H^+) are pumped out of the guard cells. The protons are produced when malic acid ionizes. As protons leave the guard cells, an **electrochemical gradient** (a charge and concentration difference) forms on the two sides of the guard cell plasma membrane.
- The electrochemical gradient drives the uptake of potassium ions through **voltage-activated potassium channels** into the guard cells. Chloride ions are also taken into the guard cells through ion channels. These osmotically active ions increase the solute concentration in the guard cell vacuoles. The resulting osmotic movement of water into the guard cells causes them to become turgid, forming a pore.
- As the day progresses, potassium ions slowly leave the guard cells and starch is hydrolyzed to sucrose, which increases in concentration in the guard cells. Stomata close when water leaves the guard cells as a result of a decline in the concentration of sucrose, an osmotically active solute. The sucrose is converted to starch, which is osmotically inactive.

ThomsonNOW™ Watch stomata in action by clicking on the figure in ThomsonNOW.

7 Discuss transpiration and its effects on plants (page 724).
- **Transpiration** is the loss of water vapor from aerial parts of plants. Transpiration occurs primarily through the stomata.
- The rate of transpiration is affected by environmental factors such as temperature, wind, and relative humidity.
- Transpiration appears to be both beneficial and harmful to the plant—that is, transpiration represents a trade-off between the CO_2 requirement for photosynthesis and the need for water conservation.

8 Distinguish between transpiration and guttation (page 724).
- **Guttation,** the release of liquid water from leaves of some plants, occurs through special structures when transpiration is negligible and available soil moisture is high. In contrast, transpiration is the loss of water vapor and occurs primarily through the stomata.

9 Define leaf *abscission,* explain why it occurs, and describe the physiological and anatomical changes that precede it (page 725).
- Leaf **abscission** is the loss of leaves that often occurs as winter approaches in temperate climates or at the beginning of the dry period in tropical climates with wet and dry seasons.
- Abscission is a complex process involving physiological and anatomical changes that occur prior to leaf fall. An **abscission zone** develops where the petiole detaches from the stem. Sugars, amino acids, and many essential minerals are transported from the leaves to other plant parts. Chlorophyll breaks down, and **carotenoids** and **anthocyanins** become evident.

10 List at least four examples of modified leaves, and give the function of each (page 726).
- **Spines** are leaves adapted to deter herbivores. Some **tendrils** are leaves modified for grasping and holding on to other structures (to support weak stems). **Bud scales** are leaves modified to protect delicate meristematic tissue or dormant buds. **Bulbs** are short, underground stems with fleshy leaves specialized for storage. Many plants adapted to arid conditions have succulent leaves for water storage. Carnivorous plants have leaves modified to trap insects.

TEST YOUR UNDERSTANDING

1. Plants with an alternate leaf arrangement have (a) blades divided into two or more leaflets (b) major veins that radiate out from one point (c) one leaf at each node (d) major veins branching off along the entire length of the midvein (e) two leaves at each node

2. The photosynthetic ground tissue in the middle of the leaf is called (a) cutin (b) mesophyll (c) the abscission zone (d) subsidiary cells (e) palisade and spongy stomata

3. The primary function of the spongy mesophyll is (a) reducing water loss from the leaf surface (b) changing the shape of the guard cells (c) supporting the leaf to prevent it from collapsing under its own weight (d) diffusing gases within the leaf (e) deterring herbivores
4. Gas exchange occurs through microscopic pores formed by two (a) subsidiary cells (b) abscission cells (c) mesophyll cells (d) guard cells (e) stipules
5. Most stomata are usually located in the _____ of the leaf. (a) upper epidermis (b) lower epidermis (c) cuticle (d) spongy mesophyll (e) palisade mesophyll
6. The thin, noncellular layer of wax secreted by the epidermis of leaves is the (a) stoma (b) subsidiary cell (c) trichome (d) bundle sheath (e) cuticle
7. The _____ encircles a vein. (a) palisade mesophyll (b) guard cell (c) bundle sheath (d) blade (e) cuticle
8. The _____ of a leaf vein transports water and dissolved minerals, whereas the _____ transports sugars produced by the leaf during photosynthesis. (a) xylem; phloem (b) xylem; bundle sheath (c) phloem; xylem (d) phloem; vein (e) vascular bundle; bundle sheath
9. Which of the following is *not* an adaptation of pine needles to conserve water? (a) less surface area exposed to the air than thin-bladed leaves (b) a relatively thick cuticle (c) sunken stomata (d) netted veins instead of parallel veins (e) both c and d are not adaptations of pine needles
10. Most of the water that a plant absorbs from the soil is lost by the process of (a) guttation (b) circadian rhythm (c) abscission (d) transpiration (e) photosynthesis
11. When transpiration is negligible, plants such as grasses exude excess water by (a) guttation (b) circadian rhythm (c) abscission (d) pumping H^+ out of and K^+ into guard cells (e) photosynthesis
12. At sunrise, the accumulation in the guard cells of the osmotically active substance _____ causes an inflow of water and the opening of the pore. (a) protons (b) starch (c) ATP synthase (d) sucrose (e) potassium ions
13. Stomatal opening is most pronounced in response to _____ light. (a) green (b) yellow (c) blue (d) ultraviolet (e) infrared
14. The seasonal detachment of leaves is known as (a) forest decline (b) transpiration (c) abscission (d) guttation (e) dormancy
15. Anatomically, the abscission zone where a petiole detaches from a stem consists of (a) thin-walled parenchyma cells with few fibers (b) thick-walled cork parenchyma cells (c) clusters of fibers and collenchyma strands (d) hard, pointed stipules (e) epidermal cells with sunken stomata
16. Modified leaves that enable a stem to climb are called _____, whereas modified leaves that cover the winter buds of a dormant woody plant are called _____. (a) spines; bud scales (b) bud scales; tendrils (c) tendrils; bud scales (d) tendrils; spines (e) carnivorous leaves; spines
17. There is a trade-off between photosynthesis and transpiration in leaves because (a) numerous stomatal pores provide both gas exchange for photosynthesis and openings through which water vapor escapes (b) a waxy layer, the cuticle, reduces water loss (c) blue light triggers an influx of potassium ions (K^+) into the guard cells (d) leaves of deciduous plants abscise as winter approaches in temperate climates (e) stomata are closed at night, although water continues to move into the roots by osmosis

CRITICAL THINKING

1. Suppose that you are asked to observe a micrograph of a leaf cross section and distinguish between the upper and lower epidermis. How would you make this decision?
2. Given that (a) xylem is located toward the upper epidermis in leaf veins and phloem is toward the lower epidermis and (b) the vascular tissue of a leaf is continuous with that of the stem, suggest one possible arrangement of vascular tissues in the stem that might account for the arrangement of vascular tissue in the leaf.
3. What might be some of the advantages of a plant having a few large leaves? What might be some disadvantages? What might be some advantages of having many small leaves? What disadvantages might this entail? How would your answers differ for plants growing in a humid environment compared to those in a desert?
4. Briefly explain why research on the molecular mechanism of stomatal closure might be of future use in agriculture.
5. **Evolution Link.** Why did natural selection favor the evolution of seasonal leaf abscission in woody flowering plants living in colder climates? What adaptations enable conifers to survive these climates without leaf abscission?

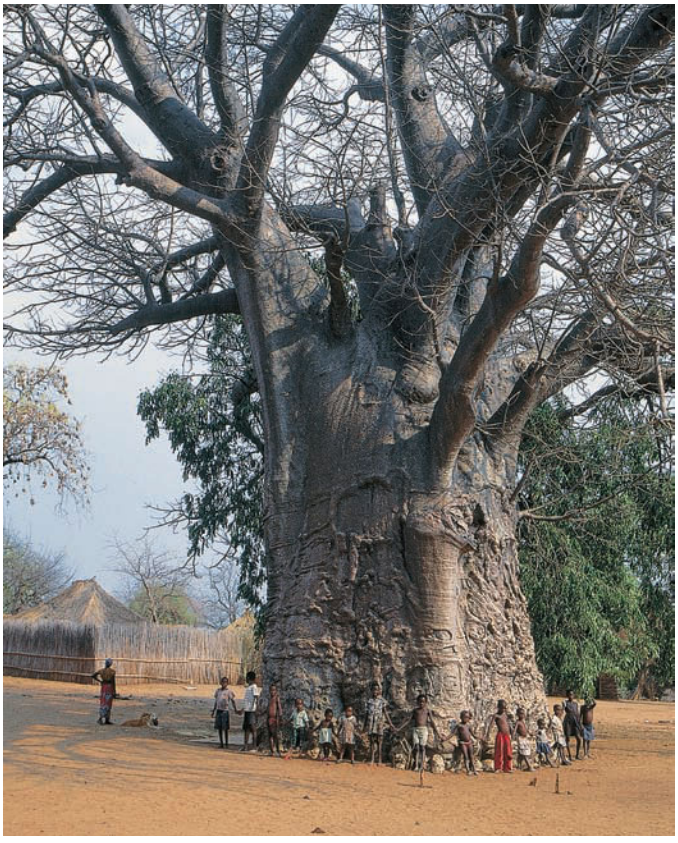
Stems and Transport in Vascular Plants



Michael Fairchild/Peter Arnold, Inc.

Baobab tree. Baobabs (*Adansonia digitata*), which are native to Africa, Madagascar, and Australia, store large volumes of water and starch in their massive trunks. Baobab trees are relatively short (growing to 18 m, or 60 ft), but their trunks can be as much as 9 m (30 ft) in diameter. Photographed in Namibia, with children around the tree as a size reference.

KEY CONCEPTS

Primary tissues (epidermis, cortex, pith, xylem, and phloem) of stems develop from shoot apical meristems.

Secondary tissues (wood and bark) of stems develop from two lateral meristems, vascular cambium and cork cambium.

The concept of water potential explains the direction of water flow into, through, and out of a plant.

According to the tension–cohesion model, transpiration pulls water up through the stem as water evaporates from leaves by transpiration.

According to the pressure–flow hypothesis, sucrose is transported in phloem sap from the source, where the sugar is loaded into phloem, to the sink, where the sugar is removed from phloem.

A vegetative (not sexually reproductive) vascular plant has three parts: roots, leaves, and stems. As discussed in Chapter 32, roots serve to anchor the plant and absorb materials from the soil, whereas leaves are primarily for photosynthesis, converting radiant energy into the chemical energy of carbohydrate molecules. Stems, the focus of this chapter, link a plant's roots to its leaves and are usually located aboveground, although many plants have underground stems. Stems exhibit varied forms, ranging from rope-like vines to massive tree trunks. They can be either herbaceous, with soft, nonwoody tissues; or woody, with extensive hard tissues of wood and bark.

Stems perform three main functions in plants. First, stems of most species support leaves and reproductive structures. The upright position of most stems and the arrangement of the leaves on them allow each leaf to absorb light for use in photosynthesis. Reproductive structures (flowers and fruits) are located on stems in areas accessible to insects, birds, and air currents, which transfer pollen from flower to flower and help disperse seeds and fruits.

Second, stems provide internal transport. They conduct water and dissolved minerals (inorganic nutrients) from the roots, where these materials are absorbed from the soil, to leaves and other plant parts. Stems also conduct the sugar produced in leaves by photosynthesis to roots and other parts of the plant. Remember, however, that stems are not the only plant organs that conduct materials. The vascular system is continuous throughout all parts of a plant, and conduction occurs in roots, stems, leaves, and reproductive structures.

Third, stems produce new living tissue. They continue to grow throughout a plant's life, producing *buds* that develop into stems with new leaves and/or reproductive structures. In addition to the main functions of support, conduction, and production of new stem tissues, stems of some species are modified for asexual reproduction (see Chapter 36) or, if green, to manufacture sugar by photosynthesis. Also, some stems are specialized to store starch (see photograph on previous page). ■

EXTERNAL STEM STRUCTURE IN WOODY TWIGS

Learning Objective

1 Describe the external features of a woody twig.

Although stems exhibit great variation in structure and growth, they all have **buds,** which are embryonic shoots. A **terminal bud** is the embryonic shoot located at the tip of a stem. The dormant (not actively growing) apical meristem of a terminal bud is covered and protected by an outer layer of **bud scales,** which are modified leaves (see Fig. 33-13c). **Axillary buds,** also called **lateral buds,** are located in the axils of a plant's leaves (see Fig. 33-1). An *axil* is the upper angle between a leaf and the stem to which it is attached. When terminal and axillary buds grow, they form branches that bear leaves and/or flowers. The area on a stem where each leaf is attached is called a **node,** and the region between two successive nodes is an **internode.**

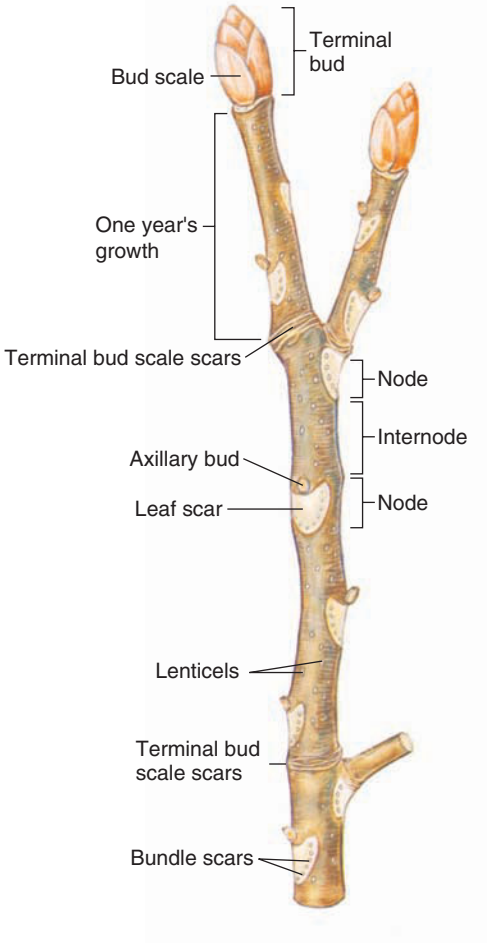


Figure 34-1 ***Animated*** External structure of a woody twig in its winter condition

The age of a woody twig can be determined by the number of sets of bud scale scars (do not count side branches). How old is this twig?

To demonstrate certain structural features of the stem, we can use a woody twig of a deciduous tree that has shed its leaves, as shown in Figure 34-1. Bud scales cover the terminal bud and protect its delicate apical meristem during dormancy. When the bud resumes growth, the bud scales covering the terminal bud fall off, leaving **bud scale scars** on the stem where they were attached. Because temperate-zone woody plants form terminal buds at the end of each year's growing season, the number of sets of bud scale scars on a twig indicates its age. A **leaf scar** shows where each leaf was attached on the stem; the pattern of leaf scars can be used to determine leaf arrangement on a stem—alternate, opposite, or whorled (see Fig. 33-2b). The vascular (conducting) tissue that extends from the stem out into the leaf forms **bundle scars** within a leaf scar. Axillary buds may be found above the leaf scars. Also, the bark of a woody twig has **lenticels,** sites of loosely arranged cells that allow oxygen to diffuse into the interior of the woody stem. Lenticels look like tiny specks on the bark of a twig.

Review

- What is the difference between terminal and axillary buds?
- What is the function of bud scales? Of lenticels?
- How can you tell the age of a woody twig?

STEM GROWTH AND STRUCTURE

Learning Objectives

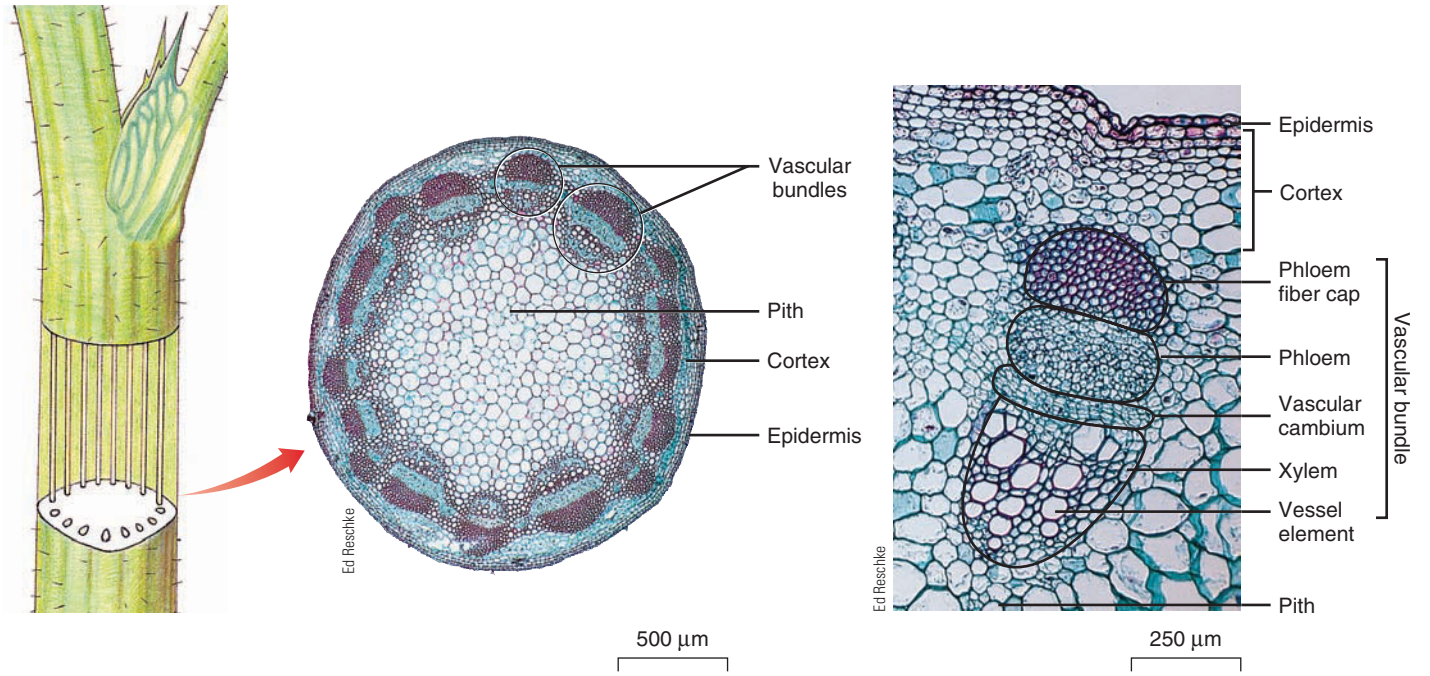
2 Label cross sections of herbaceous eudicot and monocot stems, and describe the functions of each tissue.

3 Name the two lateral meristems, and describe the tissues that arise from each.

4 Outline the transition from primary growth to secondary growth in a woody stem.

You may recall from Chapter 32 that plants have two different types of growth. **Primary growth** is an increase in the length of a plant and occurs at **apical meristems** located at the tips of roots and shoots and also within the buds of stems. **Secondary growth** is an increase in the girth (thickness) of a plant as a result of the activity of **lateral meristems** located within stems and roots. The new tissues formed by the lateral meristems are called *secondary tissues* to distinguish them from *primary tissues* produced by apical meristems.

All plants have primary growth; some plants have both primary and secondary growth. Stems with only primary growth



(a) Cross section of a sunflower (*Helianthus annuus*) stem. Note the vascular bundles arranged in a circle around a central core of pith.

(b) Close-up of a vascular bundle. In each bundle, xylem is located toward the stem's interior, and phloem toward the exterior. Each vascular bundle is "capped" by a batch of fibers for additional support.

Figure 34-2 ***Animated*** LMs of a herbaceous eudicot stem

are herbaceous, whereas those with both primary and secondary growth are woody.[1] A woody plant increases in length by primary growth at the tips of its stems and roots, whereas its older stems and roots farther back from the tips increase in girth by secondary growth. In other words, at the same time that secondary growth is adding wood and bark, thereby causing the stem to thicken, primary growth is increasing the length of the stem.

Herbaceous eudicot and monocot stems differ in internal structure

Although considerable structural variation exists in stems, they all possess an outer protective covering (epidermis or periderm), one or more types of ground tissue, and vascular tissues (xylem and phloem). Let us first consider the structure of herbaceous eudicot stems and then of monocot stems.

Vascular bundles of herbaceous eudicot stems are arranged in a circle in cross section

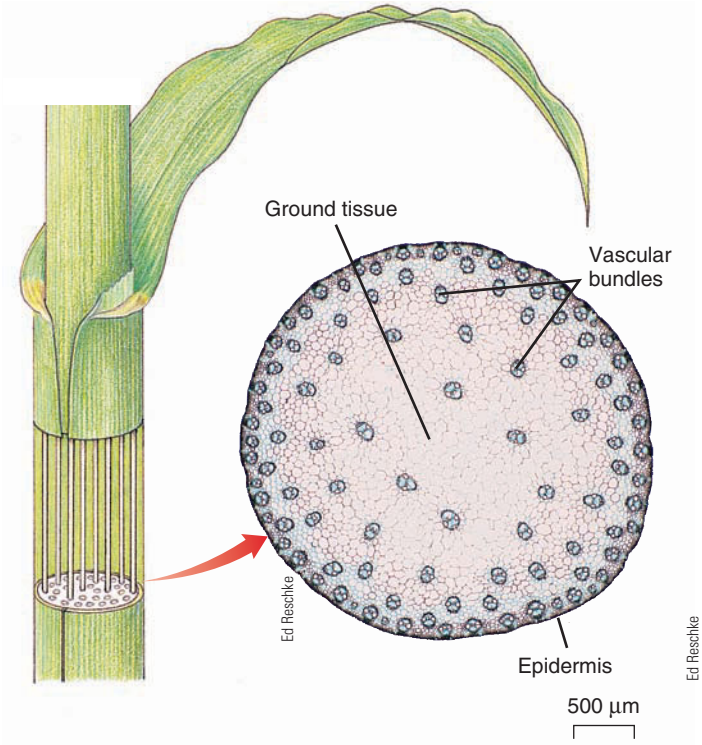
A young sunflower stem is a representative herbaceous eudicot stem that exhibits primary growth (Fig. 34-2). Its outer covering, the **epidermis,** provides protection in herbaceous stems, as it does in leaves and herbaceous roots (see Table 32-4 and Fig. 32-6). The **cuticle,** a waxy layer of *cutin,* covers the stem epidermis and reduces water loss from the stem surface. **Stomata** permit gas exchange. (Recall from Chapter 33 that a cuticle and stomata are also associated with the leaf epidermis.)

Inside the epidermis is the **cortex,** a cylinder of ground tissue that may contain parenchyma, collenchyma, and sclerenchyma cells (see Table 32-2 and Fig. 32-4). As might be expected from the various types of cells that it contains, the cortex in herbaceous eudicot stems can have several functions, such as photosynthesis, storage, and support. If a stem is green, photosynthesis occurs in chloroplasts of cortical parenchyma cells. Parenchyma in the cortex also stores starch (in amyloplasts) and crystals (in vacuoles). Collenchyma and sclerenchyma in the cortex confer strength and structural support for the stem.

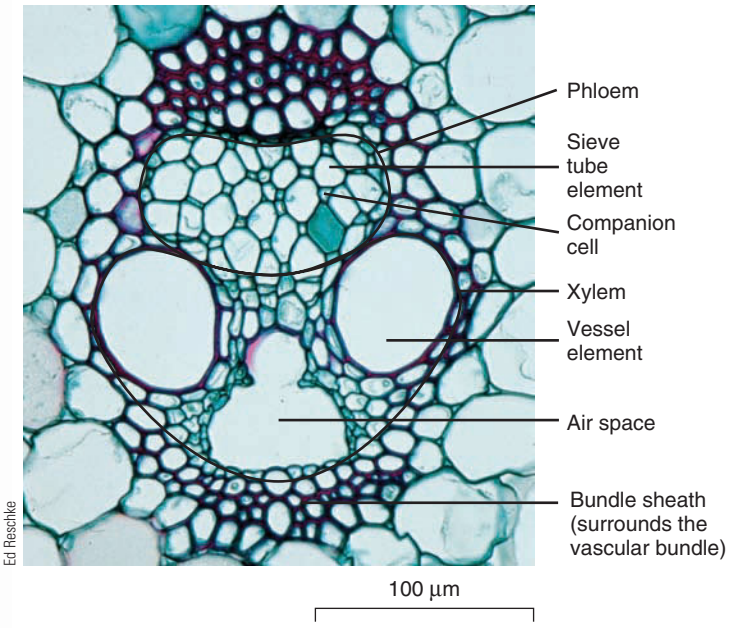
The vascular tissues provide conduction and support. In herbaceous eudicot stems, the vascular tissues are located in bundles that, when viewed in cross section, are arranged in a circle. However, viewed lengthwise, these bundles extend as long strands throughout the length of a stem and are continuous with vascular tissues of both roots and leaves.

Each vascular bundle contains both **xylem,** which transports water and dissolved minerals from roots to leaves, and **phloem,** which transports dissolved sugar (see Table 32-3 and Fig. 32-5). Xylem is located on the inner side of the vascular bundle, and phloem is found toward the outside. Sandwiched between xylem and phloem in some herbaceous stems is a single layer of cells called the *vascular cambium,* a lateral meristem responsible for secondary growth (discussed later).

[1] Certain herbaceous stems, such as geranium and sunflower, also have a limited amount of secondary growth.



(a) Cross section of a corn (*Zea mays*) stem shows vascular bundles scattered throughout ground tissue.



(b) Close-up of a vascular bundle. The air space is the site where the first xylem elements were formed and later disintegrated. The entire bundle is enclosed in a bundle sheath of sclerenchyma for additional support.

Figure 34-3 ***Animated*** LMs of a monocot stem

Because most stems support the aerial plant body, they are much stronger than roots. The thick walls of tracheids and vessel elements in xylem help support the plant. Fibers also occur in both xylem and phloem, although they are usually more extensive in phloem. These fibers add considerable strength to the herbaceous stem. In sunflowers and certain other herbaceous eudicot stems, phloem contains a cluster of fibers toward the outside of the vascular bundle, called a **phloem fiber cap,** that helps strengthen the stem. The phloem fiber cap is not present in all herbaceous eudicot stems.

The **pith** is a ground tissue at the center of the herbaceous eudicot stem that consists of large, thin-walled parenchyma cells that function primarily in storage. Because of the arrangement of the vascular tissues in bundles, there is no distinct separation of cortex and pith between the vascular bundles. The areas of parenchyma between the vascular bundles are often referred to as **pith rays.**

Vascular bundles are scattered throughout monocot stems

An epidermis with its waxy cuticle covers monocot stems, such as the herbaceous stem of corn. As in herbaceous eudicot stems, the vascular tissues run in strands throughout the length of a stem. In cross section the vascular bundles contain xylem toward the inside and phloem toward the outside. In contrast with herbaceous eudicots, however, vascular bundles of monocots are not arranged in a circle but are scattered throughout the stem (Fig. 34-3). Each vascular bundle is enclosed in a bundle sheath of supporting sclerenchyma cells. The monocot stem does not have distinct areas of cortex and pith. The ground tissue in which the vascular tissues are embedded performs the same functions as cortex and pith in herbaceous eudicot stems.

Monocot stems do not possess lateral meristems (vascular cambium and cork cambium) that give rise to secondary growth. Monocots have primary growth only and do not produce wood and bark. Although some treelike monocots (such as palms) attain considerable size, they do so by a modified form of primary growth in which parenchyma cells divide and enlarge. Stems of some monocots (such as bamboo and palm) contain a great deal of sclerenchyma tissue, which makes them hard and woodlike in appearance.

Woody plants have stems with secondary growth

Woody plants undergo secondary growth, an increase in the girth of stems and roots. Secondary growth occurs as a result of the activity of two lateral meristems: vascular cambium and cork cambium. Among flowering plants, only woody eudicots (such as apple, hickory, and maple) have secondary growth. Cone-bearing

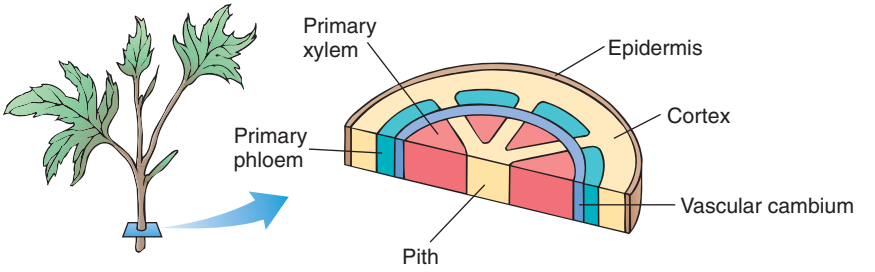
gymnosperms (such as pine, juniper, and spruce) also have secondary growth.

Cells in the **vascular cambium** divide and produce two conducting and supporting tissues: secondary xylem (wood) to replace primary xylem, and secondary phloem (inner bark) to replace primary phloem. Primary xylem and primary phloem are not able to transport materials indefinitely and so are replaced in plants that have extended life spans.

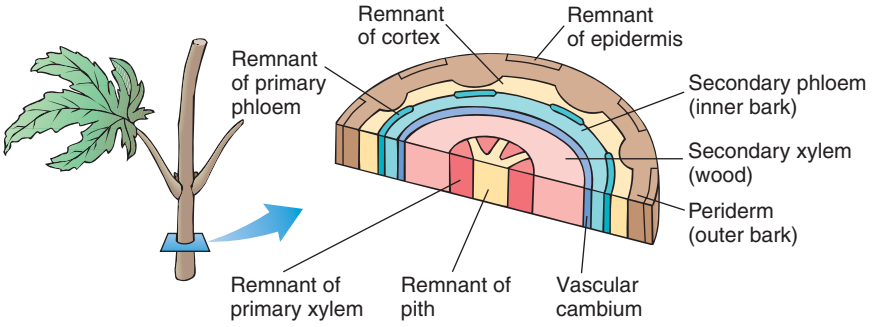
Cells of the outer lateral meristem, called **cork cambium,** divide and produce cork cells and cork parenchyma. Cork cambium and the tissues it produces are collectively referred to as **periderm** (outer bark), which functions as a replacement for the epidermis (see the last LM in Table 32-4).

Vascular cambium gives rise to secondary xylem and secondary phloem

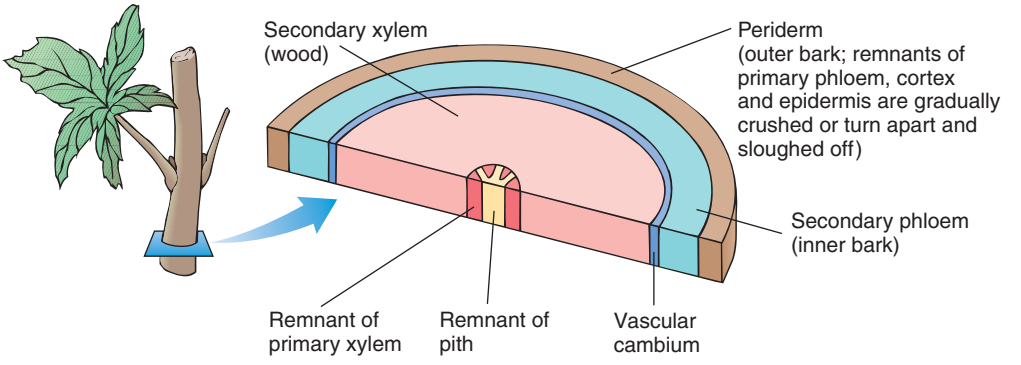
Primary tissues in woody eudicot stems are organized like those in herbaceous eudicot stems, with the vascular cambium a thin layer of cells sandwiched between xylem and phloem in the vascular bundles. Once secondary growth begins, the internal structure of a stem changes considerably (Fig. 34-4). Although vascular cambium is not initially a continuous cylinder of cells (because the vascular bundles are separated by pith rays), it becomes continuous when production of secondary tissues begins. This continuity develops because certain parenchyma cells in each pith ray retain the ability to divide. These cells connect to vascular cambium cells in each vascular bundle, forming a complete ring of vascular cambium.



(a) At the onset of secondary growth, vascular cambium arises in the parenchyma between the vascular bundles (that is, in the pith rays), forming a cylinder of meristematic tissue (*blue circle in cross section*).



(b) Vascular cambium begins to divide, forming secondary xylem on the inside and secondary phloem on the outside.



(c) A young woody stem. Vascular cambium produces significantly more secondary xylem than secondary phloem.

Figure 34-4 ***Animated*** Development of secondary growth

Vascular cambium and the tissues it produces are shown in cross section; cork cambium is not depicted. (The figures change in scale because of space limitations; pith and primary xylem are actually the same size in all three diagrams, but the change in scale makes those tissues appear to shrink in each succeeding diagram.)

Cells in the vascular cambium divide and produce daughter cells in two directions. The cells formed from the dividing vascular cambium are located either *inside* the ring of vascular cambium (to become secondary xylem, or wood) or *outside* it (to become secondary phloem, or inner bark) (Fig. 34-5). When a cell in the vascular cambium divides tangentially (inward or outward), one daughter cell remains meristematic; that is, it remains part of the vascular cambium. The other cell may divide again several times, but eventually it stops dividing and develops into mature secondary tissue. Thus, vascular cambium is a thin layer of cells sandwiched between the wood and inner bark, the two tissues it produces (Fig. 34-6).

As the stem increases in circumference, the number of cells in the vascular cambium also increases. This increase in cells occurs by an occasional radial division of a vascular cambium cell, at right angles to its normal direction of division. In this case, both daughter cells remain meristematic.

What happens to the original primary tissues of a stem once secondary growth develops? As a stem increases in thickness, the orientation of the original primary tissues changes. For example,

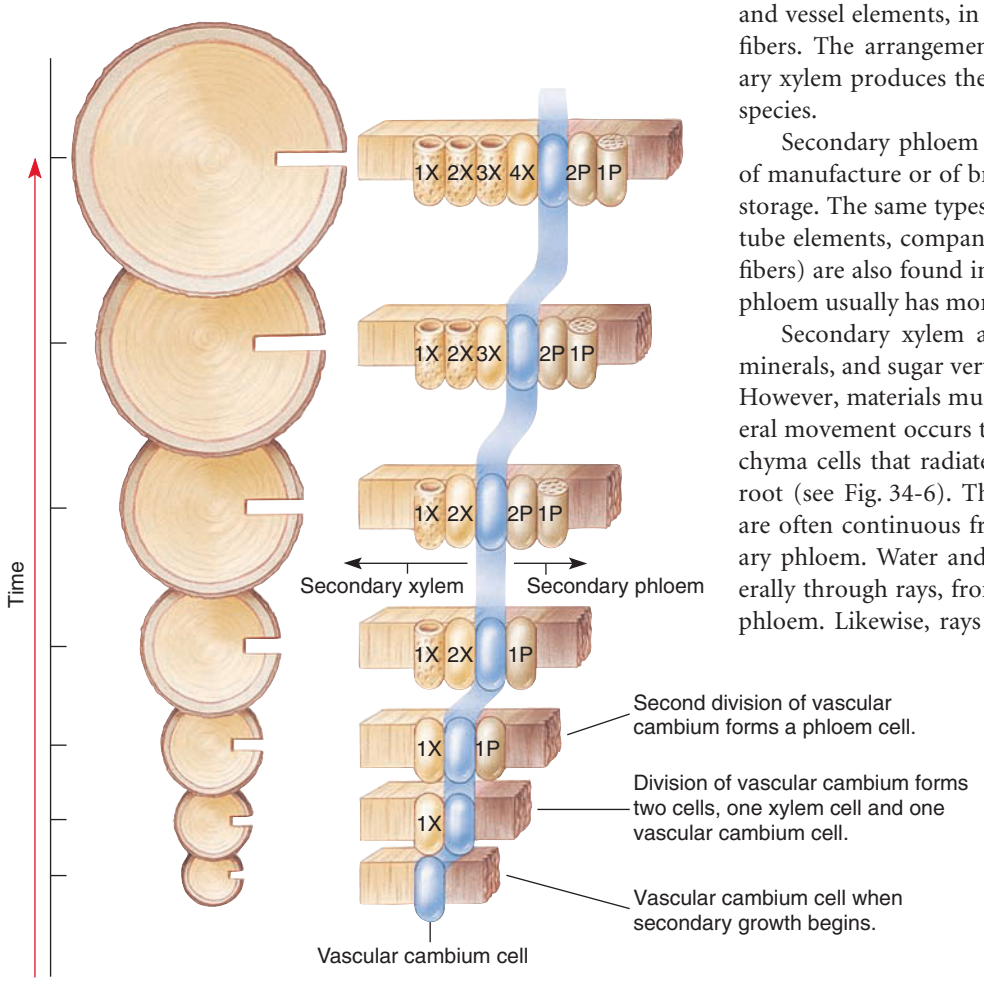


Figure 34-5 ***Animated*** Development of secondary xylem and secondary phloem

To study the figure, which shows a radial view of a dividing vascular cambium cell, start at the bottom and move up. Note that vascular cambium (*the blue cell*) divides in two directions, forming secondary xylem (X) to the inside and secondary phloem (P) to the outside. These cells, which are numbered in the order in which they are produced, differentiate to form the mature cell types associated with xylem and phloem. As secondary xylem accumulates, vascular cambium "moves" outward, and the woody stem increases in diameter.

secondary xylem and secondary phloem are laid down between the primary xylem and primary phloem within each vascular bundle. Therefore, as vascular cambium forms secondary tissues, the primary xylem and primary phloem in each vascular bundle become separated from one another. The primary tissues located outside the cylinder of secondary growth (that is, primary phloem, cortex, and epidermis) are subjected to the mechanical pressures produced by secondary growth and are gradually crushed or torn apart and sloughed off.

Secondary tissues replace the primary tissues in function. Secondary xylem conducts water and dissolved minerals from roots to leaves in the woody plant. It contains the same types of cells found in primary xylem: water-conducting tracheids and vessel elements, in addition to xylem parenchyma cells and fibers. The arrangement of the different cell types in secondary xylem produces the distinctive wood characteristics of each species.

Secondary phloem conducts dissolved sugar from its place of manufacture or of breakdown of starch to a place of use and storage. The same types of cells found in primary phloem (sieve tube elements, companion cells, phloem parenchyma cells, and fibers) are also found in secondary phloem, although secondary phloem usually has more fibers than primary phloem.

Secondary xylem and secondary phloem transport water, minerals, and sugar vertically throughout the woody plant body. However, materials must also move horizontally (laterally). Lateral movement occurs through **rays,** which are chains of parenchyma cells that radiate from the center of the woody stem or root (see Fig. 34-6). The vascular cambium forms rays, which are often continuous from the secondary xylem to the secondary phloem. Water and dissolved minerals are transported laterally through rays, from the secondary xylem to the secondary phloem. Likewise, rays form pathways for the lateral transport of dissolved sugar, from the secondary phloem to the secondary xylem, and of waste products to the center, or heart, of the tree (discussed later).

Cork cambium produces periderm

Cork cambium, which usually arises from parenchyma cells in the outer cortex, produces **periderm,** the functional replacement for the epidermis. Cork cambium is either a continuous cylinder of dividing cells (similar to vascular cambium) or a series of overlapping arcs of meristematic cells that form from parenchyma cells in successively deeper layers of the cortex and, eventually, secondary phloem. Variation in cork cambia and their rates of division explain why the outer bark of some tree species is fissured (as in bur oak), rough and shaggy (shagbark hickory), scaly (Norway pine), or smooth and peeling (paper birch).

As is true of vascular cambium, cork cambium divides to form new tissues in two directions—to its inside and its outside. Cork cells, formed to the outside of cork cambium, are dead at maturity and have walls that contain layers of *suberin* and waxes, making them waterproof. These cork cells protect the woody stem against mechanical injury, mild fires, attacks by insects and fungi, temperature extremes, and water loss. To its inside, cork cambium sometimes forms cork parenchyma cells that store water and starch granules. Cork parenchyma is only one to several cells thick, much thinner than the cork cell layer.

Cork cells are impermeable to water and gases, yet the living internal cells of the woody stem require oxygen and must be able to exchange gases with the surrounding atmosphere. As a stem thickens from secondary growth, the epidermis, including stomata that exchange gases for the herbaceous stem, dies. Stomata are replaced by lenticels, which permit gas exchange through the periderm (Fig. 34-7).

Common terms associated with wood are based on plant structure

If you have ever examined different types of lumber, you may have noticed that some trees have wood with two different colors (Fig. 34-8). The functional secondary xylem, that is, the part that conducts water and dissolved minerals, is the *sapwood,* a thin layer of younger, lighter-colored wood that is closest to the bark. *Heartwood,* the older wood in the center of the tree, is typically a brownish red. A microscopic examination of heartwood reveals that its vessels and tracheids are plugged with pigments, tannins, gums, resins, and other materials. Therefore, heartwood no longer functions in conduction but instead functions as a storage site for waste products. Because it is denser than sapwood, heartwood provides structural support for trees. Some evidence suggests that heartwood is also more resistant to decay.

Almost everyone has heard of hardwood and softwood. Botanically speaking, *hardwood* is the wood of flowering plants and *softwood* is the wood of conifers (cone-bearing gymnosperms). The wood of pine and other conifers typically lacks fibers (with their thick secondary cell walls) and vessel elements; the conducting cells in gymnosperms are tracheids. These cell differences generally make conifer wood softer than the wood of flowering plants, although there is a substantial variation from one species to another. The balsa tree, for example, is a flowering plant whose extremely light, soft wood is used to fashion airplane models.

Woody plants that grow in temperate climates where there is a growing period (during spring and summer) and a dormant period (during winter) exhibit *annual rings,* concentric circles found in cross sections of wood. To determine the age of a woody stem in the temperate zone, simply count the annual rings. In the tropics, environmental conditions, particularly seasonal or year-round precipitation patterns, determine the presence or absence of rings, so rings are not a reliable method of determining the ages of most tropical trees.

TREE-RING ANALYSIS

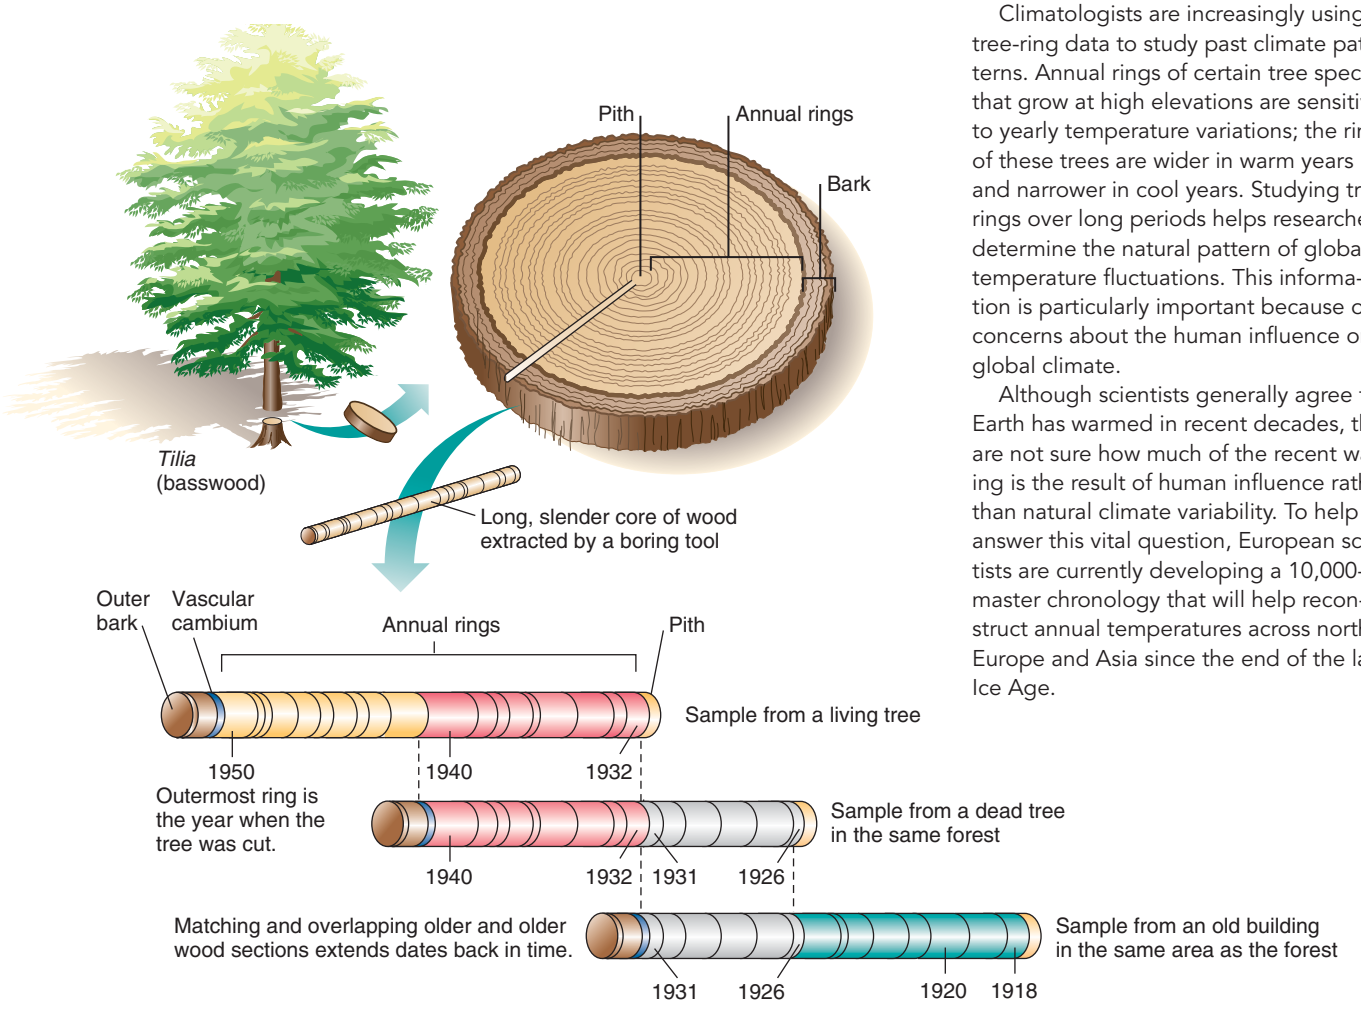
In temperate climates, the number of annual rings indicates the age of a tree. The size of each ring varies depending on local weather conditions. Sometimes the variation can be attributed to a single environmental factor, and similar patterns appear in the rings of different species over a large geographic area. For example, years with adequate precipitation produce wider growth rings, and years of drought produce narrower rings.

It is possible to study ring sequences that are several thousand years old by constructing a *master chronology,* a complete sample of rings dating back as far as possible (see figure). First, a small core of wood is bored out of the trunk of a living tree. The oldest rings (toward the center of the tree) are matched with the youngest rings (toward the outside) of an older tree, perhaps a dead one in the forest. The master chronology is extended back in time by overlapping matching ring sequences of successively older and older sections of wood, even those found in prehistoric dwellings. Currently, the longest master chronology—of bristlecone pines in the western United States—goes back almost 9000 years.

Dendrochronology, the study of both visible and microscopic details of tree rings, has been used extensively in several fields. Tree-ring analysis has helped date Native American prehistoric sites in the Southwest. For example, using tree-ring analysis, scientists have determined that the Cliff Palace in Mesa Verde National Park dates back to the year 1073. Tree-ring analysis is also useful in ecology (to study changes in a forest community over time), environmental science (to study the effects of air pollution on tree growth), and geology (to date earthquakes and volcanic eruptions).

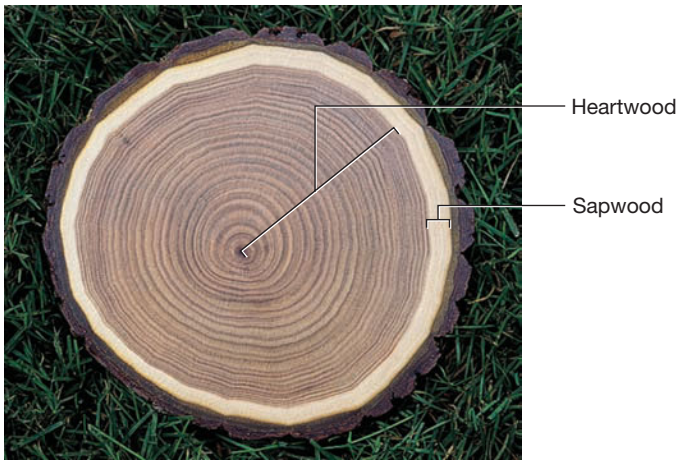
Climatologists are increasingly using tree-ring data to study past climate patterns. Annual rings of certain tree species that grow at high elevations are sensitive to yearly temperature variations; the rings of these trees are wider in warm years and narrower in cool years. Studying tree rings over long periods helps researchers determine the natural pattern of global temperature fluctuations. This information is particularly important because of concerns about the human influence on global climate.

Although scientists generally agree that Earth has warmed in recent decades, they are not sure how much of the recent warming is the result of human influence rather than natural climate variability. To help answer this vital question, European scientists are currently developing a 10,000-year master chronology that will help reconstruct annual temperatures across northern Europe and Asia since the end of the last Ice Age.



Animated Tree-ring dating

A master chronology is developed using progressively older pieces of wood from the same geographic area. By matching the rings of a wood sample of unknown age to the master chronology, investigators can accurately determine the age of the sample. Ring matching, once a tediously painstaking job, today is usually performed by computers.



Carlyn Iverson

Figure 34-8 ***Animated*** Heartwood and sapwood

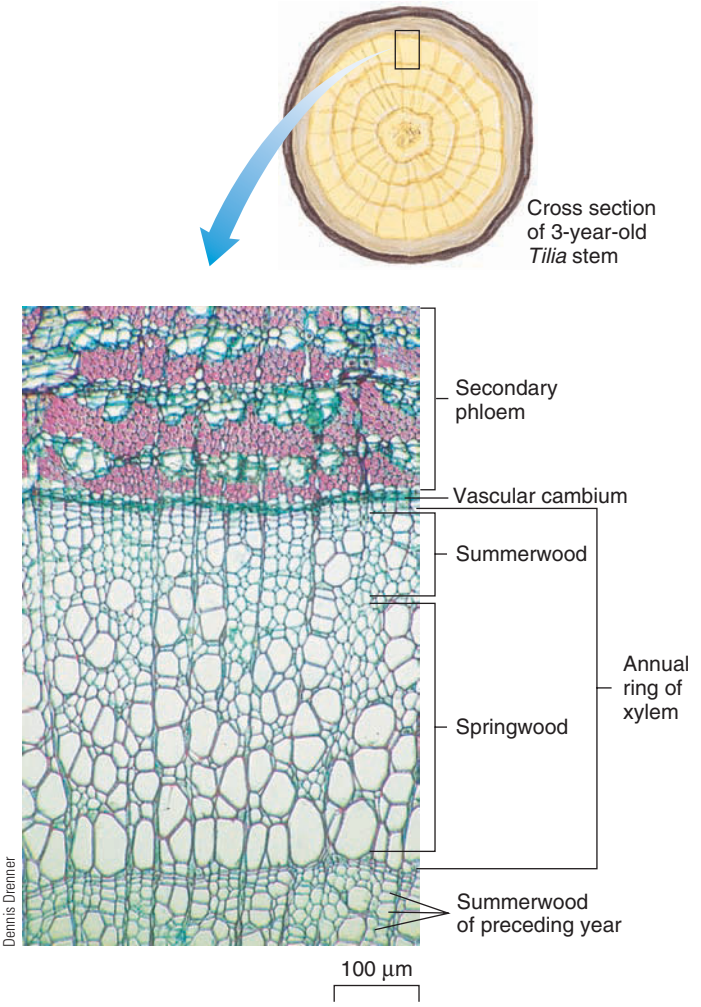
The wood of older trees consists of a dense, central heartwood and an outer layer of sapwood. The sapwood is the functioning xylem that conducts water and dissolved minerals. The annual rings in the heartwood are very conspicuous.

Examination of annual rings with a magnifying lens reveals no actual "ring," or line, separating one year's growth from the next. The appearance of a ring in cross section is due to differences in cell size and cell wall thickness between secondary xylem formed at the end of the preceding year's growth and that formed at the beginning of the following year's growth. In the spring, when water is plentiful, wood formed by vascular cambium has large-diameter conducting cells (tracheids and vessel elements) and few fibers and is appropriately called *springwood* or *early wood.* As summer progresses and water becomes less plentiful, the wood formed, known as *summerwood* or *late wood,* has narrower conducting cells and many fibers. It is this difference in cell size between the summerwood of one year and the springwood of the following year that gives the appearance of rings (Fig. 34-9). A great deal of information about climate in past times can be learned from the study of annual rings of ancient trees (see *Focus On: Tree-Ring Analysis*).

As a woody stem increases in girth over the years, the branches that it bears grow along with it as long as they are alive. If a branch dies, it no longer continues to grow with the stem. In time, as the stem increases in girth, it surrounds the base of the dead branch. The basal portion of an embedded dead branch is called a *knot.* It is possible for a knot to contain bark as well as wood. The presence of knots in wood reduces its commercial value, except for ornamental purposes.

Review

- How does the arrangement of vascular tissue differ in primary eudicot stems and monocot stems in cross section?
- What is the difference between vascular cambium and cork cambium? What tissues arise from vascular cambium? From cork cambium?
- What happens to the primary tissues of a stem when secondary growth occurs?
- How do growth rings form in woody stems?



Dennis Drenner

One annual ring, or growth increment, is shown. Note the differences in cell size between the vessel elements of springwood and summerwood. The pink cells in the secondary phloem are fibers.

TRANSPORT IN THE PLANT BODY

Learning Objectives

5 Describe the pathway of water movement in plants.
6 Define *water potential.*
7 Explain the roles of tension–cohesion and root pressure as mechanisms responsible for the rise of water and dissolved minerals in xylem.
8 Describe the pathway of sugar translocation in plants.
9 Discuss the pressure–flow hypothesis of sugar translocation in phloem.

Now that we have discussed stem structure and primary and secondary growth, we examine internal transport in the vascular system of the plant (Fig. 34-10). Roots obtain water and dissolved minerals from the soil. Once inside roots, these materi-

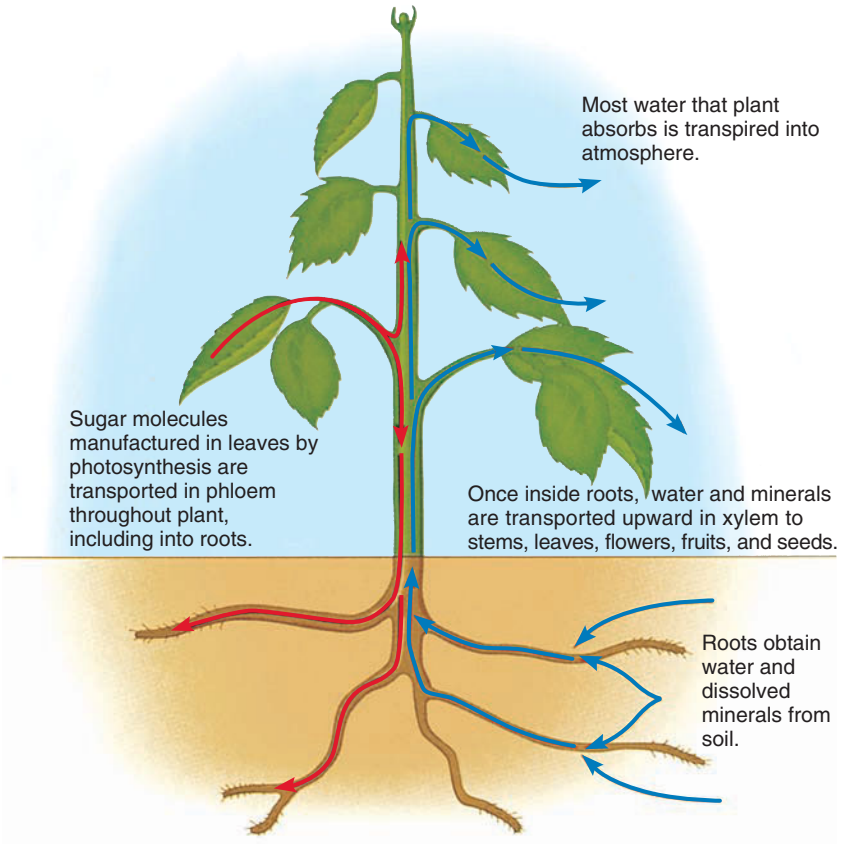

Figure 34-10 An overview of transport in vascular plants

Xylem transport is explained on the right side of the figure (start at the bottom and work upward), whereas phloem transport is on the left side.

als are transported upward to stems, leaves, flowers, fruits, and seeds. Furthermore, sugar molecules are transported from their place of manufacture or of breakdown of starch throughout the plant body, including into the subterranean roots. Water and dissolved minerals are transported from roots to other parts of the plant in xylem, whereas dissolved sugar is **translocated** in phloem.

Xylem transport and phloem translocation do not resemble the movement of materials in animals, because in plants nothing *circulates* in a system of vessels. Water and minerals, transported in xylem, travel in one direction only (upward), whereas translocation of dissolved sugar may occur upward or downward in separate phloem cells. In addition, xylem transport and phloem translocation differ from internal circulation in animals because movement in both xylem and phloem is driven largely by natural physical processes rather than by a pumping organ, or heart.

How do materials travel in the continuous system of the plant's vascular tissues? We first examine water and its movement through the plant, and later we discuss the translocation of dissolved sugar.

Water and minerals are transported in xylem

Water initially moves horizontally into roots from the soil, passing through several tissues until it reaches xylem. Once the water moves into the tracheids and vessel elements of root xylem, it travels upward through a continuous network of these hollow, dead cells from root to stem to leaf. Dissolved minerals are carried along passively in the water. The plant does not expend any energy of its own to transport water, which moves as a result of natural physical processes. The transport of xylem sap is the most rapid of any movement of materials in plants (▮ Table 34-1).

How does water move to the tops of plants? It is either pushed up from the bottom of the plant or pulled up at the top of the plant. Although plants use both mechanisms, current evidence indicates that most water is transported through xylem by being *pulled* to the top of the plant.

Water movement can be explained by a difference in water potential

To understand how water moves, it is helpful to introduce **water potential,** which is defined as the **free energy** of water (see Chapter 7). Water potential is important in plant physiology because it is a measure of a cell's ability to absorb water by **osmosis** (see Chapter 5). Water potential also provides a measure of water's tendency to evaporate from cells.

The water potential of pure water is conventionally set at 0 megapascals (MPa), because it cannot be measured directly. (A megapascal is a unit of pressure equal to about 10 atmospheres, or 145.1 lb/in^2.) However, botanists can measure differences in the free energy of water molecules in different situations. When solutes dissolve in water, the free energy of water decreases. Sol-

TABLE 34-1

Xylem and Phloem Transport Rates in Selected Plants

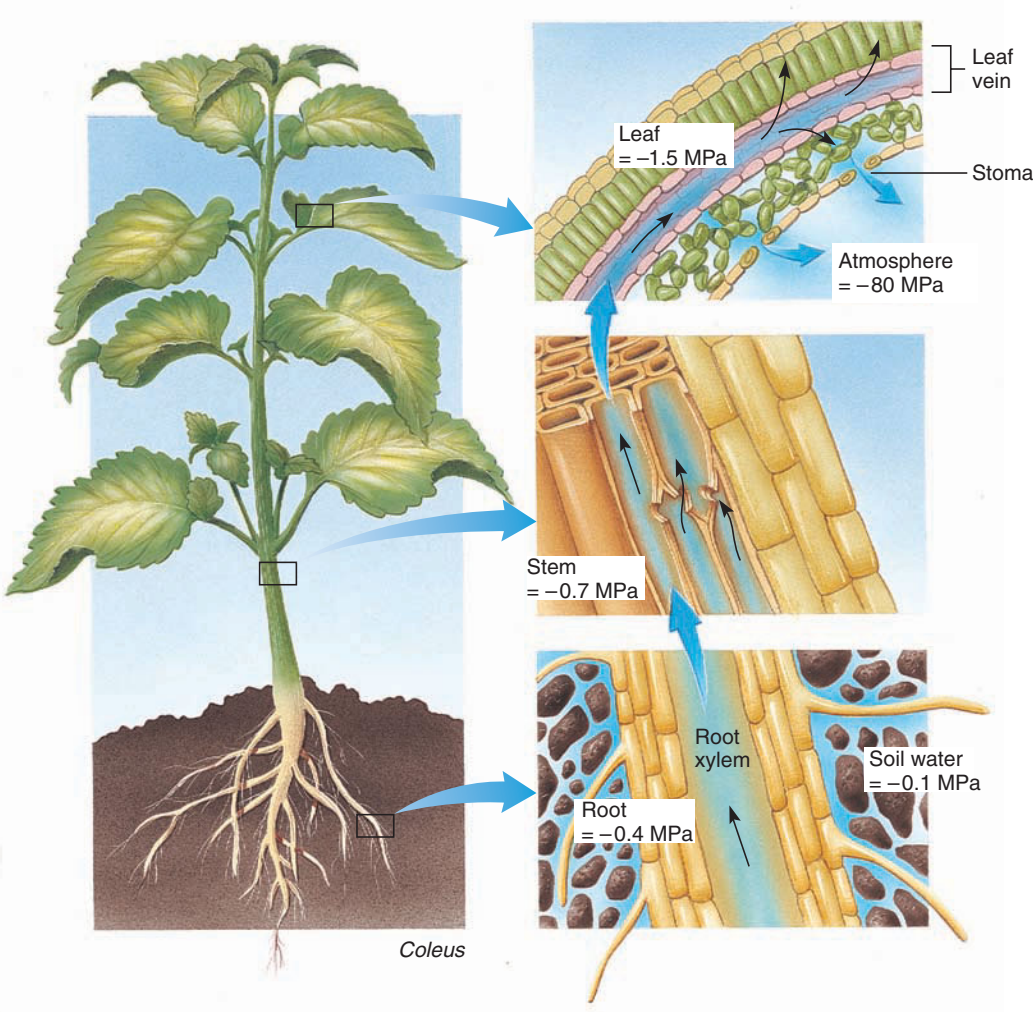
Plant	Maximum Rate in Xylem (cm/min)	Maximum Rate in Phloem (cm/min)
Conifer	2	0.8
Woody eudicot	73	2
Herbaceous eudicot or monocot	100	2.8–11
Herbaceous vine	250	1.2

Source: Adapted from J. D. Mauseth, *Botany: An Introduction to Plant Biology,* 2nd ed., Philadelphia, Saunders College Publishing, 1995.

Note: Xylem and phloem rates are from different plants within each general group and should be used for comparative purposes only.

Key Point

Transpiration is the driving force of the tension–cohesion model.



1. This model hypothesizes that water vapor transpires from surfaces of leaf mesophyll cells to drier atmosphere through stomata. This produces tension that pulls water out of leaf xylem toward mesophyll cells (MPa = megapascal).

2. Cohesion of water molecules, caused by hydrogen bonding, allows unbroken columns of water to be pulled up narrow vessels and tracheids of stem xylem.

3. This in turn pulls water up root xylem, forming continuous column of water from root xylem to stem xylem to leaf xylem. Movement of water upward in root produces pull that causes soil water to diffuse into root.

Figure 34-11 ***Animated*** The tension–cohesion model

utes induce **hydration,** in which water molecules surround ions and polar molecules, keeping them in solution by preventing them from coming together (see Fig. 2-10). The association of water molecules with hydrated molecules and ions reduces the motion of water molecules, decreasing their free energy. Thus, *dissolved solutes lower the water potential to a negative number. Water moves from a region of higher (less negative) water potential to a region of lower (more negative) water potential.*

The water potential of the soil varies, depending on how much water it contains. When a soil is extremely dry, its water potential is very low (very negative). When a soil is moister, its water potential is higher, although it still has a negative value because dissolved minerals are present in dilute concentrations.

The water potential in root cells is also negative because of the presence of dissolved solutes. Roots contain more dissolved materials than soil water does, unless the soil is extremely dry. This means that under normal conditions the water potential of the root is more negative than the water potential of the soil. Thus, water moves by osmosis from the soil into the root.

According to the tension–cohesion model, water is pulled up a stem

In 1896, Irish botanist Henry Dixon proposed the tension–cohesion model to explain the ascent of water against the force of gravity. Although initially met with widespread skepticism in the scientific community, this model has withstood the test of time. According to the **tension–cohesion model,** also known as the **transpiration–cohesion model,** water is pulled up the plant as a result of a *tension* produced at the top of the plant (Fig. 34-11). This tension, which resembles that produced when drinking a liquid through a straw, is caused by the evaporative pull of transpiration. Recall from Chapter 33 that **transpiration** is the evaporation of water vapor from plants.

Most water loss from transpiration takes place through stomata, the numerous microscopic pores present on leaf and stem surfaces. The tension extends from leaves, where most transpiration occurs, down the stems and into the roots. It draws water up stem xylem to leaf cells that have lost water as a result of transpiration and pulls water from root xylem into stem xylem. As water is pulled upward, additional water from the soil is drawn into the roots. Thus, the pathway of water movement is as follows:

Soil ⟶ root tissues (epidermis, cortex, and so forth) ⟶ root xylem ⟶ stem xylem ⟶ leaf xylem ⟶ leaf mesophyll ⟶ atmosphere

This upward pulling of water is possible only as long as there is an unbroken column of water in xylem throughout the plant. Water forms an unbroken column in xylem because of the *cohesiveness* of water molecules. Recall from Chapter 2 that water molecules are **cohesive,** that is, strongly attracted to one another, because of **hydrogen bonding.** In addition, the **adhesion** of water to the walls of xylem cells, also the result of hydrogen bonding, is an important factor in maintaining an unbroken column of water. Thus, the cohesive and adhesive properties of water enable it to form a continuous column that can be pulled up through the xylem.

The movement of water in xylem by the tension–cohesion mechanism can be explained in terms of water potential. The atmosphere has an extremely negative water potential. For example, air with a relative humidity of 50% has a water potential of −100 MPa; even moist air at a relative humidity of 90% has a negative water potential of −13 MPa. Thus, *there is a water potential gradient from the least negative (the soil) up through the plant to the most negative (the atmosphere).* This gradient literally pulls the water from the soil up through the plant.

Although the tension–cohesion model was first proposed toward the end of the 19th century, conclusive experimental evidence to support this mechanism was not obtained until the late 1990s and early 2000s. At that time, several research groups made direct measurements of the large negative pressure that exists in xylem, indicating that the water potential gradients in root, stem, and leaf xylem are adequate to explain the observed movement of water.

Is the tension–cohesion model powerful enough to explain the rise of water in the tallest plants? Plant biologists have studied this question for years. For example, a 2004 study of five of the eight tallest trees in the world (all redwoods, or *Sequoia sempervirens*) concluded that the tension produced by transpiration is strong enough to pull water upward to a maximum height of 130 m (422 ft). Because the height of the tallest known living tree, located in the Humboldt Redwoods State Park in California, is about 113 m (367 ft), the tension–cohesion model easily accounts for the transport of water. Currently, most botanists consider the tension–cohesion model to be the dominant mechanism of xylem transport in most plants.

Root pressure pushes water from the root up a stem

In the less important mechanism for water transport, known as **root pressure,** water that moves into roots from the soil is *pushed* up through xylem toward the top of the plant. Root pressure occurs because mineral ions that are actively absorbed from the soil are pumped into the xylem, decreasing its water potential. This accumulation of ions has an osmotic effect, causing water to move into xylem cells from surrounding root cells. In turn, water moves into roots by osmosis because of the difference in water potential between the soil and root cells. The accumulation of water in root tissues produces a positive pressure (as high as +0.2 MPa) that forces the water up through the root xylem into the shoot.

Guttation, a phenomenon in which liquid water is forced out through special openings in the leaves (see Chapter 33), results from root pressure. However, root pressure is not strong enough to explain the rise of water to the tops of coastal redwoods and other tall trees. Root pressure exerts an influence in smaller plants, particularly in the spring when the soil is quite wet, but it clearly does not cause water to rise 100 m (330 ft) or more in the tallest plants. Furthermore, root pressure does not occur to any appreciable extent in summer (when water is often not plentiful in soil), yet water transport is greatest during hot summer days.

Sugar in solution is translocated in phloem

The sugar produced during photosynthesis is converted into sucrose (common table sugar), a disaccharide composed of one molecule of glucose and one of fructose (see Fig. 3-8b), before being loaded into phloem and translocated to the rest of the plant. Sucrose is the predominant photosynthetic product carried in phloem. Phloem sap also contains much smaller amounts of other materials, such as amino acids, organic acids, proteins, hormones, certain minerals, and sometimes disease-causing plant viruses. Translocation of phloem sap is not as rapid as xylem transport (see Table 34-1).

Fluid within phloem tissue moves both upward and downward. Sucrose is translocated in individual sieve tubes from a *source,* an area of excess sugar supply (usually a leaf), to a *sink,* an area of storage (as insoluble starch) or of sugar use, such as roots, apical meristems, fruits, and seeds.

The pressure–flow hypothesis explains translocation in phloem

Current experimental evidence supports the translocation of dissolved sugar in phloem by the **pressure–flow hypothesis,** which was first proposed in 1926 by the German scientist Ernst Münch. The pressure–flow hypothesis states that solutes (such as dissolved sugars) move in phloem by means of a pressure gradient—that is, a difference in pressure. The pressure gradient exists between the source, where the sugar is loaded into phloem, and the sink, where the sugar is removed from phloem.

At the source, the dissolved sucrose is moved from a leaf's mesophyll cells, where it was manufactured, into the companion cells, which load it into the sieve tube elements of phloem. This loading occurs by active transport, a process that requires adenosine triphosphate (ATP) (Fig. 34-12). The ATP supplies energy to pump protons out of the sieve tube elements, producing a proton gradient that drives the uptake of sugar through specific channels by the **cotransport** of protons back into the sieve tube

Key Point

In phloem, solutes move from sources to sinks.

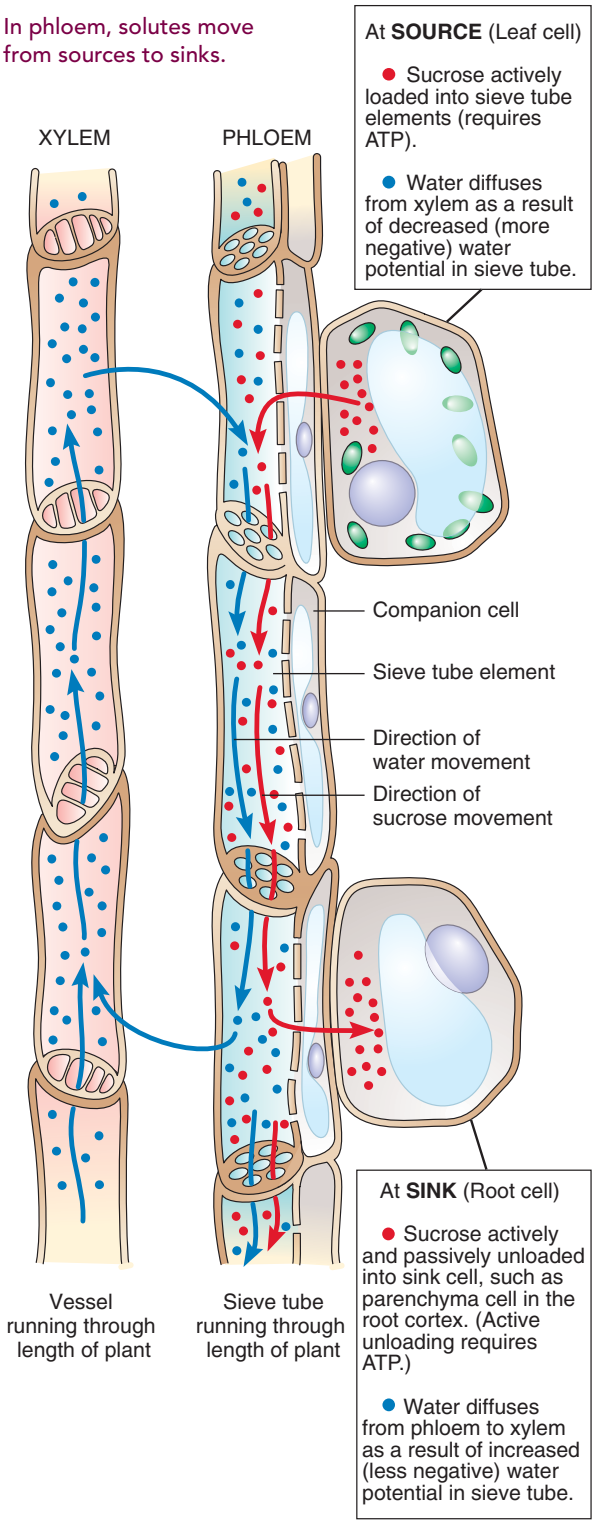


Figure 34-12 ***Animated*** The pressure–flow hypothesis

Sugar is actively loaded into the sieve tube element at the source. As a result, water diffuses from the xylem into the sieve tube element. At the sink, the sugar is actively or passively unloaded, and water diffuses from the sieve tube element into the xylem. The pressure gradient within the sieve tube, from source to sink, causes translocation from the area of higher turgor pressure (the source) to the area of lower turgor pressure (the sink).

elements (an example of a linked cotransport system, discussed in Chapter 5). The sugar therefore accumulates in the sieve tube element. The increase in dissolved sugars in the sieve tube element at the source—a concentration that is 2 to 3 times as great as in surrounding cells—decreases (makes more negative) the water potential of that cell. As a result, water moves by osmosis from the xylem cells into the sieve tubes, increasing the **turgor pressure** (hydrostatic pressure) inside them. Thus, phloem loading at the source occurs as follows:

> Proton pump moves H^+ out of sieve tube element ⟶ sugar is actively transported into sieve tube element ⟶ water diffuses from xylem into sieve tube element ⟶ turgor pressure increases within sieve tube

At its destination (the sink), sugar is unloaded by various mechanisms, both active and passive, from the sieve tube elements. With the loss of sugar, the water potential in the sieve tube elements at the sink increases (becomes less negative). Therefore, water moves out of the sieve tubes by osmosis and into surrounding cells where the water potential is more negative. Most of this water diffuses back to the xylem to be transported upward. This water movement decreases the turgor pressure inside the sieve tubes at the sink. Thus, phloem unloading at the sink proceeds as follows:

> Sugar is transported out of sieve tube element ⟶ water diffuses out of sieve tube element and into xylem ⟶ turgor pressure decreases within sieve tube

The pressure–flow hypothesis explains the movement of dissolved sugar in phloem by means of a pressure gradient. The difference in sugar concentrations between the source and the sink causes translocation in phloem as water and dissolved sugar flow along the pressure gradient. This pressure gradient pushes the sugar solution through phloem much as water is forced through a hose.

The actual translocation of dissolved sugar in phloem does not require metabolic energy. However, the loading of sugar at the source and the active unloading of sugar at the sink require energy derived from ATP to move the sugar across cell membranes by active transport.

Although the pressure–flow hypothesis adequately explains current data on phloem translocation, much remains to be learned about this complex process. Phloem translocation is difficult to study in plants. Because phloem cells are under pressure, cutting into phloem to observe it releases the pressure and causes the contents of the sieve tube elements (the phloem sap) to exude and mix with the contents of other severed cells that are also unavoidably cut. In the 1950s, scientists developed a unique research tool to avoid contaminating the phloem sap: aphids, which are small insects that insert their mouthparts into phloem sieve tubes for feeding (▮ Fig. 34-13). The pressure in the punctured phloem drives the sugar solution through the aphid's mouthpart into its digestive system. When the aphid's mouthpart is severed from its body by a laser beam, the sugar solution continues to flow through the mouthpart at a rate proportional to the pressure in phloem. This rate can be measured, and the effects on phloem

Key Experiment

QUESTION: How can phloem sap be studied without cutting nonphloem cells that would contaminate the sap?

HYPOTHESIS: An aphid mouthpart can be used to penetrate a single sieve tube.

EXPERIMENT: After allowing aphids to insert their mouthparts into phloem of a stem, researchers anesthetized the feeding aphids with CO_2 and used a laser to cut their bodies away from their mouthparts. The mouthparts remained in the phloem and functioned like miniature pipes.

M. H. Zimmermann, SCIENCE, Vol. 133, pp. 73–79 (Fig. 4), 13 Jan. 1961. © 1961 by the American Association for the Advancement of Science

(a) Aphid feeding on a stem.

(b) LM of phloem cells, showing an aphid mouthpart penetrating a sieve tube element.

RESULTS AND CONCLUSION: About 1 mm^3 of phloem sap exuded from each severed mouthpart per hour for several days, so researchers were able to collect and analyze the composition of the sap.

Figure 34-13 Collecting and analyzing phloem sap

This method, first used in the 1950s by insect physiologists studying aphids, was quickly adopted by plant physiologists studying phloem translocation.

transport of different environmental conditions—varying light intensities, darkness, and mineral deficiencies, for example—can be ascertained.

The identity and proportions of translocated substances can also be determined using severed aphid mouthparts. This technique has verified that in most plant species the sugar sucrose is the primary carbohydrate transported in phloem; however, some species transport other sugars, such as raffinose, or sugar alcohols, such as sorbitol.

Review

- How does the direction of transport differ in xylem and phloem?
- What is water potential? How is the movement of water related to water potential?
- How does the tension–cohesion model explain the rise of water in the tallest trees?
- How does the pressure–flow hypothesis explain sugar movement in phloem? Include in your answer the activities at source and sink.

SUMMARY WITH KEY TERMS

Learning Objectives

1 Describe the external features of a woody twig (page 732).

- Woody twigs demonstrate the external structure of stems. **Buds** are undeveloped embryonic shoots. A **terminal bud** is located at the tip of a stem, whereas **axillary buds (lateral buds)** are located in leaf axils. A dormant bud is covered and protected by **bud scales.** When the bud re-

sumes growth, bud scales covering the bud fall off, leaving **bud scale scars.**

- The area on a stem where each leaf is attached is called a **node,** and the region of a stem between two successive nodes is an **internode.** A **leaf scar** shows where each leaf was attached to the stem. **Bundle scars** are the areas within a leaf scar where the vascular tissue extended from the stem to the leaf. **Lenticels** are sites of loosely arranged cells that allow oxygen to diffuse into the interior of a woody stem.

2 Label cross sections of herbaceous eudicot and monocot stems, and describe the functions of each tissue (page 732).

- Herbaceous stems possess an epidermis, vascular tissue, and either ground tissue or cortex and pith. The **epidermis** is a protective layer covered by a water-conserving **cuticle. Stomata** permit gas exchange. **Xylem** conducts water and dissolved minerals, and **phloem** conducts dissolved sugar. The **cortex, pith,** and ground tissue function primarily for storage.
- All herbaceous stems have the same basic tissues, but their arrangement varies. Herbaceous eudicot stems have the vascular bundles arranged in a circle (in cross section) and have a distinct cortex and pith. Monocot stems have vascular bundles scattered in ground tissue.

ThomsonNOW™ Learn more about eudicot and monocot stems by clicking on the figures in ThomsonNOW.

3 Name the two lateral meristems, and describe the tissues that arise from each (page 732).

- **Vascular cambium** is the lateral meristem that produces secondary xylem (wood) and secondary phloem (inner bark).
- **Cork cambium** produces **periderm,** which consists of cork parenchyma and cork cells. Cork cells are the functional replacement for epidermis in a woody stem. Cork parenchyma functions primarily for storage in a woody stem.

4 Outline the transition from primary growth to secondary growth in a woody stem (page 732).

- **Secondary growth** (the production of the secondary tissues, wood and bark) occurs in some flowering plants (woody eudicots) and in all cone-bearing gymnosperms. During secondary growth, the vascular cambium divides in two directions to form secondary xylem (to the inside) and secondary phloem (to the outside). The primary xylem and primary phloem in the original vascular bundles become separated as secondary growth proceeds.

ThomsonNOW™ Learn more about secondary growth by clicking on the figures in ThomsonNOW.

5 Describe the pathway of water movement in plants (page 739).

- Water and dissolved minerals move from the soil into root tissues (epidermis, cortex, and so forth). Once in root xylem, water and minerals move upward, from root xylem to stem xylem to leaf xylem. Much of the water entering the leaf exits leaf veins and passes into the atmosphere.

6 Define *water potential* (page 739).

- **Water potential** is a measure of the **free energy** of water. Pure water has a water potential of 0 megapascals, whereas water with dissolved solutes has a negative water potential. Water moves from an area of higher (less negative) water potential to an area of lower (more negative) water potential.

7 Explain the roles of tension–cohesion and root pressure as mechanisms responsible for the rise of water and dissolved minerals in xylem (page 739).

- The **tension–cohesion model** explains the rise of water in even the tallest plants. The evaporative pull of **transpiration** causes tension at the top of the plant. This tension is the result of a water potential gradient that ranges from the slightly negative water potentials in the soil and roots to the very negative water potentials in the atmosphere. As a result of the **cohesive** and **adhesive** properties of water, the column of water pulled up through the plant remains unbroken.

ThomsonNOW™ Learn more about the tension–cohesion model by clicking on the figure in ThomsonNOW.

- **Root pressure,** caused by the movement of water into roots from the soil as a result of the active absorption of mineral ions from the soil, helps explain the rise of water in smaller plants, particularly when the soil is wet. Root pressure pushes water up through xylem.

8 Describe the pathway of sugar translocation in plants (page 739).

- Dissolved sugar is **translocated** upward or downward in phloem, from a source (an area of excess sugar, usually a leaf) to a sink (an area of storage or of sugar use, such as roots, apical meristems, fruits, and seeds). Sucrose is the predominant sugar translocated in phloem.

9 Discuss the pressure–flow hypothesis of sugar translocation in phloem (page 739).

- Movement of materials in phloem is explained by the **pressure–flow hypothesis.** Companion cells actively load sugar into the sieve tubes at the source; ATP is required for this process. The ATP supplies energy to pump protons out of the sieve tube elements. The proton gradient drives the uptake of sugar by the cotransport of protons back into the sieve tube elements. Sugar therefore accumulates in the sieve tube element, causing the movement of water into the sieve tubes by **osmosis.**

ThomsonNOW™ Learn more about how sugar travels by clicking on the figure in ThomsonNOW.

- Companion cells actively (requiring ATP) and passively (not requiring ATP) unload sugar from the sieve tubes at the sink. As a result, water leaves the sieve tubes by osmosis, decreasing the **turgor pressure** (hydrostatic pressure) inside the sieve tubes.
- The flow of materials between source and sink is driven by the turgor pressure gradient produced by water entering phloem at the source and water leaving phloem at the sink.

TEST YOUR UNDERSTANDING

1. The three main functions of stems are (a) support, conduction, and photosynthesis (b) support, anchorage in soil, and production of new living tissues (c) conduction, production of new living tissues, and sexual reproduction (d) conduction, asexual reproduction, and sexual reproduction (e) support, conduction, and production of new living tissues

2. Stems have undeveloped embryonic shoots called (a) lenticels (b) buds (c) vines (d) phloem fiber caps (e) periderm

3. Axillary buds are located (a) at the tips of stems (b) in unusual places, such as on roots (c) in the region between two successive nodes (d) in the upper angle between a leaf and the stem to which it is attached (e) within the loosely arranged cells of lenticels

4. The protective outer layer of cells covering herbaceous stems is the (a) periderm (b) cork cambium (c) lateral meristem (d) epidermis (e) bud scale

5. Ground tissue in monocot stems performs the same functions as _____ and _____ in herbaceous eudicot stems. (a) phloem; xylem (b) cork cambium; vascular cambium (c) epidermis; periderm (d) primary xylem; secondary xylem (e) cortex; pith

6. Which of the following statements is *false?* (a) primary growth is an increase in the length of a plant (b) primary growth occurs at both apical and lateral meristems (c) all plants have primary growth (d) herbaceous stems have primary growth, whereas woody stems have both primary and secondary growth (e) buds are embryonic shoots that contain apical meristems

7. The two lateral meristems responsible for secondary growth are (a) phloem and xylem (b) cork cambium and vascular cambium (c) epidermis and periderm (d) primary xylem and secondary xylem (e) cortex and pith

8. Cork cambium and the tissues it produces are collectively called (a) periderm (b) lenticels (c) cortex (d) epidermis (e) wood

9. Horizontal movement of materials in woody plants occurs in (a) bud scales (b) cortex (c) rays (d) lenticels (e) pith rays

10. The older, darker wood in the center of a tree trunk is commonly called (a) hardwood (b) softwood (c) sapwood (d) heartwood (e) cork

11. Each annual ring in a section of wood represents 1 year's growth of (a) primary xylem (b) secondary xylem (c) primary xylem or secondary xylem in alternate years (d) primary phloem (e) secondary phloem

12. Water potential is (a) the formation of a proton gradient across a cell membrane (b) the transport of a watery solution of sugar in phloem (c) the transport of water in both xylem and phloem (d) the removal of sucrose at the sink, causing water to move out of the sieve tubes (e) the free energy of water in a particular situation

13. Which of the following is a mechanism of water movement in xylem that is responsible for guttation: (a) pressure–flow hypothesis (b) tension–cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) transpiration

14. Which of the following is a mechanism of water movement in xylem that combines the evaporative pull of transpiration with the cohesive and adhesive properties of water? (a) pressure–flow (b) tension–cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) guttation

15. Which of the following is a mechanism of phloem transport in which dissolved sugar is moved by means of a pressure gradient that exists between the source and the sink? (a) pressure–flow (b) tension–cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) guttation

16. How does increasing solute concentration affect water potential? (a) water potential becomes more positive (b) water potential becomes more negative (c) water potential becomes more positive under certain conditions and more negative under other conditions (d) water potential is not affected by solute concentration (e) water potential is always zero when solutes are dissolved in water

17. Label the various tissues, give at least one function for each tissue, and identify the stem as a herbaceous eudicot, monocot, or woody plant. Use Figure 34-2 to check your answers.

CRITICAL THINKING

1. When secondary growth is initiated, certain cells become meristematic and begin to divide. Could a mature tracheid ever do this? A sieve tube element? Why or why not?
2. Why does the wood of many tropical trees lack annual rings? Why does the wood of other tropical trees possess annual rings?
3. Why is hardwood more desirable than softwood for making furniture? Explain your answer, based on the structural differences between hardwood and softwood.
4. Why should you cut off a few inches from the stem ends of cut flowers before placing them in water? Base your answer on what you have learned about the tension–cohesion model.
5. When a strip of bark is peeled off a tree branch, what tissues are usually removed?
6. Could a tree grow to a height of 150 m (488 ft)? Why or why not?
7. **Evolution Link.** Like stems in general, some vines are herbaceous and others are woody. Tropical rain forests have a greater diversity of vines than in any other environment on Earth, and most of these vines are woody. Develop a hypothesis to explain why natural selection has favored the evolution of more species of woody vines (as opposed to herbaceous vines) in tropical rain forests.

Roots and Mineral Nutrition

R. Calentine/Visuals Unlimited

Storage roots. Carrots (*Daucus carota*) are biennials (plants that live for 2 years). During the first year's growth, food is stored in the fleshy root system; during the second year, the shoot elongates and produces flowers. Carrots and other root crops are important sources of human food.

KEY CONCEPTS

Roots anchor the plant in the soil, absorb water and minerals, conduct these materials to the rest of the plant body, and store carbon compounds and water.

Primary tissues (epidermis, cortex, endodermis, pericycle, xylem, and phloem) of roots develop from root apical meristems. Secondary tissues (wood and bark) of woody roots develop from lateral meristems.

The endodermis absorbs mineral ions from the soil solution by an active, energy-requiring process.

Many roots form associations with soil bacteria and fungi.

Soil, the layer of Earth's crust that has been modified by contact with weather, wind, water, and organisms, contains most of the essential elements required by plants.

Branching underground root systems are often more extensive than a plant's aerial parts. The roots of a corn plant, for example, may grow to a depth of 2.5 m (about 8 ft) and spread outward 1.2 m (4 ft) from the stem. Desert-dwelling tamarisk (*Tamarix*) trees reportedly have roots that grow to a depth of 50 m (163 ft) to tap underground water. The extent of a plant's root depth and spread varies considerably among different species and even among different individuals in the same species.

Because roots are usually underground and out of sight, people do not always appreciate the important functions they perform. First, as anyone who has ever pulled weeds can attest, roots anchor a plant securely in the soil. A plant needs a solid foundation from which to grow. Firm anchorage is essential to a plant's survival so that the stem remains upright, enabling leaves to absorb sunlight effectively. Second, roots absorb water and dissolved minerals (inorganic nutrients) such as nitrates, phosphates, and sulfates, which are necessary for synthesizing important organic molecules. These dissolved minerals are then transported throughout the plant in the xylem.

Many roots perform the function of storage. Carrots (see photograph), sweet potatoes, cassava, and other root crops are important sources of human food. Surplus sugars produced in the leaves by photosynthesis are transported in the phloem to the roots for food storage (usually as starch or sucrose) until needed. Other plants, particularly those living in arid regions, possess storage roots adapted to store water.

In certain species, roots are modified for functions other than anchorage, absorption, conduction, and storage. Roots specialized to perform uncommon functions are discussed later in the chapter. ■

ROOT STRUCTURE AND FUNCTION

Learning Objectives

1. Distinguish between taproot and fibrous root systems.
2. Label cross sections of a primary eudicot root and a monocot root, and describe the functions of each tissue.
3. Trace the pathway of water and mineral ions from the soil through the various root tissues, and distinguish between the symplast and apoplast.
4. Discuss the structure of roots with secondary growth.
5. Describe at least three roots that are modified to perform uncommon functions.

Two types of root systems, a taproot system and a fibrous root system, occur in plants (Fig. 35-1). A **taproot** system consists of one main root that formed from the seedling's enlarging **radicle,** or embryonic root. Many lateral roots of various sizes branch out of a taproot. Taproots are characteristic of many eudicots and gymnosperms. A dandelion is a good example of a common herbaceous plant with a taproot system. A few trees, such as hickory, retain their taproots, which become quite massive as the plants age. Most trees, however, have taproots when young and later develop large, shallow, lateral roots from which other roots branch off and grow downward.

A **fibrous root** system has several to many roots of similar size developing from the end of the stem, with lateral roots branching off these roots. Fibrous root systems form in plants that have a short-lived embryonic root. The roots originate first from the base of the embryonic root and later from stem tissue. The main roots of a fibrous root system do not arise from pre-existing roots but from the stem; such roots are called **adventitious roots.** Adventitious organs occur in an unusual location, such as roots that develop on a stem, or buds that develop on roots. Onions, crabgrass, and other monocots have fibrous root systems.

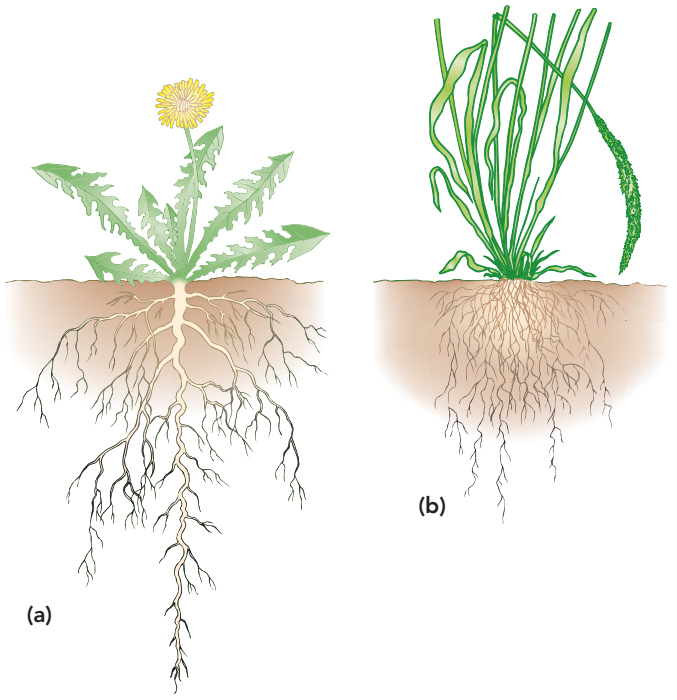

Figure 35-1 ***Animated*** Root systems

(a) A taproot system develops from the embryonic root in the seed. **(b)** The roots of a fibrous root system are adventitious and develop from stem tissue.

Taproot and fibrous root systems are adapted to obtain water in different sections of the soil. Taproot systems often extend down into the soil to obtain water located deep underground, whereas fibrous root systems, which are located relatively close to the soil surface, are adapted to obtain rainwater from a larger area as it drains into the soil.

Roots have root caps and root hairs

Because of the need to adapt to the soil environment instead of the atmospheric environment, roots have several structures, such as root caps and root hairs, that shoots lack. Although stems and leaves have various types of hairs, they are distinct from root hairs in structure and function.

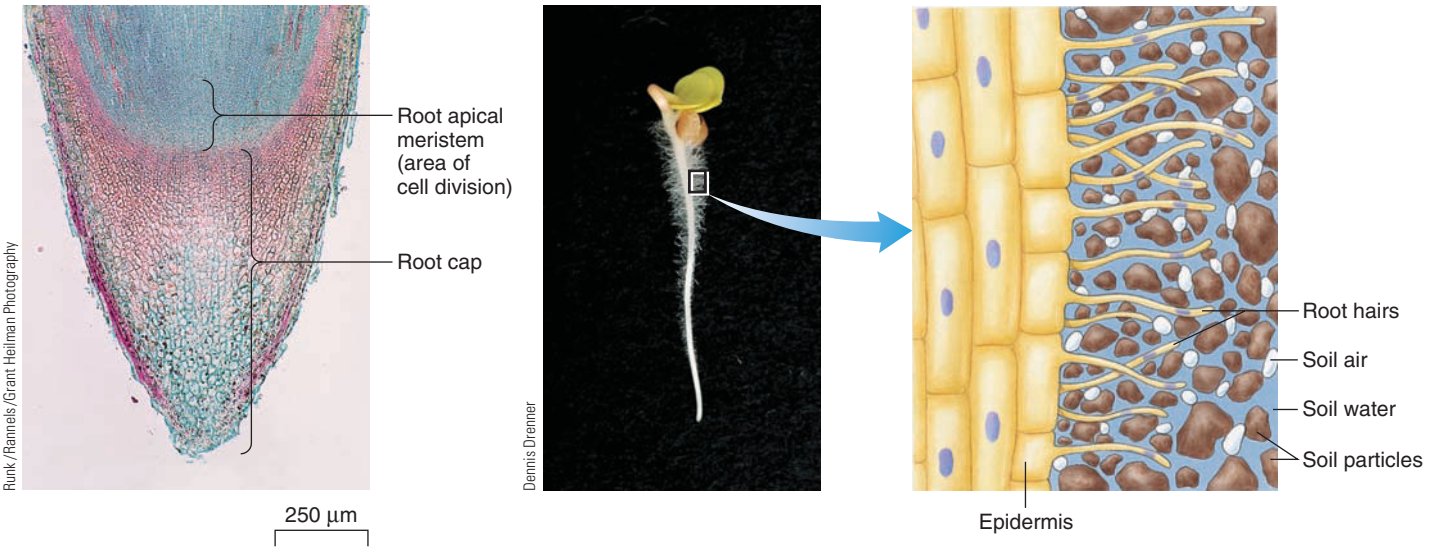
Each root tip is covered by a **root cap,** a protective, thimble-like layer many cells thick that covers the delicate root **apical meristem** (Fig. 35-2a; also see Fig. 32-7). As the root grows, pushing its way through the soil, cells of the root cap are sloughed off by the frictional resistance of the soil particles and replaced by new cells formed by the root apical meristem. The root cap cells secrete lubricating polysaccharides that reduce friction as the root passes through the soil. The root cap also appears to be involved in orienting the root so that it grows downward (see discussion of gravitropism in Chapter 37). When a root cap is removed, the root apical meristem grows a new cap. However, until the root cap has regenerated, the root grows randomly rather than in the direction of gravity.

Root hairs are short-lived tubular extensions of epidermal cells located just behind the growing root tip. Root hairs continually form in the area of cell maturation closest to the root tip to replace those that are dying off at the more mature end of the root-hair zone (Fig. 35-2b; also see Fig. 32-7). Each root hair is short (typically less than 1 cm, or 0.4 in, in length), but they are quite numerous. Root hairs greatly increase the absorptive capacity of roots by increasing their surface area in contact with moist soil. Soil particles are coated with a microscopically thin layer of water in which minerals are dissolved. The root hairs establish an intimate contact with soil particles, which allows efficient absorption of water and minerals.

Unlike stems, roots lack nodes and internodes and do not usually produce leaves or buds. Although herbaceous roots have certain primary tissues (such as epidermis, xylem, phloem, cortex, and pith) found in herbaceous stems, these tissues are arranged quite differently.

The arrangement of vascular tissues distinguishes the roots of herbaceous eudicots and monocots

Although considerable variation exists in herbaceous eudicot and monocot roots, they all have an outer protective covering (epidermis), a cortex for storage of starch and other organic mol-



(a) Root cap. LM of an oak (*Quercus* sp.) root tip showing its root cap. The root apical meristem is protected by the root cap.

(b) Root hairs. Each delicate hair is an extension of a single cell of the root epidermis. Root hairs increase the surface area of the root in contact with the soil. This radish (*Raphanus sativus*) seedling is approximately 5 cm (2 in) long.

Figure 35-2 ***Animated*** Structures unique to roots

ecules, and vascular tissues for conduction. Let us first consider the structure of herbaceous eudicot roots.

In most herbaceous eudicot roots, the central core of vascular tissue lacks pith

The buttercup root is a representative eudicot root with primary growth (Fig. 35-3). Like other parts of this herbaceous eudicot, a single layer of protective tissue, the **epidermis,** covers its roots. The root hairs are a modification of the root epidermis that enables it to absorb more water from the soil. The root epidermis does not secrete a thick, waxy cuticle in the region of root hairs, because this layer would impede the absorption of water from the soil. Both the lack of a cuticle and the presence of root hairs increase absorption.

Beginning with the root hairs, most of the water that enters the root moves along the cell walls rather than enters the cells. One of the major components of cell walls is cellulose, which absorbs water as a sponge does. An example of the absorptive properties of cellulose is found in cotton balls, which are almost pure cellulose.

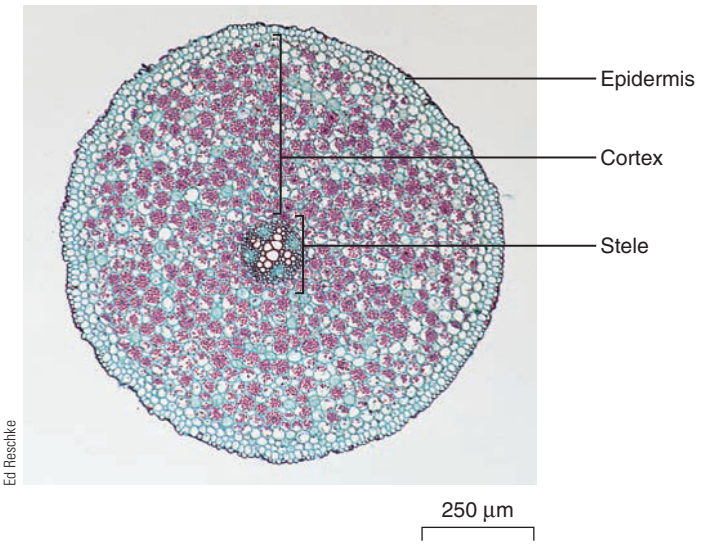
The **cortex,** which is composed primarily of loosely packed **parenchyma** cells, composes the bulk of a herbaceous eudicot root. Roots usually lack supporting **collenchyma** cells, probably because the soil supports the root, although roots as they age may develop some **sclerenchyma** (another supporting tissue; see Chapter 32). The primary function of the root cortex is storage. A microscopic examination of the parenchyma cells that form the cortex often reveals numerous amyloplasts (see Figs. 35-3b and 3-9a), which store starch. Starch, an insoluble carbohydrate composed of glucose subunits, is the most common form of stored energy in plants. When used at a later time, these reserves provide energy for such activities as growth and cell replacement following an injury.

The large intercellular (between-cell) spaces, a common feature of the root cortex, provide a pathway for water uptake and allow for aeration of the root. The oxygen that root cells need for aerobic respiration diffuses from air spaces in the soil into the intercellular spaces of the cortex and from there into the cells of the root.

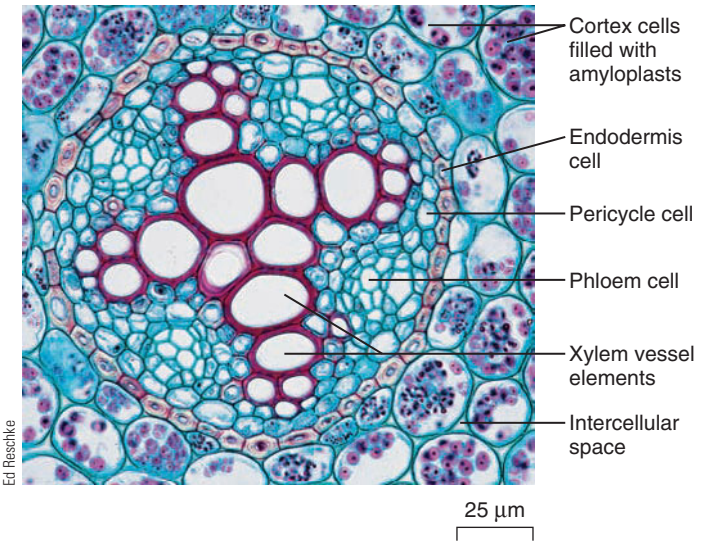
The water and dissolved minerals that enter the root cortex from the epidermis move in solution along two pathways: the symplast and apoplast (Fig. 35-4). The **symplast** is the continuum of living cytoplasm, which is connected from one cell to the next by cytoplasmic bridges called **plasmodesmata** (see Fig. 5-27). Some dissolved mineral ions move from the epidermis through the cortex via the symplast. The **apoplast** consists of the interconnected porous cell walls of a plant, along which water and mineral ions move freely. The water and mineral ions can diffuse across the cortex without ever crossing a plasma membrane to enter a living cell.

The inner layer of the cortex, the **endodermis,** regulates the movement of water and minerals that enter the xylem in the root's center. Structurally, the endodermis differs from the rest of the cortex. Endodermal cells fit snugly against each other, and each has a special bandlike region, called a **Casparian strip** (Fig. 35-5), on its radial (side) and transverse (upper and lower) walls. Casparian strips contain *suberin,* a fatty material that is waterproof. (Recall from Chapter 34 that suberin is also the waterproof material in cork cell walls.)

Until the endodermis is reached, most of the water and dissolved minerals have traveled along the apoplast and therefore



(a) Eudicot root. Cortex composes the bulk of herbaceous eudicot roots. Note the X-shaped xylem in the center of the root.



(b) Stele of eudicot root. Surrounding the solid core of vascular tissues is a single layer of pericycle, which is meristematic in growing roots.

Figure 35-3 ***Animated*** LMs of cross sections of a herbaceous eudicot root

Shown is a buttercup (*Ranunculus*) root.

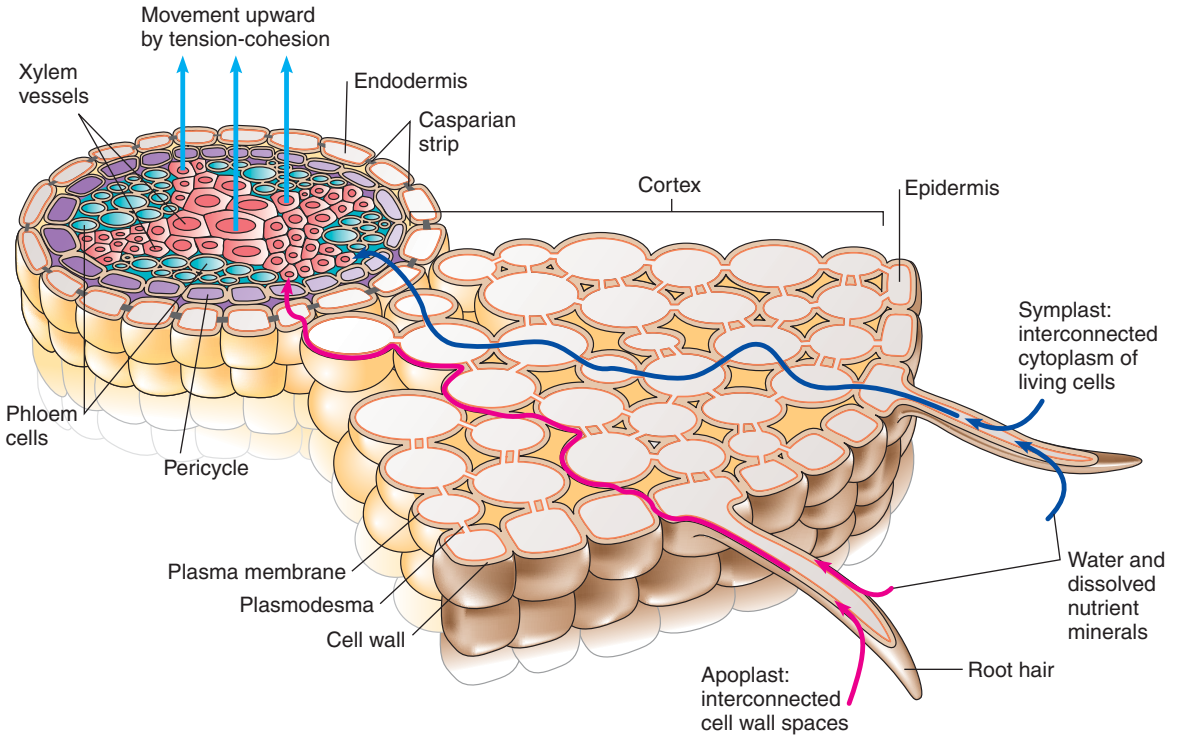


Figure 35-4 ***Animated*** Pathways of water and dissolved minerals in the root

Water and dissolved minerals travel from cell to cell along the interconnected porous cell walls (the apoplast) or from one cell's cytoplasm to another through plasmodesmata (the symplast). On reaching the endodermis, water and minerals can continue to move into the root's center only if they pass through a plasma membrane and enter the cytoplasm of an endodermal cell. The Casparian strip blocks the passage of water and minerals along the cell walls between adjoining endodermal cells.

Key Point

The endodermis regulates the kinds of minerals that are absorbed from the soil and conducted to the rest of the plant body.

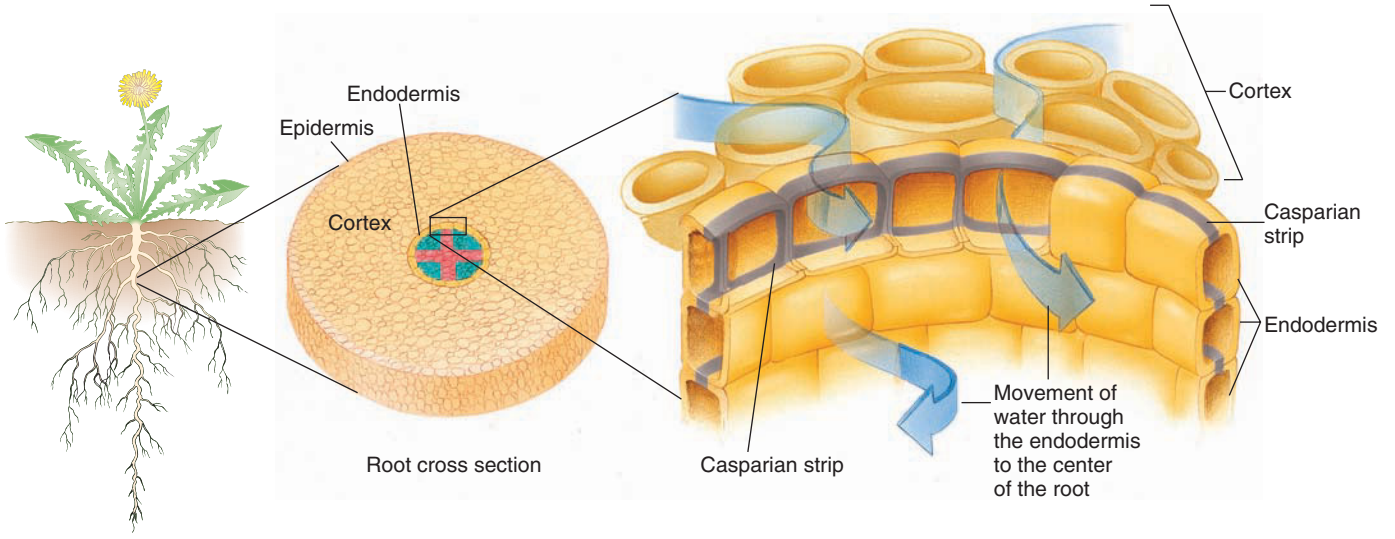

Figure 35-5 ***Animated*** Endodermis and mineral uptake

Note the Casparian strip around the radial and transverse walls that prevents water and dissolved minerals from passing into the stele along endodermal cell walls. To reach the vascular tissues, water and dissolved minerals must pass through the plasma membranes of endodermal cells.

have not passed through a plasma membrane or entered the cytoplasm of a root cell. However, the waterproof Casparian strip on the radial and transverse walls of the endodermal cells prevents water and minerals from continuing to move passively along the cell walls. For substances to pass farther into the root interior, they must move from the cell walls into the cytoplasm of the endodermal cells. Water enters by osmosis, both directly across the lipid bilayer of the endodermal plasma membrane and through **aquaporins,** integral membrane proteins that facilitate the rapid transport of water across the membrane. As in water movement across the lipid bilayer, water moves through aquaporins only along the osmotic gradient, from a region of higher concentration to a region of lower concentration. The key role of aquaporins in the uptake of water by root cells is currently under active study.

Minerals enter the endodermal cells by passing through carrier proteins in their plasma membranes. In **carrier-mediated active transport,** the mineral ions are pumped *against* their concentration gradient—that is, from an area of *low* concentration of that mineral in the soil solution to an area of *high* concentration in the plant's cells. One of many reasons why root cells require sugar and oxygen for aerobic respiration is that this active transport requires the expenditure of energy, usually in the form of ATP. From the endodermis, water and mineral ions enter the root xylem (botanists do not know precisely how this is done) and are conducted to the rest of the plant.

At the center of a eudicot primary root is the **stele,** or **vascular cylinder,** a central cylinder of vascular tissues (see Fig. 35-3a).

The outermost layer of the stele is the **pericycle,** which is just inside the endodermis. The pericycle consists of a single layer of parenchyma cells that give rise to multicellular *lateral roots,* also called branch roots (Fig. 35-6). Lateral roots originate when cells in a portion of the pericycle start dividing. As it grows, the lateral root pushes through several layers of root tissue (endodermis, cortex, and epidermis) before entering the soil. Each lateral root has all the structures and features—root cap, root hairs, epidermis, cortex, endodermis, pericycle, xylem, and phloem—of the larger root from which it emerges. In addition to producing lateral roots, the pericycle is involved in forming the lateral meristems that produce secondary growth in woody roots (discussed later in the chapter).

Xylem, the centermost tissue of the stele, often has two, three, four, or more extensions, or "xylem arms" (see Fig. 35-3b). **Phloem** is located in patches between the xylem arms. The xylem and phloem of the root have the same functions and kinds of cells as in the rest of the plant: Water and dissolved minerals are conducted in **tracheids** and **vessel elements** of xylem, and dissolved sugar (sucrose) is conducted in **sieve tube elements** of phloem.

After passing through the endodermal cells, water enters the root xylem, often at one of the xylem arms. Up to this point the pathway of water has been horizontal from the soil into the center of the root:

Root hair/epidermis ⟶ cortex ⟶ endodermis ⟶ pericycle ⟶ root xylem

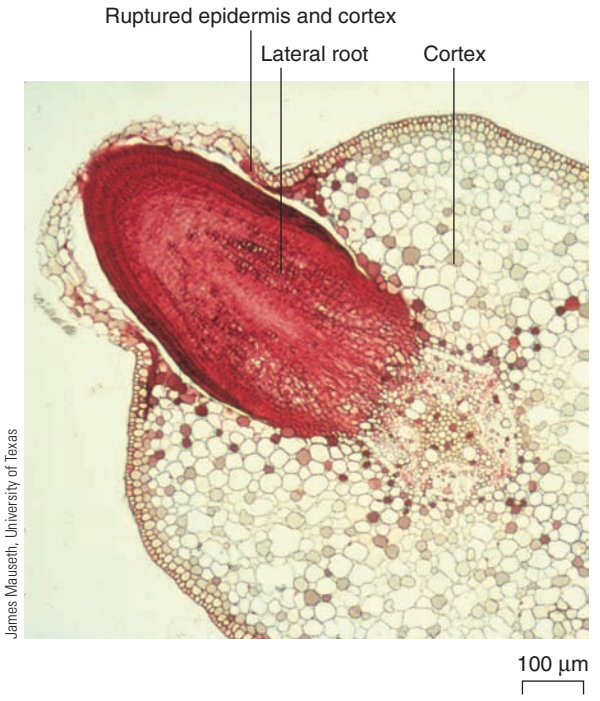

Figure 35-6 LM of a lateral root

Lateral roots originate at the pericycle.

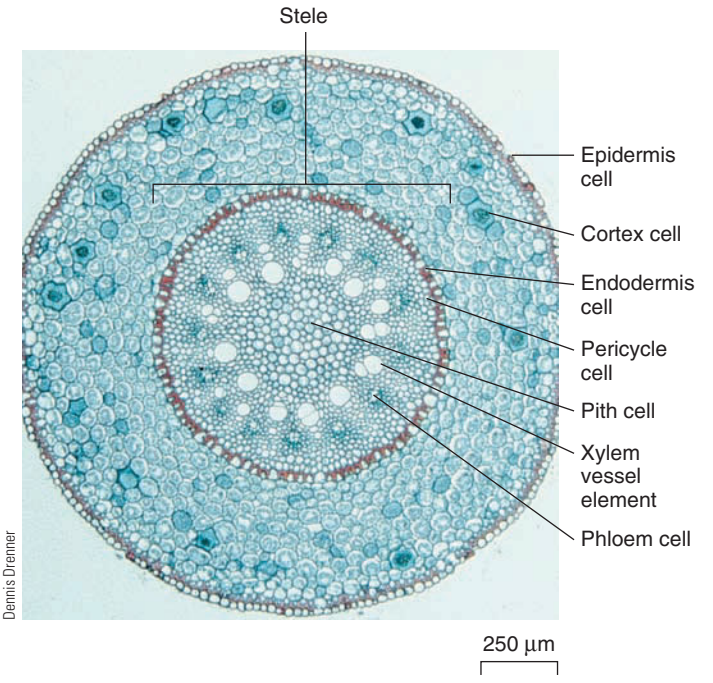

Figure 35-7 LM of a cross section of a monocot root

Shown is a greenbrier (*Smilax*) root. As in herbaceous eudicot roots, the cortex of a monocot root is extensive.

Once water enters the xylem, it is transported upward through root xylem into stem xylem and from there to the rest of the plant.

One direction of phloem conduction is from the leaves, where sugar is made by photosynthesis, to the root, where sugar is used for the growth and maintenance of root tissues or stored, usually as starch. Another direction of phloem conduction is from the root, where sugar is stored as starch, to other parts of the plant, where sugar is used for growth and maintenance of tissues.

The *vascular cambium,* which gives rise to secondary tissues in woody plants, is sandwiched between the xylem and phloem. Because it has an inner core of vascular tissue, the primary eudicot root lacks **pith,** a ground tissue found in the centers of many stems and roots.

Xylem does not form the central tissue in some monocot roots

Monocot roots vary considerably in internal structure, compared with eudicot roots. The layers found in some monocot roots, starting from the outside, are epidermis, cortex, endodermis, and pericycle (Fig. 35-7). Unlike the xylem in herbaceous eudicot roots, the xylem in many monocot roots does not form a solid cylinder in the center. Instead, the phloem and xylem are in separate, alternating bundles arranged around the central pith, which consists of parenchyma cells.

Because virtually no monocots have secondary growth, no vascular cambium exists in monocot roots. Despite their lack of secondary growth, long-lived monocots, such as palms, may have thickened roots produced by a modified form of primary growth in which parenchyma cells in the cortex divide and enlarge.

Woody plants have roots with secondary growth

Plants that produce stems with secondary growth also produce roots with secondary growth. These plants—gymnosperms and woody eudicots—have primary growth at apical meristems and secondary growth at lateral meristems. The production of secondary tissues occurs some distance back from the root tips and results from the activity of the same two lateral meristems found in woody stems: the vascular cambium and the cork cambium. Major roots of trees are often massive and have both wood and bark. In temperate climates, the wood of both roots and stems exhibits annual rings in cross section.

Before secondary growth starts in a root, the **vascular cambium** is sandwiched between the primary xylem and the primary phloem (Fig. 35-8 1). At the onset of secondary growth, the vascular cambium extends out to the pericycle, which develops into vascular cambium opposite the xylem arms. As a result, the pericycle links the separate sections of vascular cambium so that the vascular cambium becomes a continuous, noncircular loop of cells in cross section (Fig. 35-8 2). As the vascular cambium divides to produce secondary tissues, it eventually forms a cylinder of vascular cambium that continues to divide, producing secondary xylem (wood) to the inside and secondary phloem (inner bark) to the outside (Fig. 35-8 3 and 4). The root increases in

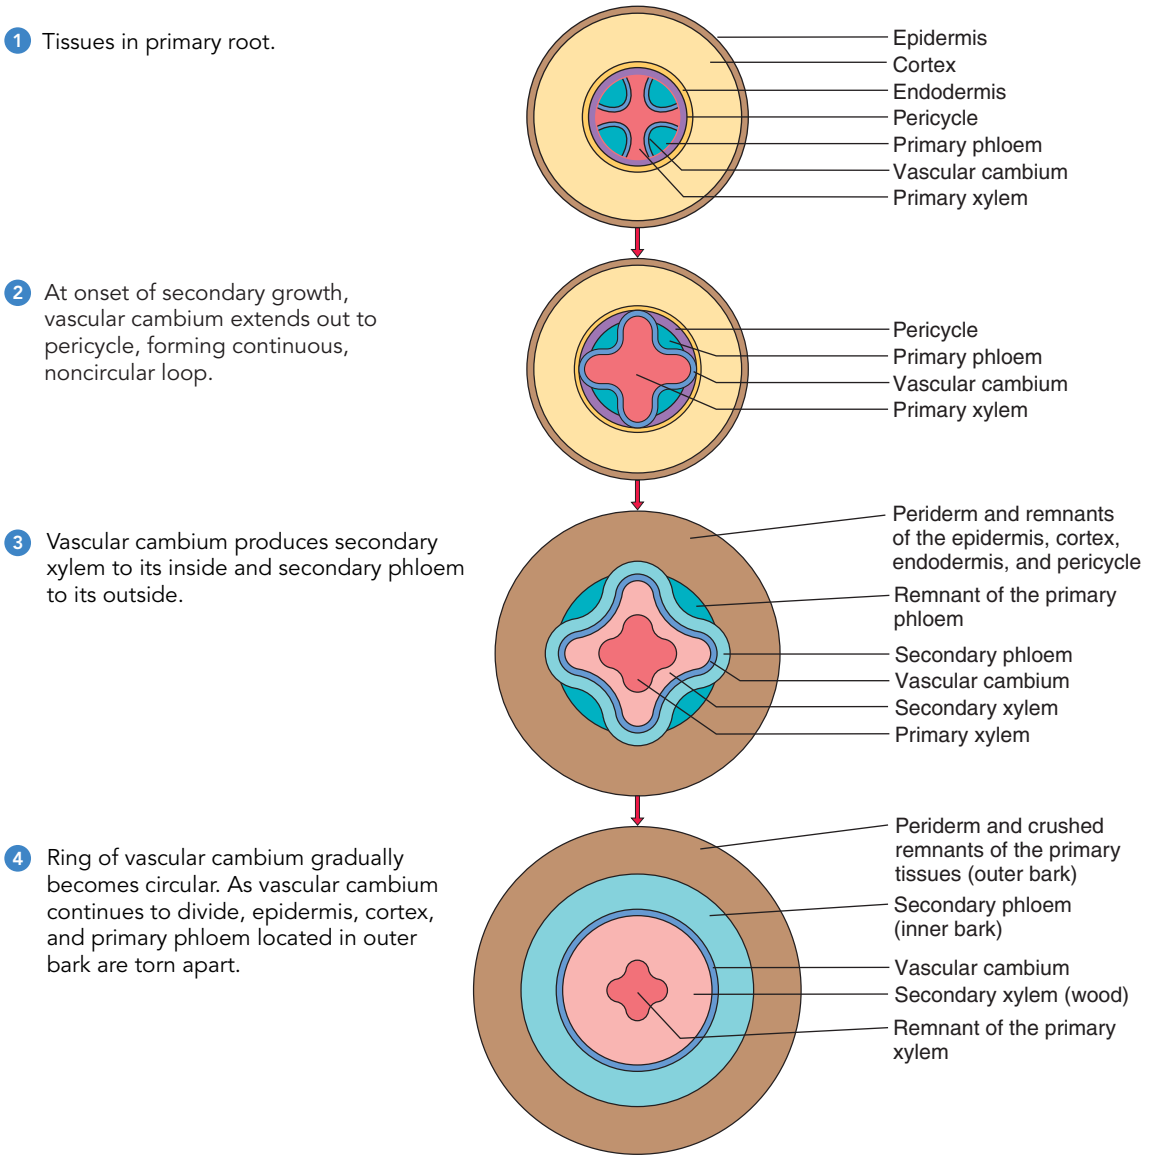

Figure 35-8 Development of secondary vascular tissues in a primary root

The figures are not drawn to scale because of space limitations; the primary xylem is actually the same size in all four diagrams, but differences in scale make the xylem appear different sizes.

girth (thickness), and the vascular cambium continues to move outward.

The epidermis, cortex, endodermis, and primary phloem are gradually torn apart as the root increases in girth. The root epidermis is replaced by **periderm,** composed of cork cells and cork parenchyma, both produced by the **cork cambium** (the last figure in Table 32-4 shows an LM of periderm). The cork cambium in the root initially arises from regions in the pericycle.

Some roots are specialized for unusual functions

Adventitious roots often arise from the nodes of stems. Many aerial adventitious roots are adapted for functions other than anchorage, absorption, conduction, or storage. **Prop roots** are adventitious roots that develop from branches or a vertical stem and grow downward into the soil to help support the plant in an upright position (▮ Fig. 35-9a). Prop roots are more common in monocots than in eudicots. Corn and sorghum, both monocots, are herbaceous plants that produce prop roots. Many tropical and subtropical eudicot trees, such as red mangrove and banyan, also produce prop roots.

The roots of many tropical rainforest trees are shallow and concentrated near the surface in a mat only a few centimeters (an inch or so) thick. The root mat catches and absorbs almost all minerals released from leaves by decomposition. Swollen bases or braces called **buttress roots** hold the trees upright and aid in the extensive distribution of the shallow roots (▮ Fig. 35-9b).

In swampy or tidal environments where the soil is flooded or waterlogged, some roots grow upward until they are above

Figure 35-9 Specialized roots

the high-tide level. Even though roots live in the soil, they still require oxygen for aerobic respiration. Flooded soils are depleted of oxygen, so these aerial "breathing" roots, known as **pneumatophores,** may assist in getting oxygen to the submerged roots (Fig. 35-9c). Pneumatophores, which also help anchor the plant, have a well-developed system of internal air spaces that is continuous with the submerged parts of the root, presumably allowing gas exchange. Black mangrove, white mangrove, and bald cypress are examples of plants with pneumatophores.

Climbing plants and **epiphytes,** which are plants that grow attached to other plants, have aerial roots that anchor the plant to the bark, branch, or other surface on which they grow. Some epiphytes have aerial roots specialized for functions other than anchorage. Certain epiphytic orchids, for example, have photosynthetic roots (Fig. 35-9d). Epiphytic roots may absorb moisture as well.

Some parasitic epiphytes, such as mistletoe, have modified roots that penetrate the host-plant tissues and absorb water. Another plant that starts its life as an epiphyte is the strangler fig, which produces long roots that eventually reach the ground and anchor the plant (now a tree rather than an epiphyte) in the soil. The tree on which the strangler fig originally grew is often killed as the strangler fig grows around it, competing with it for light and other resources and crushing its secondary phloem.

ROOT ASSOCIATIONS WITH FUNGI AND BACTERIA

Learning Objective

6 List and describe two mutualistic relationships between roots and other organisms.

The roots of terrestrial plant species may form **mutualistic**—that is, mutually beneficial—relationships with certain soil microorganisms: *mycorrhizal fungi* and *rhizobial bacteria.* These mutualistic relationships provide plants with access to essential minerals that are in limited supply in the soil.

Mycorrhizae facilitate the uptake of essential minerals by roots

Subterranean associations between roots and certain fungi, known as **mycorrhizae,** permit the transfer of materials (such as carbon compounds produced by photosynthesis) from roots to the fungus. At the same time, essential minerals, such as phosphorus, move from the fungus to the roots of the host plant. The threadlike body of the fungal partner extends into the soil, extracting minerals well beyond the reach of the plant's roots. In some mycorrhizae, the fungal mycelium encircles the root like a sheath; in others, the fungus penetrates cell walls of the root cortex and forms branching **arbuscules** (Fig. 35-10; also see Fig. 26-11).

The mycorrhizal relationship is an ancient one: some of the earliest known plant fossils (about 400 million years old) contain mycorrhizal fungi in the roots. The mycorrhizal relationship is mutually beneficial because when mycorrhizae are not present, neither the fungus nor the plant grows as well (see Fig. 26-19). The hyphal network of mycorrhizae appears to interconnect different plant species in the community so that carbon compounds may flow from one plant to another through their mutual fungal partner.

Rhizobial bacteria fix nitrogen in the roots of leguminous plants

Certain nitrogen-fixing bacteria, collectively called **rhizobia,** form associations with the roots of leguminous plants—clover, peas, and soybeans, for example. **Nodules** (swellings) that house millions of the rhizobia develop on the roots (see Fig. 54-9). Evidence indicates that the rhizobial relationship evolved much later than the mycorrhizal relationship; unlike mycorrhizae, which infect most plant species, rhizobia almost exclusively infect plants of the legume family, which evolved about 70 million years ago. (A few other plant–bacteria associations that fix nitrogen have also evolved.)

As with mycorrhizae, the association between nitrogen-fixing bacteria and the roots of legumes is mutually beneficial. Bacteria receive photosynthetic products from plants while helping them meet their nitrogen requirements by producing ammonia (NH_3) from atmospheric nitrogen.

For several decades, biologists have been studying the molecular basis of associations between plants and nitrogen-fixing bacteria. The two partners in this association use **cell signaling,** that is, a molecular dialogue back and forth between them, to establish contact and develop nodules. When soil contains a low level of nitrogen, legume roots secrete chemical attractants (flavonoids) toward which the rhizobial bacteria swim.

The initial signal molecules produced by rhizobial bacteria are called *nodulation factors,* or *nod factors.* These nod factors help root-hair cells in the roots of leguminous plants recognize the presence of the bacteria; recognition is the first step in the infection by rhizobia and the development of root nodules. The nod factor apparently attaches to a plant receptor on the root-hair plasma membrane. This attachment triggers an elaborate **signal transduction** cascade within root cells that alters gene expression and metabolism, resulting in nodule formation (Fig. 35-11).

Some of the same plant genes are involved in the initiation of both mycorrhizal and rhizobial associations

Because both mycorrhizae and rhizobia infect plant roots, some biologists have hypothesized that the genes and signal transduc-

(b) LM of endomycorrhizae, fungal associations in which the fungal hyphae penetrate root cells of the cortex and form branched arbuscules (absorbing organs) within the cells to aid in delivering and receiving nutrients. Roots of most vascular plant species are colonized by endomycorrhizae.

Figure 35-10 Mycorrhizae

Mycorrhizae enhance plant growth by providing essential minerals to the roots.

tion components involved in mycorrhizal relationships may have been recruited for the rhizobial relationships that evolved much later. There is experimental evidence to support this hypothesis. Some of the same genes that trigger infection and changes in root development to form rhizobial nodules are also involved in establishing mycorrhizal infections. Evidence includes several legume mutants that biologists have identified; these mutants lack the ability to develop nodules for rhizobial bacteria and cannot form mycorrhizal associations. Molecular findings also support the hypothesis.

Review

- What are mycorrhizal fungi?
- What are rhizobial bacteria?
- How are mycorrhizae and root nodules similar? How are they different?

THE SOIL ENVIRONMENT

Learning Objectives

7 Describe the roles of weathering, organisms, climate, and topography in soil formation.
8 List the four components of soil, and give the ecological significance of each.
9 Describe how roots absorb positively charged mineral ions by the process of cation exchange.
10 Distinguish between macronutrients and micronutrients.
11 Explain the impacts of mineral depletion and soil erosion on plant growth.

We now examine the soil environment in which most roots live. **Soil** is a relatively thin layer of Earth's crust that has been modified by the natural actions of weather, wind, water, and organisms. It is easy to take soil for granted. We walk on and over it throughout our lives but rarely stop to think about how important it is to our survival. Vast numbers and kinds of organisms colonize soil and depend on it for shelter and food. Most plants anchor themselves in soil, and from it they receive water and minerals. Almost all of the elements essential for plant growth are obtained directly from the soil. With few exceptions, plants cannot survive on their own without soil, and because we depend on plants for our food, neither could humans exist without soil.

Soils are generally formed from rock (called *parent material*) that is gradually broken down, or fragmented, into smaller and smaller particles by biological, chemical, and physical **weathering processes.** Two important factors that work together in the weathering of rock are climate and organisms. When plant roots and other organisms living in the soil respire, they produce carbon dioxide (CO_2), which diffuses into the soil and reacts with soil water to form carbonic acid (H_2CO_3). Soil organisms such

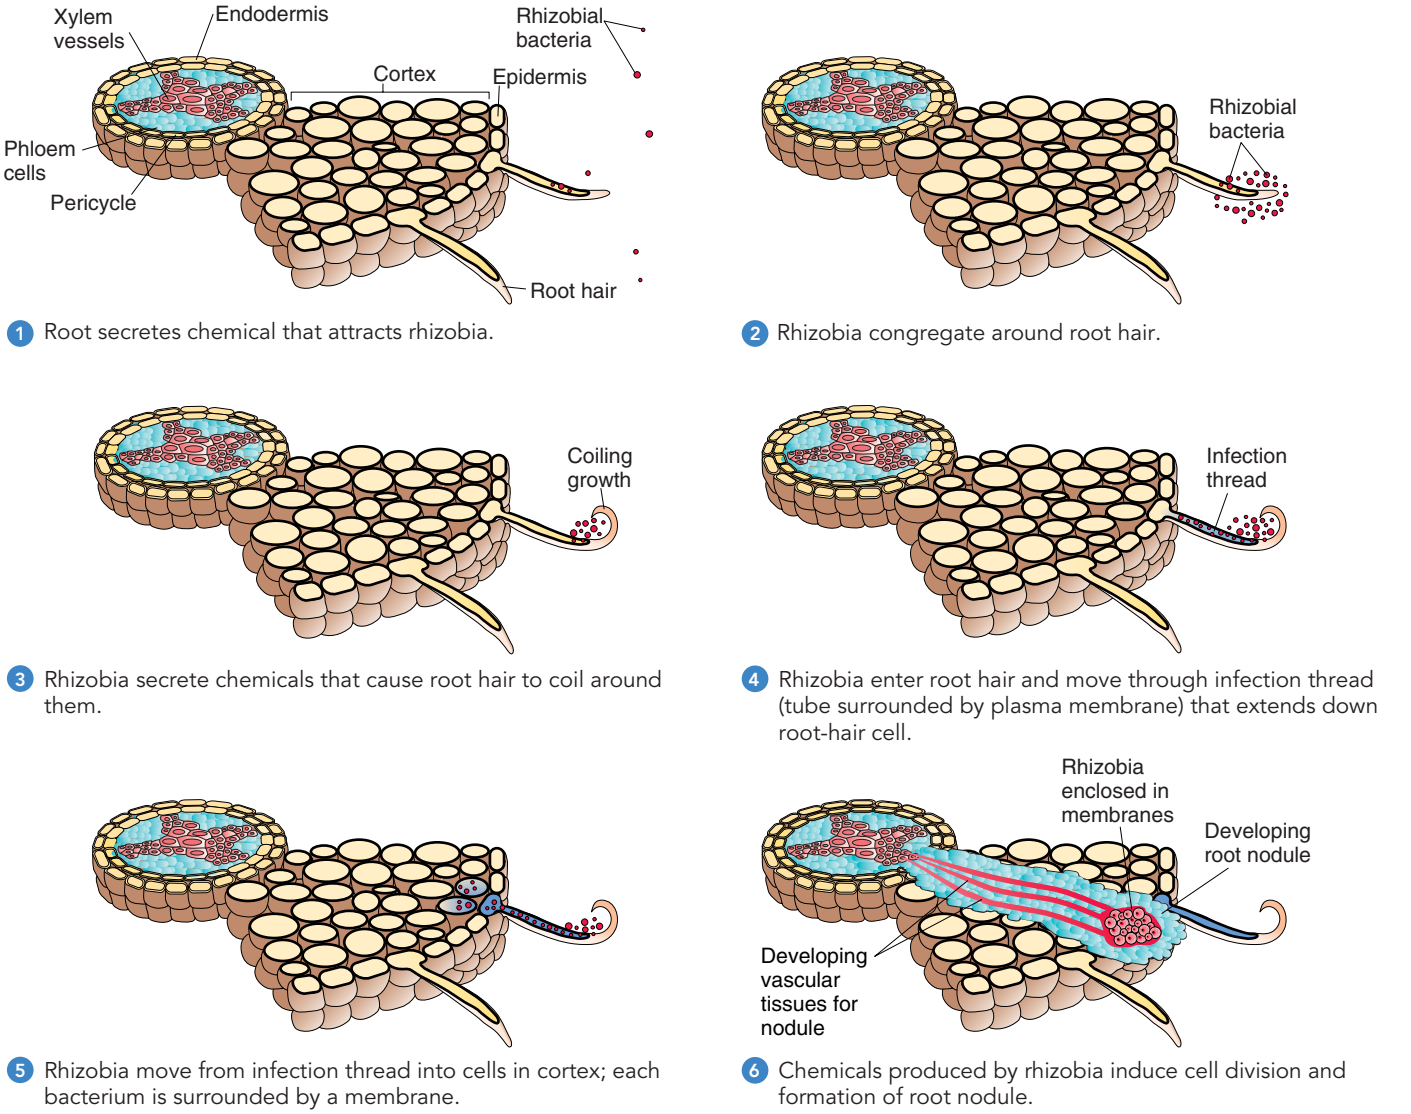

Figure 35-11 Steps in the establishment of a relationship between rhizobial bacteria and leguminous plants

as lichens produce other kinds of acids.[1] These acids etch tiny cracks, or fissures, in the rock surface; water then seeps into these cracks. If the parent material is located in a temperate climate, the alternate freezing and thawing of the water during winter cause the cracks to enlarge, breaking off small pieces of rock. Small plants can then become established and send their roots into the larger cracks, fracturing the rock further.

Topography, a region's surface features, such as the presence or absence of mountains and valleys, is also involved in soil formation. Steep slopes often have little or no soil on them, because the soil and rock are continually transported down the slopes by gravity. Runoff from precipitation tends to amplify erosion on steep slopes. Moderate slopes, in contrast, may encourage the formation of deep soils.

[1]A lichen is a dual organism composed of a fungus and a phototroph (photosynthetic organism) (see Chapter 26).

The disintegration of solid rock into finer and finer mineral particles in the soil takes an extremely long time, sometimes thousands of years. Soil forms constantly as the weathering of parent material beneath soil that is already formed continues to add new soil.

Soil is composed of inorganic minerals, organic matter, air, and water

Soil comprises four distinct components—inorganic mineral particles (which make up about 45% of a typical soil), organic matter (about 5%), water (about 25%), and air (about 25%). The plants, animals, fungi, and microorganisms that inhabit soil interact with it, and minerals are continually cycled from the soil to organisms, which use them in their biological processes. When the organisms die, bacteria and other soil organisms decompose the remains, returning the minerals to the soil.

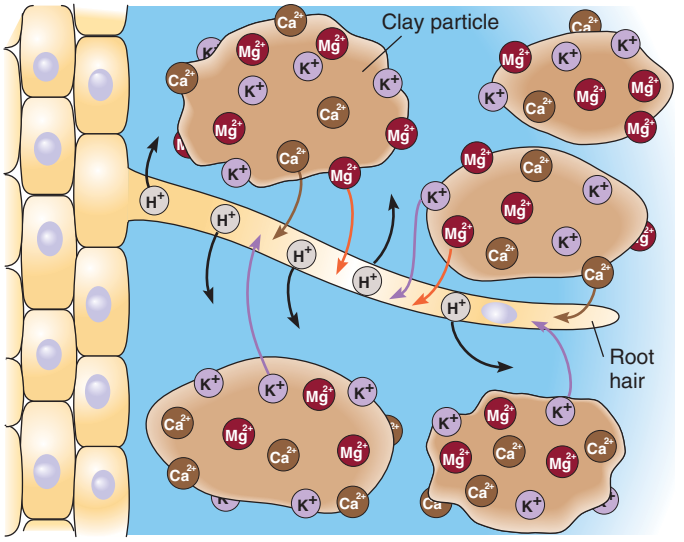

Figure 35-12 Cation exchange

Negatively charged clay particles bind to positively charged mineral cations, holding them in the soil. Roots pump out protons (H^+), which are exchanged for the cations, facilitating their absorption.

The inorganic mineral particles, which come from weathered rock, provide anchorage and essential minerals for plants, as well as pore space for water and air. Because different rocks consist of different minerals, soils vary in mineral composition and chemical properties. Rocks rich in aluminum form acidic soils, for example, whereas rocks that contain silicates of magnesium and iron form soils that may be deficient in calcium, nitrogen, and phosphorus. Also, soils formed from the same kind of parent material may not develop in the same way, because other factors, such as weather, topography, and organisms, differ.

The *texture,* or structural characteristic, of a soil is determined by the percentages (by weight) of the different-sized inorganic mineral particles—sand, silt, and clay—in it. The size assignments for sand, silt, and clay give soil scientists a way to classify soil texture. Particles larger than 2 mm in diameter, called gravel or stones, are not considered soil particles, because they do not have any direct value to plants. The largest soil particles are called *sand* (0.02 to 2 mm in diameter); the medium-sized particles, *silt* (0.002 to 0.02 mm in diameter); and the smallest particles, *clay* (less than 0.002 mm in diameter). Sand particles are large enough to be seen easily with the eye, and silt particles (about the size of flour particles) are barely visible. Most individual clay particles are too small to be seen with an ordinary light microscope; they can be seen only under an electron microscope.

A soil's texture affects many of that soil's properties, in turn influencing plant growth. The clay component of a soil is particularly important in determining many of its characteristics because clay particles have the greatest surface area of all soil particles. If the surface areas of about 450 g (1 lb) of clay particles were laid out side by side, they would occupy 1 hectare (2.5 acres).

Each clay particle has predominantly negative electric charges on its outer surface that attract and reversibly bind **cations,** which are positively charged mineral ions such as potassium (K^+) and magnesium (Mg^{2+}). Because many cations are essential for plant growth, cation adhesion to soil particles is an important aspect of soil fertility. Roots secrete protons (hydrogen ions, H^+), which are exchanged for other positively charged mineral ions adhering to the surface of soil particles, in a process known as **cation exchange.** These "freed" ions and the water that forms a film around the soil particles are absorbed by the plant's roots (Fig. 35-12).

In contrast, **anions,** which are negatively charged mineral ions, are repelled by the negative surface charges of clay particles and tend to remain in solution. Anions such as nitrate (NO_3^-) are often washed out of the root zone by water moving through the soil.

Soil always contains a mixture of different-sized particles, but the proportions vary from one soil to another. A *loam,* which is an ideal agricultural soil, has an optimum combination of different soil particle sizes: it contains approximately 40% each of sand and silt and about 20% of clay. Generally, the larger particles provide structural support, aeration, and permeability to the soil, whereas the smaller particles bind into aggregates, or clumps, and hold minerals and water. Soils with larger proportions of sand are not as desirable for most plants, because they do not hold water and mineral ions well. Plants grown in such soils are more susceptible to drought and mineral deficiencies. Soils with larger proportions of clay are also not desirable for most plants because they provide poor drainage and often do not provide enough oxygen. Clay soils used in agriculture tend to compact, which reduces the number of soil spaces that can be filled by water and air.

A soil's organic matter consists of the wastes and remains of soil organisms

The organic matter in soil is composed of litter (dead leaves and branches on the soil's surface); droppings (animal dung); and the dead remains of plants, animals, and microorganisms in various stages of decomposition. Organic matter is decomposed by microorganisms, particularly bacteria and fungi, that inhabit the soil. During decomposition, essential mineral ions are released into the soil, where they may be bound by soil particles or absorbed by plant roots. Organic matter increases the soil's water-holding capacity by acting much like a sponge. For this reason gardeners often add organic matter to soils, especially sandy soils, which are naturally low in organic matter.

The partly decayed organic portion of the soil is referred to as **humus.** Humus, which is not a single chemical compound but a mix of many organic compounds, binds mineral ions and holds water. On average, humus persists in agricultural soil for about 20 years. Certain components of humus may persist in the soil for hundreds of years. Although humus is somewhat resistant to decay, a succession of microorganisms gradually reduces it to carbon dioxide, water, and minerals.

About 50% of soil volume is composed of pore spaces

Soil has numerous pore spaces of different sizes around and among the soil particles. Pore spaces occupy roughly 50% of a soil's volume and are filled with varying proportions of air and water. Both soil air and soil water are necessary to produce a

moist but aerated soil that sustains plants and other soil-dwelling organisms. Water is usually held in the smaller pores, whereas air is found in the larger pores. After a prolonged rain, almost all the pore spaces may be filled with water, but water drains rapidly from the larger pore spaces, drawing air from the atmosphere into those spaces.

Soil air contains the same gases as atmospheric air, although they are usually present in different proportions. As a result of respiration by soil organisms, there is less oxygen and more carbon dioxide in soil air than in atmospheric air. (Aerobic respiration uses oxygen and produces carbon dioxide.) Among the important gases in soil are oxygen (O_2), required by soil organisms for aerobic respiration; nitrogen (N_2), used by nitrogen-fixing bacteria; and carbon dioxide (CO_2), involved in soil weathering.

Soil water originates as precipitation, which drains downward, or as groundwater (water stored in porous underground rock), which rises upward from the water table (the uppermost level of groundwater). Soil water contains low concentrations of dissolved minerals that enter the roots of plants when they absorb water. Water not bound to soil particles or absorbed by roots percolates (moves down) through soil, carrying dissolved minerals with it. The removal of dissolved materials from soil by percolating water is called **leaching.** The deposition of leached material in the lower layers of soil is known as **illuviation.** Iron and aluminum compounds, humus, and clay are some illuvial materials that can gather in the subsurface portion of the soil. Some substances completely leach out of the soil because they are so soluble that they migrate down into the groundwater. It is also possible for water that is moving *upward* through the soil to carry dissolved materials with it.

The organisms living in the soil form a complex ecosystem

A single teaspoon of fertile agricultural soil may contain millions of microorganisms, such as bacteria, fungi, algae, protozoa, and microscopic nematodes and other worms. Many other organisms also colonize the soil ecosystem, including plant roots, earthworms, insects, moles, snakes, and groundhogs (Fig. 35-13). Most numerous in soil are bacteria, which number in the hundreds of millions per gram of soil. Scientists have identified about 170,000 species of soil organisms, but thousands remain to be identified. Little is known about the roles of soil organisms, in part because it is hard to study their activities under natural conditions.

Worms are some of the most important organisms living in soil. Earthworms, probably one of the most familiar soil inhabitants, ingest soil and obtain energy and raw materials by digesting humus. *Castings,* bits of soil that have passed through the gut of an earthworm, are deposited on or near the soil surface. In this way, minerals from deeper layers are brought to upper layers. Earthworm tunnels serve to aerate the soil, and the worms' waste products and corpses add organic material to the soil.

Ants live in the soil in enormous numbers, constructing tunnels and chambers that help aerate it. Members of soil-dwelling ant colonies forage on the surface for bits of food, which they carry back to their nests. Not all this food is eaten, however, and its eventual decomposition helps increase the organic matter in the soil. Many ants are also indispensable in plant reproduction because they bury seeds in the soil (discussed in Chapter 36).

Soil pH affects soil characteristics and plant growth

Acidity is measured using the pH scale, which extends from 0 (extremely acidic) through 7.0 (neutral) to 14.0 (extremely alkaline). The pH of most soils ranges from 4.0 to 8.0, but some soils are outside this range. The soil of the Pygmy Forest in Men-

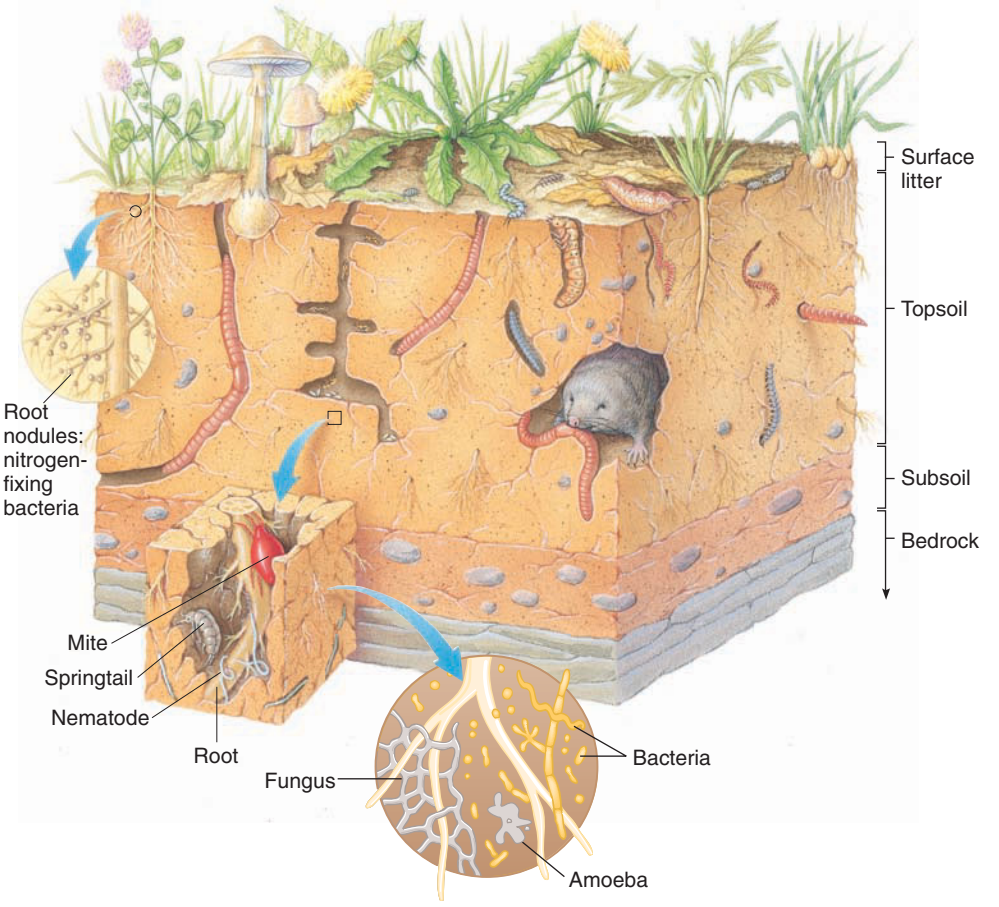

Figure 35-13 Diversity of life in fertile soil

Plants, algae, protozoa, fungi, bacteria, earthworms, flatworms, roundworms, insects, spiders and mites, and burrowing animals such as moles and groundhogs live in soil.

docino County, California, is extremely acidic (pH 2.8 to 3.9). At the other extreme, certain soils in Death Valley, California, have a pH of 10.5.

Plants are affected by soil pH, partly because the solubility of certain minerals varies with differences in pH. Soluble minerals can be absorbed by the plant, whereas insoluble forms cannot. At a low pH, for example, aluminum and manganese in soil water are more soluble and are sometimes absorbed by the roots in toxic concentrations. At a higher pH, certain mineral salts essential for plant growth, such as calcium phosphate, become less soluble and thus less available to plants.

Soil pH also affects the leaching of minerals. An acidic soil has less ability to bind positively charged ions to it because the soil particles also bind the abundant protons (Fig. 35-14). As a result, certain mineral ions essential for plant growth, such as potassium (K^+), are leached more readily from acidic soil. The optimum soil pH for most plant growth is 6.0 to 7.0, because most essential minerals are available to plants in that pH range.

Acid precipitation, a type of air pollution in which sulfuric and nitric acids produced by human activities fall to the ground as acid rain, sleet, snow, or fog, can seriously decrease soil pH. Acid precipitation is one of several factors implicated in **forest decline,** the gradual deterioration, and often death, of trees that has been observed in many European and North American forests. Forest decline may be partly the result of soil changes, such as leaching of essential cations, caused by acid precipitation. In central European forests that have experienced forest decline, for example, a strong correlation exists between forest damage and soil chemistry altered by acid precipitation.

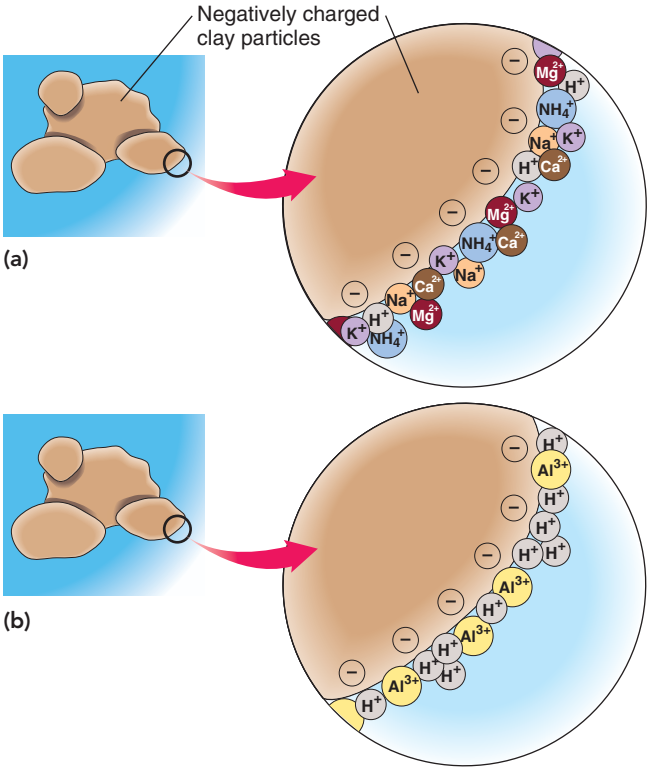

Figure 35-14 How acid alters soil chemistry

(a) In normal soil, positively charged mineral ions are attracted to the negatively charged soil particles. **(b)** In acidified soil, protons displace the cations. Aluminum ions released from inorganic mineral particles when the soil becomes acidified also adhere to soil particles.

Soil provides most of the minerals found in plants

More than 90 naturally occurring elements exist on Earth, and more than 60 of these, including elements as common as carbon and as rare as gold, have been found in plant tissues. Not all these elements are essential for plant growth, however.

Nineteen elements have been found essential for most, if not all, plants (Table 35-1). Ten of these are required in fairly large quantities (greater than 0.05% dry weight) and are therefore known as **macronutrients.** Macronutrients include carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon. The remaining nine **micronutrients** are needed in trace amounts (less than 0.05% dry weight) for normal plant growth and development. Micronutrients include chlorine, iron, boron, manganese, sodium, zinc, copper, nickel, and molybdenum.

Four of the 19 elements—carbon, oxygen, hydrogen, and nitrogen—come directly or indirectly from soil water or from gases in the atmosphere. Carbon is obtained from carbon dioxide in the atmosphere during photosynthesis. Oxygen is obtained from atmospheric oxygen (O_2) and water (H_2O).Water also supplies hydrogen to the plant. Plants absorb their nitrogen from the soil as ions of nitrogen salts, but the nitrogen in nitrogen salts ultimately comes from atmospheric nitrogen (N_2). The remaining 15 essential elements are obtained from the soil as dissolved mineral ions. Their ultimate source is the parent material from which the soil was formed.

Let us examine the main functions of essential elements. Carbon, hydrogen, and oxygen are found as part of the structure of all biologically important molecules, including lipids, carbohydrates, nucleic acids, and proteins. Nitrogen is part of proteins, nucleic acids, and chlorophyll.

Potassium, which plants use in fairly substantial amounts, is not found in a specific organic compound in plant cells. Instead, it remains as free K^+ and plays a key physiological role in maintaining the turgidity of cells because it is osmotically active. The presence of K^+ in cytoplasm causes water to pass through the plasma membrane into the cell by osmosis. Potassium is also involved in the opening of stomata.

Calcium plays a key structural role as a component of the middle lamella (the cementing layer between cell walls of adjacent plant cells). Calcium ions (Ca^{2+}) are also important in a number of physiological roles in plants, such as altering membrane permeability and as **second messengers** in various cell signaling responses (see Chapter 6).

Magnesium is critical for plants because it is part of the chlorophyll molecule. Phosphorus is a component of nucleic acids, phospholipids (part of cell membranes), and energy transfer molecules such as ATP. Sulfur is essential because it is found in certain amino acids and vitamins. Many plants accumulate sili-

TABLE 35-1

Functions of Elements Required by Most Plants

Element	Taken Up As	Major Functions
Macronutrients		
Carbon	CO_2	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Hydrogen	H_2O	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Oxygen	CO_2, H_2O	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Nitrogen	NO_3^-, NH_4^+	Component of proteins, nucleic acids, chlorophyll, certain coenzymes
Potassium	K^+	Osmotic and ionic balance; opening of stomata; enzyme activator (for 40+ enzymes)
Calcium	Ca^{2+}	In cell walls; involved in membrane permeability; enzyme activator; second messenger
Magnesium	Mg^{2+}	In chlorophyll; enzyme activator in carbohydrate metabolism
Phosphorus	HPO_4^{2-}, $H_2PO_4^-$	In nucleic acids, phospholipids, ATP (energy transfer compound)
Sulfur	SO_4^{2-}	In certain amino acids and vitamins
Silicon	SiO_3^{2-}	In cell walls
Micronutrients		
Chlorine	Cl^-	Ionic balance; involved in photosynthesis
Iron	Fe^{2+}, Fe^{3+}	In enzymes and electron transport molecules involved in photosynthesis, respiration, and nitrogen fixation
Boron	$H_2BO_3^-$	In cell walls; involved in nucleic acid metabolism and in cell growth
Manganese	Mn^{2+}	In enzymes involved in respiration and nitrogen metabolism; required for photosynthesis
Sodium	Na^+	Involved in photosynthesis; substitutes for potassium in osmotic and ionic balance
Zinc	Zn^{2+}	In enzymes involved in respiration and nitrogen metabolism
Copper	Cu^+, Cu^{2+}	In enzymes involved in photosynthesis
Nickel	Ni^{2+}	In enzymes (urease) involved in nitrogen metabolism
Molybdenum	MoO_4^{2-}	In enzymes involved in nitrogen metabolism

con in their cell walls and intercellular spaces. Silicon enhances the growth and fertility of some species and may help reinforce cell walls.

Chlorine and sodium are micronutrients that help maintain cell turgor. In addition to this osmotic role, chloride (Cl^-) and sodium (Na^+) ions are essential for photosynthesis. Six of the micronutrients (iron, manganese, zinc, copper, nickel, and molybdenum) are associated with various plant enzymes, often as **cofactors,** and are involved in certain enzymatic reactions. Boron, present in cell walls, is also involved in nucleic acid metabolism and in cell growth.

How do biologists determine whether an element is essential?

It is impossible to conduct mineral nutrition experiments by growing plants in soil, because soil is too complex and contains too many elements. Therefore, nutritional studies require special methods. One of the most useful techniques to test whether an element is essential is **hydroponics,** which is the growing of plants in aerated water to which mineral salts have been added. Hydroponics has commercial applications in addition to its scientific use (Fig. 35-15).

If biologists suspect that a particular element is essential for plant growth, they grow plants in a nutrient solution that contains all known essential elements *except* the one in question. If plants grown in the absence of that element cannot develop normally or complete their life cycle, the element may be essential. Additional criteria are used to confirm whether an element is essential. For example, it must be demonstrated that the element has a direct effect on the plant's metabolism and that the element is essential for a wide variety of plants.

Soil can be damaged by human mismanagement

Soil is a valuable natural resource on which humans depend for food. Many human activities generate or aggravate soil problems, including mineral depletion, soil erosion, and accumulation of salt.

Mineral depletion may occur in soils that are farmed

In a natural ecosystem, the essential minerals removed from the soil by plants are returned when the plants or the animals that eat them die and are decomposed. An agricultural system disrupts this pattern of nutrient cycling when the crops are harvested. Plant material containing minerals is removed from the nutrient cycle, and the harvested crops fail to decay and release their nutrients back to the soil. Over time, farmed soil inevitably loses its fertility, that is, its ability to produce abundant crops. Homeowners often mow their lawns and remove the clippings, similarly preventing decomposition and cycling of minerals that were in the grass blades.

Hank Morgan/Photo Researchers, Inc.

Figure 35-15 Hydroponically grown lettuce

Lettuce is one of several hydroponic crops grown commercially. The white boards support the plants, which are not anchored in soil. A chemically defined liquid solution of minerals trickles over their roots, which also have access to atmospheric oxygen.

USDA/Natural Resources Conservation Service

Figure 35-16 Soil erosion in an open field

Removal of plant cover exposes bare soil to erosion in heavy rains. Precipitation can cause gullies to enlarge rapidly, because they provide channels for the runoff of water.

The essential material (water, sunlight, or some essential element) that is in shortest supply usually limits plant growth. This phenomenon is sometimes called the concept of **limiting resources.** The three elements that are most often limiting resources for plants are nitrogen, phosphorus, and potassium. To sustain the productivity of agricultural soils, farmers periodically add fertilizers to depleted soils to replace the minerals that limit plant growth.

Soil erosion is the loss of soil from the land

Water, wind, ice, and other agents cause **soil erosion,** the wearing away or removal of soil from the land. Water and wind are particularly effective in moving soil from one place to another. Rainfall loosens soil particles that can then be transported by moving water (Fig. 35-16).Wind loosens soil and blows it away, particularly if the soil is barren and dry. Soil erosion is a natural process that can be greatly accelerated by human activities.

Soil erosion is a national and international problem that does not make the headlines very often. The U.S. Department of Agriculture estimates that approximately 4.2 billion metric tons (4.6 billion tons) of topsoil are eroded each year from U.S. croplands and rangelands. Erosion causes a loss in soil fertility because essential minerals and organic matter that are a part of the soil are removed. As a result of these losses, the productivity of eroded agricultural soils declines, and more fertilizer must be used to replace the nutrients lost to erosion.

Humans often accelerate soil erosion through poor soil management practices. Agriculture is not the only culprit, because the removal of natural plant communities during surface mining, unsound logging practices (such as clear-cutting large areas of forest), and the construction of roads and buildings also accelerate erosion.

Soil erosion has an impact on other natural resources. Sediment that enters streams, rivers, and lakes degrades water quality and fish habitats. Pesticides and fertilizer residues in sediment may add pollutants to the water. Also, when forests are removed within the watershed of a hydroelectric power facility, accelerated soil erosion fills the reservoir behind the dam with sediment much faster than usual. This process reduces electricity production at that facility.

Sufficient plant cover reduces the amount of soil erosion: leaves and stems cushion the impact of rainfall, and roots help hold the soil in place. Although soil erosion is a natural process, abundant plant cover makes it negligible in many natural ecosystems.

Salt accumulates in soil that is improperly irrigated

Although irrigation improves the agricultural productivity of arid and semiarid lands, it sometimes causes salt to accumulate in the soil, a process called **salinization.** In a natural scenario, as a result of precipitation runoff, rivers carry dissolved salts away. Irrigation water, however, normally soaks into the soil and does not run off the land into rivers, so when water evaporates, the salt remains behind and accumulates in the soil. Salty soil results in a decline in productivity and, in extreme cases, renders the soil completely unfit for crop production.

Most plants cannot obtain all the water they need from salty soil, because a water balance problem exists: water moves by osmosis *out* of plant roots and into the salty soil. Obviously, most plants cannot survive under these conditions (see Fig. 5-14). Plant species that thrive in saline soils have special adaptations that enable them to tolerate the high amount of salt. Black mangroves, for example, excrete excess salt through their leaves.

Most crops, unless they have been genetically selected to tolerate high salt, are not productive in saline soil. Research on the molecular aspects of salt tolerance suggests that mutations in membrane transport proteins confer salt tolerance. Biologists genetically engineered a salt-tolerant variety of *Arabidopsis* to overexpress a single gene that codes for a sodium transport protein in the vacuolar membrane. These plants can store large quantities of sodium in their vacuoles, thereby tolerating saline soils.

Review

- What are the four components of soil, and how is each important to plants?
- What is cation exchange?
- How do weathering processes convert rock into soil?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Distinguish between taproot and fibrous root systems (page 749).

- A **taproot** system has one main root (formed from the radicle), from which many lateral roots extend.
- A **fibrous root** system has several to many **adventitious roots** of the same size developing from the end of the stem. Lateral roots branch from these adventitious roots.

ThomsonNOW™ Learn more about root systems by clicking on the figure in ThomsonNOW.

2 Label cross sections of a primary eudicot root and a monocot root, and describe the functions of each tissue (page 749).

- Primary roots have an epidermis, ground tissues (cortex and, in certain roots, pith), and vascular tissues (xylem and phloem). Each root tip is covered by a **root cap,** a protective layer that covers the delicate root **apical meristem** and may orient the root so that it grows downward.
- **Epidermis** protects the root. **Root hairs,** short-lived extensions of epidermal cells, aid in absorption of water and dissolved minerals.
- **Cortex** consists of parenchyma cells that often store starch. **Endodermis,** the innermost layer of the cortex, regulates the movement of water and minerals into the root xylem. Cells of the endodermis have a **Casparian strip** around their radial and transverse walls that is impermeable to water and dissolved minerals. Minerals are actively transported through carrier proteins in the plasma membranes of endodermal cells.
- Pericycle, xylem, and phloem collectively make up the root's **stele,** or **vascular cylinder. Pericycle** gives rise to lateral roots and lateral meristems. **Xylem** conducts water and dissolved minerals; **phloem** conducts dissolved sugar.
- Xylem of a herbaceous eudicot root forms a solid core in the center of the root. The center of a monocot root often consists of **pith** surrounded by a ring of alternating bundles of xylem and phloem. Monocot roots lack a **vascular cambium** and do not have secondary growth.

3 Trace the pathway of water and mineral ions from the soil through the various root tissues, and distinguish between the symplast and apoplast (page 749).

- As water and dissolved mineral ions move from the soil into the root, they pass through the following tissues: root hair/epidermis ⟶ cortex ⟶ endodermis ⟶ pericycle ⟶ root xylem.
- Water and dissolved minerals move through the epidermis and cortex along one of two pathways, the **apoplast** (along the interconnected porous cell walls) or the **symplast** (from one cell's cytoplasm to the next through **plasmodesmata**).

ThomsonNOW™ Explore the pathways of water and dissolved minerals in the root by clicking on the figures in ThomsonNOW.

4 Discuss the structure of roots with secondary growth (page 749).

- Roots of gymnosperms and woody eudicots develop secondary tissues (wood and bark). The production of secondary tissues is the result of the activity of two lateral meristems, the vascular cambium and cork cambium. The vascular cambium produces secondary xylem (wood) and secondary phloem (inner bark). The **cork cambium** produces **periderm** (outer bark).

5 Describe at least three roots that are modified to perform uncommon functions (page 749).

- **Prop roots** develop from branches or from a vertical stem and grow downward into the soil to help support certain plants in an upright position. **Buttress roots** are swollen bases or braces that support certain tropical rainforest trees that have shallow root systems.
- **Pneumatophores** are aerial "breathing" roots that may assist in getting oxygen to submerged roots.
- Certain epiphytes have roots modified to photosynthesize, absorb moisture, or, if parasitic, penetrate host tissues.

6 List and describe two mutualistic relationships between roots and other organisms (page 756).

- **Mycorrhizae** are mutually beneficial associations between roots and soil fungi.
- Root **nodules** are swellings that develop on roots of leguminous plants and house millions of **rhizobia** (nitrogen-fixing bacteria).

7 Describe the roles of weathering, organisms, climate, and topography in soil formation (page 757).

- Factors influencing soil formation include parent material (type of rock), climate, organisms, the passage of time, and topography. Most soils are formed from parent material that is broken into smaller and smaller particles by **weathering processes.** Climate and organisms work together in weathering rock.
- Soil organisms such as plants, algae, fungi, worms, insects, spiders, and bacteria are important not only in forming soil but also in cycling minerals.
- Topography, a region's surface features, affects soil formation. Steep slopes have little or no soil on them, whereas moderate slopes often have deep soils.

8 List the four components of soil, and give the ecological significance of each (page 757).

- Soil is composed of inorganic minerals, organic matter, air, and water. Inorganic minerals provide anchorage and essential minerals for plants. Organic matter increases

the soil's water-holding capacity and, as it decomposes, releases essential minerals into the soil. Soil air provides oxygen for soil organisms to use during aerobic respiration. Soil water provides water and dissolved minerals to plants and other organisms.

9 Describe how roots absorb positively charged mineral ions by the process of cation exchange (page 757).

- **Cations,** positively charged mineral ions, are attracted and reversibly bound to clay particles, which have predominantly negative charges on their outer surfaces. In **cation exchange,** roots secrete protons (H^+), which are exchanged for other positively charged mineral ions, freeing them into the soil water to be absorbed by roots.

10 Distinguish between macronutrients and micronutrients (page 757).

- Plants require 19 essential elements for normal growth. Ten elements are **macronutrients:** carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon. Macronutrients are required in fairly large quantities.
- Nine elements are **micronutrients:** chlorine, iron, boron, manganese, sodium, zinc, copper, nickel, and molybdenum. Micronutrients are needed in trace amounts.

11 Explain the impacts of mineral depletion and soil erosion on plant growth (page 757).

- Mineral depletion may occur in soils that are farmed because the natural pattern of nutrient cycling is disrupted when crops are harvested (and not allowed to decompose into the soil).
- **Soil erosion** is the removal of soil from the land by the actions of agents such as water and wind. Erosion causes a loss in soil fertility, because essential minerals and organic matter that are a part of the soil are removed.

TEST YOUR UNDERSTANDING

1. One main root, formed from the enlarging embryonic root, with many smaller lateral roots branching off it is a(an) (a) fibrous root system (b) adventitious root system (c) taproot system (d) storage root system (e) prop root system
2. Roots produced at unusual places on the plant are (a) fibrous (b) adventitious (c) taproots (d) rhizobial (e) mycorrhizae
3. Root hairs (a) cover and protect the delicate root apical meristem (b) increase the absorptive capacity of roots (c) secrete a waxy cuticle (d) orient the root so it grows downward (e) store excess sugars produced in the leaves
4. Certain plants adapted to flooded soil produce aerial "breathing" roots known as (a) fibrous roots (b) pneumatophores (c) mycorrhizae (d) nodules (e) prop roots
5. Unlike stems, roots produce (a) nodes and internodes (b) root caps and internodes (c) axillary buds and root hairs (d) terminal buds and axillary buds (e) root caps and root hairs
6. The waterproof region around the radial and transverse walls of endodermal cells is the (a) Casparian strip (b) pericycle (c) apoplast (d) symplast (e) pneumatophore
7. The apoplast is (a) a layer of cells that surround the vascular region in roots (b) the layer of cells just inside the endodermis (c) a system of interconnected plant cell walls through which water moves (d) the central cylinder of the root that comprises the vascular tissues (e) a continuum of cytoplasm of many cells, all connected by plasmodesmata
8. Plants obtain positively charged mineral ions from clay particles in the soil by cation exchange, in which (a) roots passively absorb the positively charged mineral ions (b) mineral ions flow freely along porous cell walls (c) roots secrete protons, which free other positively charged mineral ions to be absorbed by roots (d) the Casparian strip effectively blocks the passage of water and mineral ions along the endodermal cell wall (e) a well-developed system of internal air spaces in the root allows both gas exchange and cation exchange
9. The cell layer from which lateral roots originate is the (a) epidermis (b) cortex (c) endodermis (d) pericycle (e) vascular cambium
10. The center of a herbaceous eudicot root is composed of _____, whereas the center of a monocot root is composed of _____. (a) pith; cortex (b) xylem; phloem (c) phloem; xylem (d) xylem; pith (e) pith; xylem
11. Mutually beneficial associations between certain soil fungi and the roots of most plant species are called (a) mycorrhizae (b) pneumatophores (c) nodules (d) rhizobia (e) humus
12. Which of the following statements about soil is *true?* (a) pore spaces are always filled with about 50% air and 50% water (b) a single teaspoon of fertile agricultural soil may contain up to several hundred living microorganisms (c) the texture of a soil is determined by the soil's pH (d) a soil's organic matter includes litter, droppings, and the dead remains of plants, animals, and microorganisms (e) soil formation is unaffected by a region's climate or topography
13. The technique of growing plants in aerated water containing dissolved mineral salts is known as (a) hydration (b) hydroponics (c) hydrophilic (d) hydrostatic (e) hydrolysis
14. Carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon are collectively known as (a) micronutrients (b) microvilli (c) micronuclei (d) macronuclei (e) macronutrients
15. In roots of woody plants, (a) xylem does not form the central tissue of the root (b) the cortex composes the bulk of the root (c) the vascular cambium gives rise to secondary xylem and secondary phloem (d) the pericycle gives rise to the apical meristem (e) secondary growth occurs despite the lack of a vascular cambium
16. Corn, sorghum, red mangrove, and banyan are plants that have (a) prop roots (b) buttress roots (c) pneumatophores (d) storage roots (e) root nodules

CRITICAL THINKING

1. A mesquite root is found penetrating a mine shaft about 46 m (150 ft) below the surface of the soil. How could you determine *when* the root first grew into the shaft? (*Hint:* Mesquite is a woody plant.)
2. How would you distinguish between a root hair and a small lateral root?
3. You are given a plant part that was found growing in the soil and are asked to determine whether it is a root or an underground stem. How would you identify the structure without a microscope? With a microscope?
4. How would you design an experiment to determine whether gold is essential for plant growth? What would you use for an experimental control?
5. Why does overwatering a plant often kill it?
6. Explain why, once secondary growth has occurred, that portion of the root is no longer involved in absorption. Where does absorption of water and dissolved minerals occur in plants that have roots with secondary growth?
7. **Evolution Link.** A barrel cactus that is 60 cm tall and 30 cm in diameter has roots more than 3 m long. However, all the plant's roots are found in the soil at a depth of 5 to 15 cm. What possible adaptive value does such a shallow root system confer on a desert plant?

Reproduction in Flowering Plants

Dr. Jeremy Burgess/Science Photo Library/Photo Researchers, Inc.

Flower of the common chickweed. This plant (*Stellaria media*) is a weedy annual native to Europe but widespread in North America. Each flower has five green sepals, five deeply notched yellow petals, three to five pollen-bearing stamens (this flower has three), and a single pistil.

KEY CONCEPTS

The flower is the site of sexual reproduction in angiosperms.

A typical flower consists of four whorls: sepals, petals, stamens, and carpels.

Pollen grains are transported to stigmas by a variety of agents, such as animals and wind.

Double fertilization results in a plant embryo and endosperm.

The seed is a mature ovule, and the fruit is a mature ovary.

Many vegetative organs (roots, stems, and leaves) have evolved modifications for reproducing asexually.

Flowering plants, or **angiosperms,** include about 300,000 species and are the largest, most successful group of plants. You may have admired flowers for their fragrances as well as their appealing colors and varied shapes (see photograph). The biological function of flowers is sexual reproduction. Their colors, shapes, and fragrances increase the likelihood that pollen grains, which produce sperm cells, will be carried from one plant to another. Sexual reproduction in plants includes *meiosis* and the fusion of reproductive cells—egg and sperm cells, collectively called **gametes.** The union of gametes, called *fertilization,* occurs within the flower's ovary.

Sexual reproduction offers the advantage of new gene combinations, not found in either parent, that may make an individual plant better suited to its environment. These new combinations result from the crossing-over and independent assortment of chromosomes that occur during meiosis, before the production of egg and sperm cells (see Chapter 11).

Many flowering plants also reproduce asexually. Asexual reproduction often does not involve the formation of flowers, seeds, and fruits. Instead, offspring generally form when a vegetative organ (such as a stem, root, or leaf) expands, grows, and then becomes separated from the rest of the plant, often by the death of tissues. Because asexual reproduction requires only one parent and no meiosis or fusion of gametes occurs, the offspring of asexual reproduction are virtually genetically identical to one another and to the parent plant from which they came.[1]

[1]Somatic mutations can result in some variability among asexually derived offspring.

This chapter examines both sexual and asexual reproduction in flowering plants, including floral adaptations that are important in pollination; seed and fruit structure and dispersal; germination and early growth; and several kinds of asexual reproduction. We conclude with a discussion of the evolutionary advantages and disadvantages of sexual and asexual reproduction. ■

THE FLOWERING PLANT LIFE CYCLE

Learning Objectives

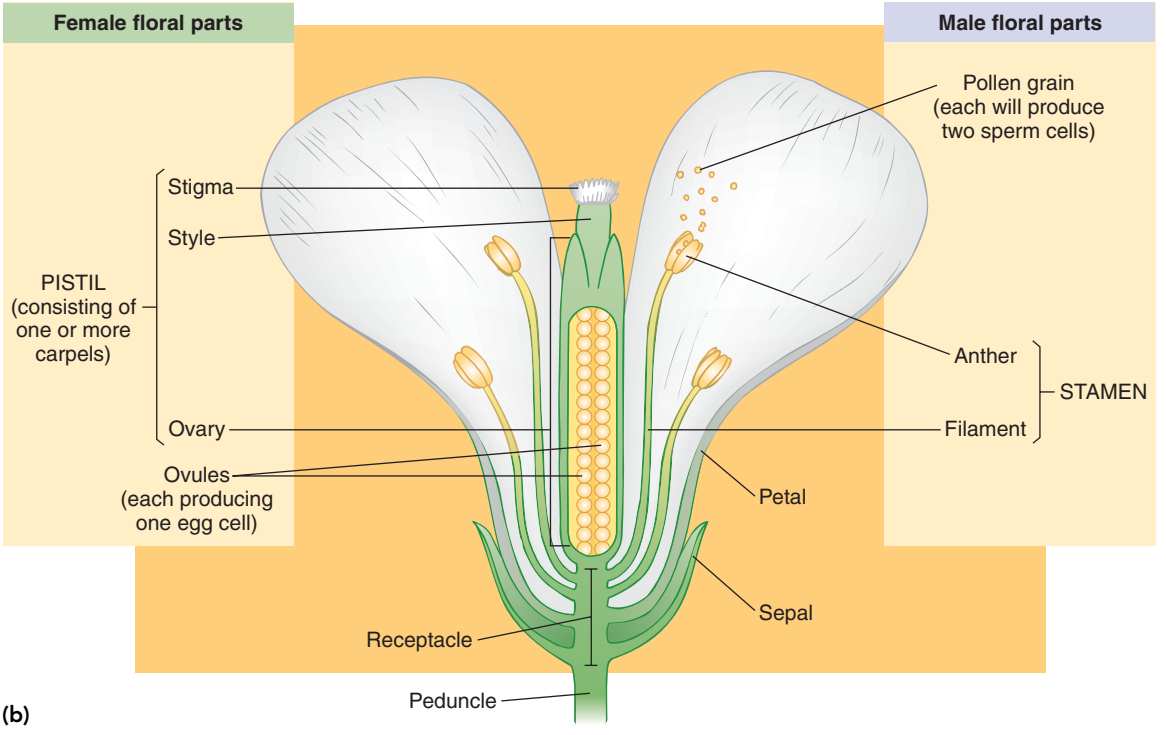
1 Describe the functions of each part of a flower.
2 Identify where eggs and pollen grains are formed within the flower.

In Chapters 27 and 28 you learned that angiosperms and other plants undergo a cyclic **alternation of generations** in which they spend a portion of their life cycle in a multicellular haploid stage and a portion in a multicellular diploid stage. The haploid portion, called the **gametophyte generation,** gives rise to gametes by mitosis. When two gametes fuse during **fertilization,** the diploid portion of the life cycle, called the **sporophyte generation,** begins. The sporophyte generation produces haploid spores by meiosis. Each spore has the potential to give rise to a gametophyte plant, and the cycle continues.

In flowering plants the diploid sporophyte generation is larger and nutritionally independent. The haploid gametophyte generation, which is located in the flower, is microscopic and nutritionally dependent on the sporophyte. We say more about alternation of generations in flowering plants after our discussion of the role of flowers as reproductive structures. It may be helpful for you to review Figure 28-13, which shows the main stages in the flowering plant life cycle.

Darwin Dale/Photo Researchers, Inc.

(a)



(b)

Figure 36-1 ***Animated*** Floral structure

(a) An *Arabidopsis thaliana* flower. **(b)** Cutaway view of an *Arabidopsis* flower. Each flower has four sepals (*two are shown*), four petals (*two are shown*), six stamens, and one long pistil. Four of the stamens are long, and two are short (*two long and two short are shown*). Pollen grains develop within sacs in the anthers. In *Arabidopsis,* the compound pistil consists of two carpels that each contain numerous ovules.

Flowers develop at apical meristems

How does a plant "know" it is time to start forming flowers? Correct timing in the switch from vegetative to reproductive development is crucial to ensure reproductive success. What happens, for example, if a plant flowers so late in the season that it does not have enough time to set seed before winter? A variety of environmental cues, such as temperature and day length, ensure proper timing, and different species are adapted to respond to distinct environmental cues. These environmental signals interact with a variety of plant hormones and developmental pathways.

In recent years some biologists have focused on the molecular aspects of developmental pathways that initiate flowering in the model organism *Arabidopsis.* When environmental conditions induce flowering, many genes are activated or inactivated. One gene, the *Flowering Locus C (FLC)* gene, codes for a **transcription factor** that represses flowering. Another gene, called *Flowering Locus D (FLD)* gene, codes for a protein that removes acetyl groups from histones in the chromatin where the *FLC* gene is located. When deacetylation occurs, the *FLC* gene is not transcribed (that is, the repressive transcription factor is not produced), and the shoot apical meristem undergoes a transition from vegetative growth to reproductive growth. It is intriguing that the plant FLD protein is homologous to a mammalian protein that also removes acetyl groups from chromatin.

Other genes are also involved in the initiation of flowering, and this area remains a focus of research interest. In Chapter 37 we discuss further the initiation of flowering.

Each part of a flower has a specific function

Flowers are reproductive shoots, usually consisting of four kinds of organs—sepals, petals, stamens, and carpels—arranged in whorls (circles) on the end of a flower stalk (Fig. 36-1; also see Fig. 28-11). In flowers with all four organs, the normal order of whorls from the flower's periphery to the center (or from the flower's base upward) is as follows:

Sepals ⟶ petals ⟶ stamens ⟶ carpels

The tip of the stalk enlarges to form a **receptacle** on which some or all of the flower parts are borne. All four floral parts are important in the reproductive process, but only the stamens (the "male" organs) and carpels (the "female" organs) participate directly in sexual reproduction—sepals and petals are sterile.

Sepals, which constitute the outermost and lowest whorl on a floral shoot, cover and protect the flower parts when the flower is a bud. Sepals are leaflike in shape and form and are often green. Some sepals, such as those in lily flowers, are colored and resemble petals (Fig. 36-2). The collective term for all the sepals of a flower is **calyx.**

The whorl just inside and above the sepals consists of **petals,** which are broad, flat, and thin (like sepals and leaves) but tremendously varied in shape and frequently brightly colored, which attracts pollinators. Petals play an important role in ensuring that sexual reproduction will occur. Sometimes petals fuse to form a tube or other floral shape. The collective term for all the petals of a flower is **corolla.**

M. P. Land/Science Photo Library/Photo Researchers, Inc.

Figure 36-2 Lily flower

In lily (*Lilium*) the three sepals and three petals are similar in size and color.

Just inside and above the petals are the **stamens,** the male reproductive organs. Each stamen has a thin stalk, called a **filament,** at the top of which is an **anther,** a saclike structure in which **pollen grains** form. For sexual reproduction to occur, pollen grains must be transferred from the anther to the female reproductive structure (the carpel), usually of another flower of the same species. At first, each pollen grain consists of two cells surrounded by a tough outer wall. One cell, the **generative cell,** divides mitotically to form two nonflagellate male gametes, known as *sperm cells.* The other cell, the **tube cell,** produces a **pollen tube,** through which the sperm cells travel to reach the ovule.

One or more **carpels,** the female reproductive organs, are located in the center or top of most flowers. Carpels bear **ovules,** which are structures with the potential to develop into seeds. The carpels of a flower may be separate or fused into a single structure. The female part of the flower, often called a **pistil,** may be a single carpel (a *simple pistil*) or a group of fused carpels (a *compound pistil*) (see Fig. 28-12). Each pistil has three sections: a **stigma,** on which the pollen grains land; a **style,** a necklike structure through which the pollen tube grows; and an **ovary,** a juglike structure that contains one or more ovules and can develop into a fruit.

Female gametophytes are produced in the ovary, male gametophytes in the anther

Before we proceed, it may be helpful to relate the stages in alternation of generations to floral structure. As discussed in Chapters 27 and 28, angiosperms and certain other plants are heterosporous and produce two kinds of spores: megaspores and microspores (Fig. 36-3).

Each young ovule within an ovary contains a diploid cell, the *megasporocyte,* which undergoes meiosis to produce four haploid **megaspores.** Three of these usually disintegrate, and the fourth, the functional megaspore, divides mitotically to produce a multicellular **female gametophyte,** also called an *embryo sac.* The fe-

Key Point

In alternation of generations in flowering plants, the female and male gametophytes are microscopic and nutritionally dependent on the sporophyte plant.

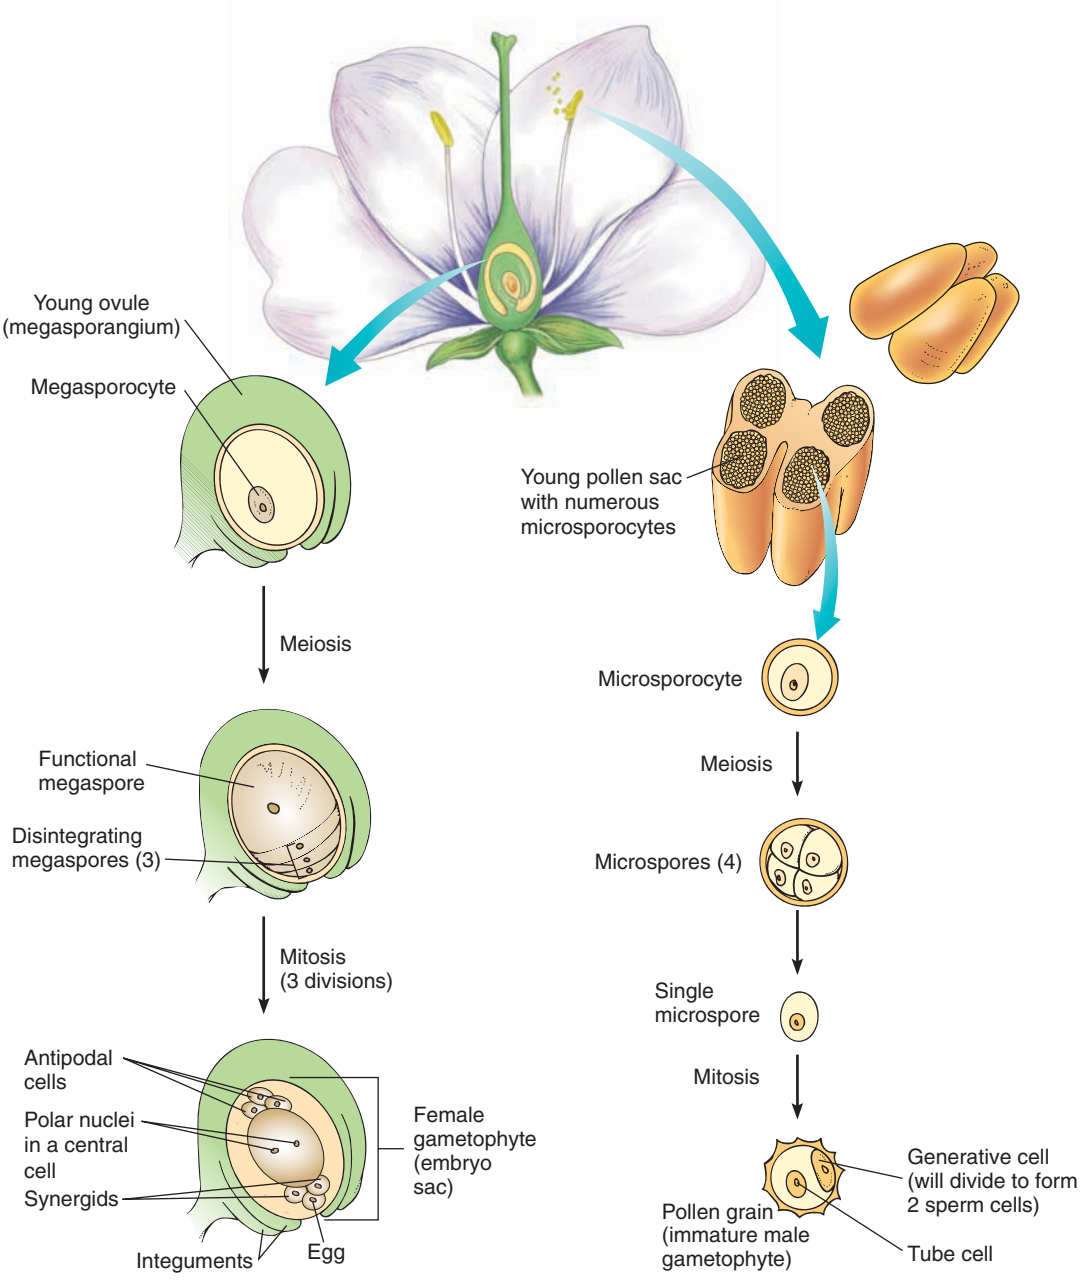


Figure 36-3 ***Animated*** Development of female and male gametophytes

(*Left side*) The female gametophyte, or embryo sac, develops within the ovule. (*Right side*) The immature male gametophytes, or pollen grains, develop within pollen sacs in the anthers. Each male gametophyte becomes mature when its generative cell divides mitotically to produce two sperm cells.

male gametophyte, which is embedded in the ovule, typically contains seven cells with eight haploid nuclei. Six of these cells, including the egg cell (the female gamete), contain a single nucleus each; a large central cell has two nuclei, called **polar nuclei.** The egg and both polar nuclei participate directly in fertilization.

Pollen sacs within the anther contain numerous diploid cells called *microsporocytes,* each of which undergoes meiosis to produce four haploid cells called **microspores.** Each microspore divides mitotically to produce an immature male gametophyte, also called a pollen grain, that consists of two cells, the tube cell

and the generative cell. The pollen grain becomes mature when its generative cell divides to form two nonmotile sperm cells.

Review

- How do petals differ from sepals? How are they similar?
- How do stamens differ from carpels? How are they similar?
- What are female gametophytes, and where are they formed?
- What are male gametophytes, and where are they formed?

POLLINATION

Learning Objectives

3 Compare the evolutionary adaptations that characterize flowers pollinated in different ways (by insects, birds, bats, and wind).

4 Define *coevolution,* and give examples of ways that plants and their animal pollinators have affected one another's evolution.

Before fertilization can occur, pollen grains must travel from the anther (where they form) to the stigma. The transfer of pollen grains from anther to stigma is known as **pollination.** Plants are *self-pollinated* if pollination occurs within the same flower or a different flower on the same individual plant. When pollen grains are transferred to a flower on another individual of the same species, the plant is *cross-pollinated.* Flowering plants accomplish pollination in a variety of ways. Beetles, bees, flies, butterflies, moths, wasps, and other insects pollinate many flowers. Animals such as birds, bats, snails, and small nonflying mammals (rodents, primates, and marsupials) also pollinate plants. Wind is an agent of pollination for certain flowers; and water, for a few aquatic flowers.

Many plants have mechanisms to prevent self-pollination

In plant sexual reproduction, the two gametes that unite to form a zygote may be from the same parent or from two different parents. The combination of gametes from two different parents increases the variation in offspring, and this variation may confer a selective advantage. Some offspring, for example, may be able to survive environmental changes better than either parent can.

Plants have evolved a variety of mechanisms that prevent self-pollination and thus prevent **inbreeding,** which is the mating of genetically similar individuals. Inbreeding can increase the concentration of harmful genes in the offspring. Some plants, such as asparagus and willow, have separate male and female individuals; the male plants have staminate flowers that lack carpels, and the female plants have pistillate flowers that lack stamens. Other species have flowers with both stamens and pistils, but the pollen is shed from a given flower either before or after the time when the stigma of that flower is receptive to pollen. These characteristics promote **outcrossing** (also called outbreeding), which is the mating of dissimilar individuals.

Many species have genes for **self-incompatibility,** a genetic condition in which the pollen is ineffective in fertilizing the same flower or other flowers on the same plant. In other words, an individual plant can identify and reject its own pollen. Genes for self-incompatibility usually inhibit the growth of the pollen tube in the stigma and style, thereby preventing delivery of sperm cells to the ovules. Self-incompatibility, which is more common in wild species than in cultivated plants, ensures that reproduction occurs only if the pollen comes from a genetically different individual.

In plants such as oilseed rape, self-incompatibility is based on a high degree of variation at a particular locus called the *S* locus; the many alleles at this locus are designated S_1, S_2, S_3, S_4, and so on. Here is an example of how the *S* locus blocks self-fertilization: A plant with the genotype S_1S_2 produces pollen grains that land on a stigma of another plant with the genotype S_1S_3. In this case, the presence of the S_1 allele in both the pollen and stigma triggers a self-recognition signaling cascade in surface cells of the stigma. As a result, the stigma cells do not undergo changes that allow the pollen grain to grow a pollen tube. Therefore, fertilization does not occur.

The molecular basis of self-incompatibility in *Arabidopsis* and related plants is an area of active scientific interest. *Arabidopsis* can self-pollinate. Biologists have determined that the genes involved in self-incompatibility and outcrossing exist in *Arabidopsis* but have undergone mutations so that they are no longer functional. Thus, it appears that self-incompatibility in these plants is the ancestral (normal) condition.

Flowering plants and their animal pollinators have coevolved

Animal pollinators and the plants they pollinate have had such close, interdependent relationships over time that they have affected the evolution of certain physical and behavioral features in one another. The term **coevolution** describes such reciprocal adaptation, in which two species interact so closely that they become increasingly adapted to one another as they each undergo evolutionary change by *natural selection.* We now examine some of the features of flowers and their pollinators that may be the products of coevolution.

Flowers pollinated by animals have various features to attract their pollinators, including showy petals (a visual attractant) and scent (an olfactory attractant). One reward for the animal pollinator is food. Some flowers produce nectar, a sugary solution, in special floral glands called *nectaries.* Pollinators use nectar as an energy-rich food. Pollen grains are also a protein-rich food for many animals. As they move from flower to flower searching for food, pollinators inadvertently carry along pollen grains on their body parts, helping the plants reproduce sexually (Fig. 36-4).

Biologists estimate that insects pollinate about 70% of all flowering plant species. Bees are particularly important as pollinators of crop plants. Crops pollinated by bees provide about 30% of human food. Plants pollinated by insects often have blue or yellow petals (see Fig. 36-4a). The insect eye does not see color

Dr. John Brackenbury/Science Photo Library/Photo Researchers, Inc.

(a) A honeybee (*Apis mellifera*) pollinates a Scotch broom flower (*Cytisus scoparius*). When the bee presses in to obtain nectar, the stamens spring out, dropping pollen grains on the bee's body.

(b) A ruby-throated hummingbird (*Archilochus colubris*) obtains nectar from a trumpet vine flower (*Campsis radicans*). The pollen grains on the bird's feathers are carried to the next plant.

© Merlin Tuttle/Bat Conservation International/Photo Researchers, Inc.

(c) A lesser longnosed bat (*Leptonycteris curasoae*) obtains nectar from a cardon cactus flower (*Pachycereus*) and transfers pollen as it moves from flower to flower. Bats pollinate several hundred species of plants.

Figure 36-4 Animal pollinators

the same way the human eye does. Most insects see well in the violet, blue, and yellow range of visible light but do not perceive red as a distinct color. So flowers pollinated by insects are not usually red. Insects also see in the ultraviolet range, wavelengths that are invisible to the human eye. Insects see ultraviolet radiation as a color called *bee's purple.* Many flowers have dramatic UV markings that may or may not be visible to humans but that direct insects to the center of the flower where the pollen grains and nectar are (Fig. 36-5).

Insects have a well-developed sense of smell, and many insect-pollinated flowers have a strong scent that may be pleasant or foul to humans. The carrion plant, for example, is pollinated by flies and smells like the rotting flesh in which flies lay their eggs. As flies move from one reeking flower to another looking for a place to lay their eggs, they transfer pollen grains.

Birds such as hummingbirds are important pollinators (see Fig. 36-4b). Flowers pollinated by birds are usually red, orange, or yellow, because birds see well in this range of visible light. Because most birds do not have a strong sense of smell, bird-pollinated flowers usually lack a scent.

Bats, which feed at night and do not see well, are important pollinators, particularly in the tropics (see Fig. 36-4c). Bat-pollinated flowers bloom at night and have dull white petals and a strong nighttime output of scent that usually smells like fermented fruit. Nectar-feeding bats are attracted to the flowers by the scent; they lap up the nectar with their long, extendible tongues. As they move from flower to flower, they transfer pollen grains. An unusual adaptation that encourages pollination by bats has evolved in the tropical vine *Mucana holtonii.* When the pollen in a given flower is mature, a concave petal lifts up. The petal bounces the echo from the bat's echo-locating calls back to the bat, helping it find the flower.

Specialized features such as petals, scent, and nectar to attract pollinators have coevolved with adaptations of animal pollinators. Specialized body parts and behaviors adapted animals to aid pollination as they obtain nectar and pollen grains as a reward. For example, coevolution has selected for bumblebees' hairy bodies, which catch and hold the sticky pollen grains for transport from one flower to another.

Coevolution may have led to the long, curved beaks of the ʻiʻiwi, one of the Hawaiian honeycreepers, that inserts its beak into tubular flowers to obtain nectar (see Figs. 1-11b and 20-16). The long, tubular corolla of the flowers that ʻiʻiwis visit probably also came about through coevolution. During the 20th century, some of the tubular flower species (such as lobelias) became rare, largely as a result of grazing by nonnative cows and feral goats, and about 25% of lobelia species have become extinct. The ʻiʻiwi now feeds largely on the flowers of the ʻohiʻa tree, which lacks petals, and the ʻiʻiwi bill appears to be adapting to this change in feeding preference. Comparison of the bills of ʻiʻiwi museum

Thomas Eisner, Cornell University

(a) The evening primrose (*Oenothera* sp.) as seen by the human eye is solid yellow.

Thomas Eisner, Cornell University

(b) The same flower viewed under ultraviolet radiation provides clues about how the insect eye perceives it. The light blue portions of the petals appear purple to a bee, whereas the dark blue inner parts appear yellow.

Figure 36-5 ***Animated*** Ultraviolet markings on insect-pollinated flowers

These markings draw attention to the center of the flower, where the pollen grains and nectar are located.

specimens collected in 1902 with the bills of live birds captured in the 1990s showed that ʻiʻiwi bills were about 3% shorter in the 1990s than in 1902.

Plants and the behavior of their animal pollinators have coevolved, sometimes in bizarre and complex ways. The flowers of certain orchids (*Ophrys*) resemble female bees in coloring and shape (Fig. 36-6). The unpollinated flowers secrete a scent similar to that produced by female bees, and the males are irresistibly attracted to it. The resemblance between *Ophrys* flowers and female bees is so strong that male bees mount the flowers and try to copulate with them. During this *pseudocopulation,* a pollen sac usually attaches to the back of the bee. When the frustrated bee departs and tries to copulate with another orchid flower, pollen grains are transferred to that flower. Interestingly, once a flower has been pollinated, it emits a scent like that released by female bees that have already mated. Male bees have no interest in visiting flowers that have been pollinated (just as they lose interest in female bees that have already been inseminated).

Nuridsany et Perrenou/Photo Researchers, Inc.

Figure 36-6 An orchid flower that mimics bees, thereby accomplishing pollination

The woodcock orchid (*Ophrys scolopax*) attracts male bees with the similarity of its flowers to female bees and the production of a scent to which the males are irresistibly attracted. The woodcock orchid is native to southern Europe.

A single mutation in a gene for flower color can result in a shift in animal pollinators

Biologists used two species of monkey flowers, both native to western North America, to determine if a single gene mutation would have any effect on animal pollinators. The wild-type *Mimulus lewisii* has violet-pink flowers and is pollinated by bumblebees, whereas the closely related *M. cardinalis* has orange-red flowers and is pollinated by hummingbirds. Alleles at the same locus in both species affect flower color.

When the researchers transferred the allele for orange-red flowers from *M. cardinalis* to *M. lewisii,* the resulting *M. lewisii* flowers were yellow-orange instead of pink. These flowers were visited by 68 times as many hummingbirds as the wild-type *M. lewisii* flowers (Fig. 36-7). A shift in pollinators also occurred when *M. cardinalis* plants received the allele for pink flowers from *M. lewisii.* These *M. cardinalis* flowers were a dark pink in color and had 74 times as many bumblebee visits as the wild-type *M. cardinalis* flowers.

Biologists think that hummingbird-pollinated flowers arose from insect-pollinated flowers many times during the course of flowering plant evolution. These data suggest that a single gene

Key Experiment

QUESTION: Can a single-gene mutation in flower color affect animal pollinators?

HYPOTHESIS: If flower color is changed by a mutation, pollinator preferences for the resulting flower may change.

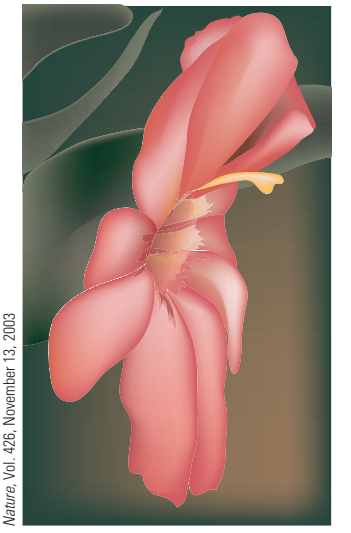
EXPERIMENT: *Mimulus lewisii* has violet-pink flowers and is pollinated by bumblebees; the closely related *M. cardinalis* has orange-red flowers and is pollinated by hummingbirds. Alleles at the same locus in both species affect flower color.

Researchers transferred the allele for orange-red flowers from *M. cardinalis* to *M. lewisii*, which then produced yellow-orange petals. They also transferred the allele for pink flowers from *M. lewisii* to *M. cardinalis*, which then produced dark pink petals.

Wild-type *M. lewisii*

Wild-type *M. cardinalis*

Altered *M. lewisii*



Altered *M. cardinalis*

RESULTS AND CONCLUSION: The modified *M. lewisii* flowers were yellow-orange in color and had 68 times as many hummingbird visits as the unaltered *M. lewisii* flowers. The modified *M. cardinalis* flowers had dark pink petals and were visited by 74 times as many bumblebees as the unaltered *M. cardinalis* flowers. Thus, a single mutation in a gene for flower color resulted in a shift in animal pollinators.

Figure 36-7 Studying how pollinator preferences may have evolved

Biologists H. D. Bradshaw Jr. from the University of Washington and Douglas Schemske from Michigan State University used monkey flowers to determine if a single gene mutation would have any effect on animal pollinators.

mutation affecting petal color could have been partly responsible for the pollinator shift that resulted in the evolution of two species, *M. lewisii* and *M. cardinalis*, from their insect-pollinated common ancestor.

Some flowering plants depend on wind to disperse pollen

Some flowering plants, such as grasses, ragweed, maples, and oaks, are pollinated by wind. Wind-pollinated plants produce many small, inconspicuous flowers (Fig. 36-8). They do not produce large, colorful petals, scent, or nectar. Some have large, feathery stigmas, presumably to trap wind-borne pollen grains. Because wind pollination is a hit-or-miss affair, the likelihood of a particular pollen grain landing on a stigma of the same species of flower is slim. Wind-pollinated plants produce large quantities of pollen grains, which increase the likelihood that some pollen grains will land on the appropriate stigma.

Review

- A flower has yellow petals, a pleasant scent, and sugary nectar. How is it probably pollinated?
- A flower has small, inconspicuous flowers without petals, a scent, or nectar. How is it probably pollinated?
- What is coevolution?

FERTILIZATION AND SEED/FRUIT DEVELOPMENT

Learning Objectives

5 Distinguish between pollination and fertilization.
6 Trace the stages of embryo development in flowering plants, and list and define the main parts of seeds.
7 Explain the relationships among the following: ovules, ovaries, seeds, and fruits.
8 Distinguish among simple, aggregate, multiple, and accessory fruits.

Once pollen grains have been transferred from anther to stigma, the tube cell, one of the two cells in the pollen grain, grows a thin pollen tube down through the style and into an ovule in the ovary. How does the pollen tube "know" where to grow? Scientists have found that molecular signals from the female gametophyte guide the growing pollen tube toward the ovule. A small protein appears to be the chemical attractant in corn, but this compound or something like it has yet to be identified in other plants.

Dr. Jeremy Burgess/Science Photo Library/Photo Researchers, Inc.

Figure 36-8 Wind pollination

Each cluster of male oak (*Quercus*) flowers dangles from a tree branch and sheds a shower of pollen when the wind blows. These flowers lack petals.

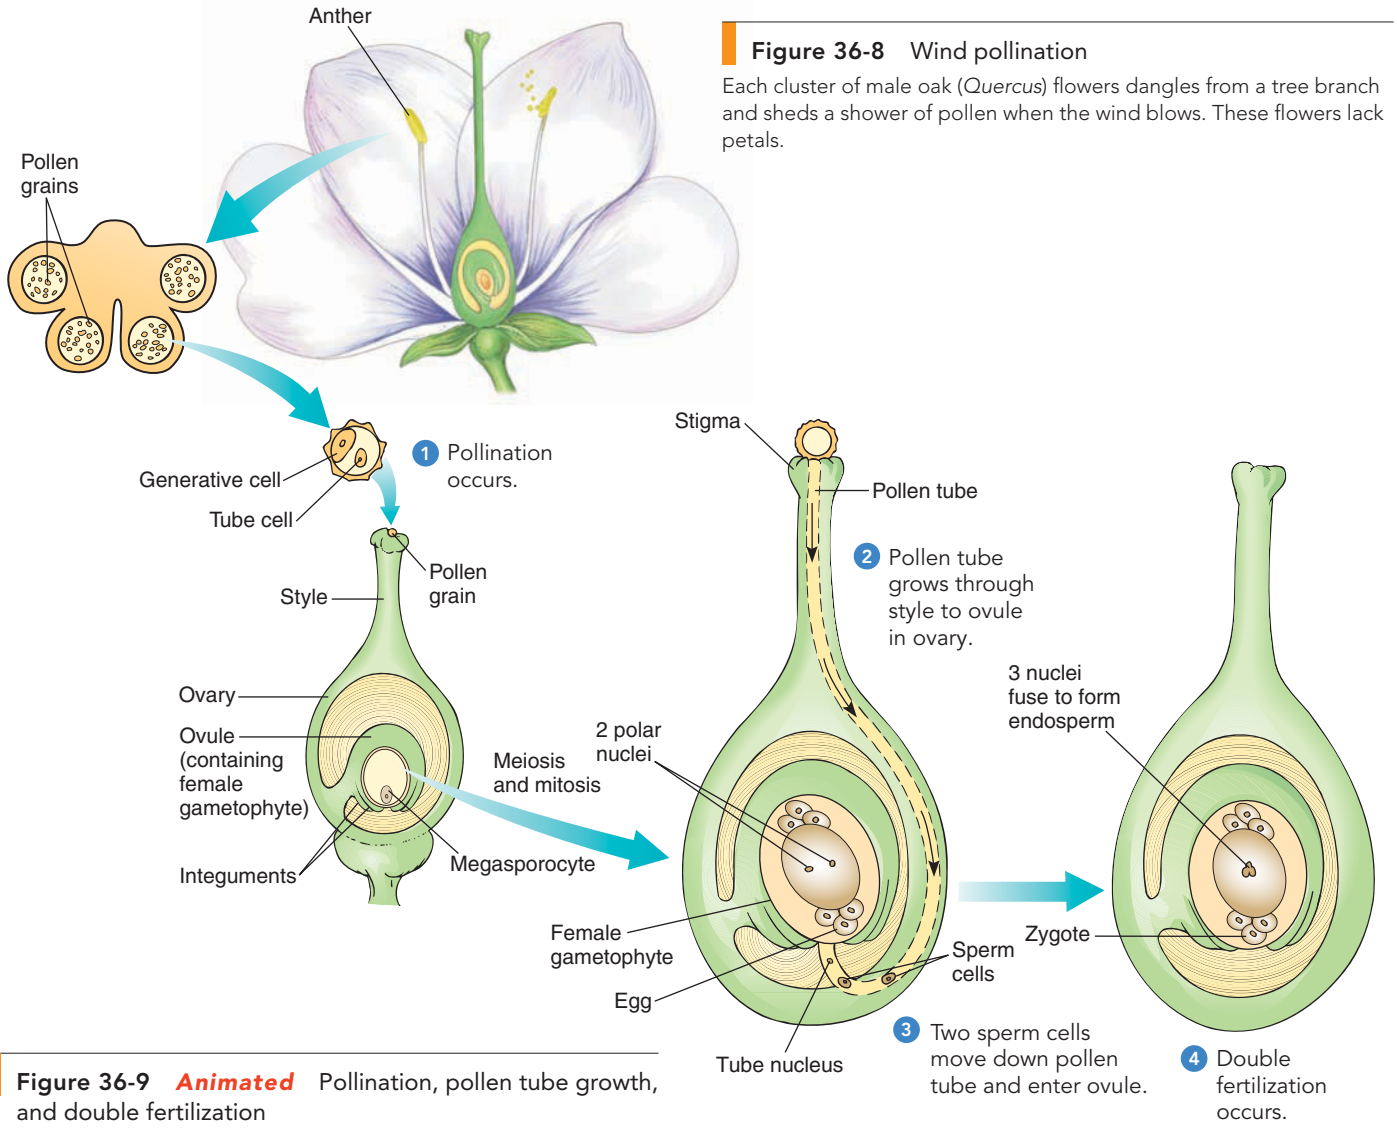


Figure 36-9 ***Animated*** Pollination, pollen tube growth, and double fertilization

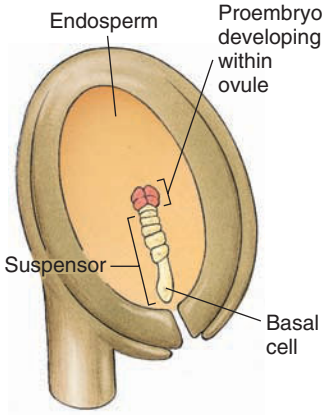
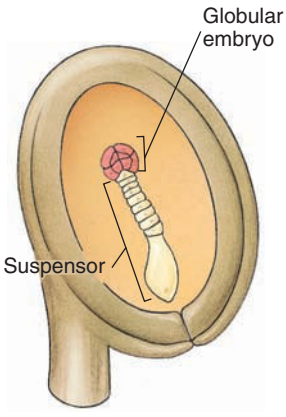
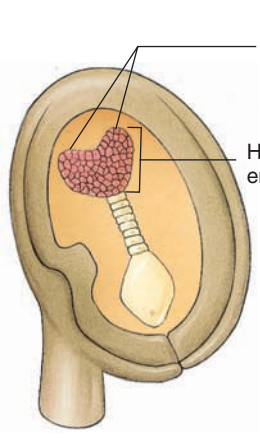


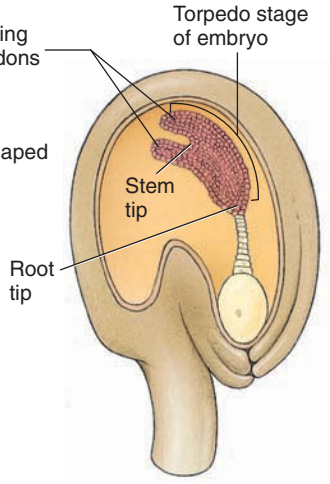
1 **Proembryo.** This is earliest multicellular stage of embryo.



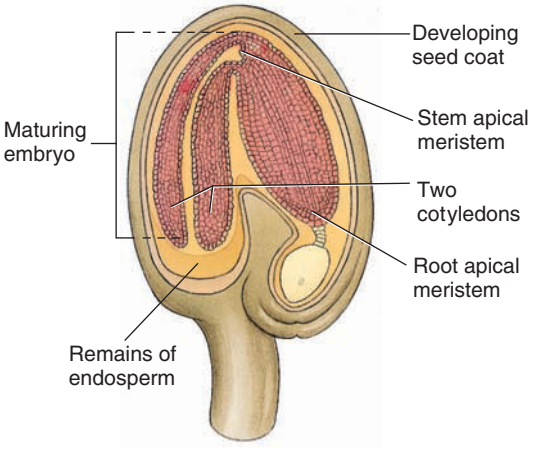
2 **Globular stage embryo.** As cell division continues, embryo becomes ball of cells.



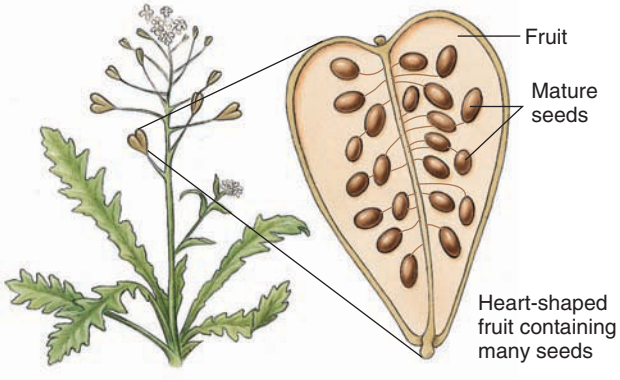
3 **Heart stage embryo.** As two cotyledons begin to emerge, embryo is shaped like heart.



4 **Torpedo stage embryo.** Cotyledons continue to elongate, forming torpedo stage.



5 **Maturing embryo within seed.** Food originally stored in endosperm has been almost completely depleted during embryonic growth and development, and most of food for embryonic plant is now stored in cotyledons.



6 **Fruit.** Longitudinal section through fruit of shepherd's purse reveals numerous tiny seeds, each containing mature embryo. Each seed developed from ovule.

Figure 36-10 ***Animated*** Embryonic development in shepherd's purse (*Capsella bursa-pastoris*)

The ovule is shown apart from the ovary in parts 1 to 5.

Once a pollen tube penetrates the ovule, the attracting signals are no longer produced. As a result, only one pollen tube enters each female gametophyte. The second cell within the pollen grain divides to form two male gametes (the sperm cells), which move down the pollen tube and enter the ovule (Fig. 36-9 on page 775).

A unique double fertilization process occurs in flowering plants

The egg within the ovule unites with one of the sperm cells, forming a zygote (fertilized egg) that develops into an embryonic plant contained in the future seed. The two polar nuclei in the central cell of the ovule fuse with the second sperm cell to form the first cell of the triploid ($3n$) **endosperm,** the tissue with nutritive and hormonal functions that surrounds the developing embryonic plant in the seed. This process, in which two separate cell fusions occur, is called **double fertilization.** It is, with few exceptions, unique to flowering plants. (A type of double fertilization has been reported in two gymnosperm species, *Ephedra nevadensis* and *Gnetum gnemon.*)

After double fertilization, the ovule develops into a *seed* and the surrounding ovary develops into a *fruit* (see discussion in Chapter 28).

Embryonic development in seeds is orderly and predictable

Flowering plants package a young plant embryo, complete with stored nutrients, in a compact **seed,** which develops from the ovule after fertilization. The nutrients in seeds are not only used

by *germinating* plant embryos but also eaten by animals, including humans. Development of the embryo and endosperm following fertilization is possible because of the constant flow of nutrients into the developing seed from the parent plant.

Cell divisions of the fertilized egg to form a multicellular embryo proceed in several ways in flowering plants. We describe eudicot embryonic development; monocot embryonic development is similar in the early stages.

The two cells (basal cell and apical cell) that are formed as a result of the first division of the fertilized egg establish *polarity,* or direction, in the embryo. The large **basal cell** (located toward the outside of the ovule) typically develops into a **suspensor,** an embryonic tissue that anchors the developing embryo and aids in nutrient uptake from the endosperm. The **apical cell** (toward the inside of the ovule) develops into the plant embryo. Scientists are currently studying molecular differences between the apical cell and basal cell to determine the initial molecular signals that are involved in establishing polarity.

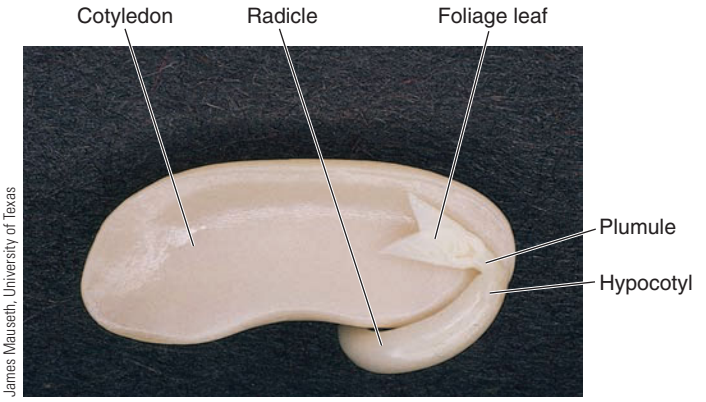
Initially, the apical cell divides to form a small cluster of cells, called a *proembryo* (Fig. 36-10). As cell division continues, a sphere of cells, often called a *globular embryo,* develops. Cells begin to develop into specialized tissues during this stage. When the eudicot embryo starts to develop its two cotyledons (seed leaves), it has two lobes and resembles a heart; this is often called the *heart stage.* During the *torpedo stage,* the embryo continues to grow as the cotyledons elongate. As the embryo enlarges, it often curves back on itself and crushes the suspensor.

The mature seed contains an embryonic plant and storage materials

A mature seed contains an embryonic plant and food (stored in the cotyledons or endosperm), surrounded by a tough, protective **seed coat** derived from the **integuments,** which are the outermost layers of an ovule. The seed, in turn, is enclosed within a fruit.

The mature embryo within the seed consists of a short embryonic root, or **radicle;** an embryonic shoot; and one or two seed leaves, or **cotyledons** (Fig. 36-11). Monocots have a single cotyledon, whereas eudicots have two. The short portion of the embryonic shoot connecting the radicle to one or two cotyledons is the **hypocotyl.** The shoot apex, or terminal bud, located above the point of attachment of the cotyledon(s) is the **plumule.** After the radicle, hypocotyl, cotyledon(s), and plumule have formed, the young plant's development is arrested, usually by desiccation (drying out) or **dormancy** (a temporary state of arrested physiological activity). When conditions are right for continuing the developmental program, the seed **germinates,** or sprouts, and the embryo resumes growth.

Because the embryonic plant is nonphotosynthetic, it must be nourished during germination until it becomes photosynthetic and therefore self-sufficient. The cotyledons of many plants function as storage organs and become large, thick, and fleshy as they absorb the food reserves (starches, oils, and proteins) initially produced as endosperm. Seeds that store nutrients in cotyledons have little or no endosperm at maturity. Examples of such seeds are peas, beans, squashes, sunflowers, and peanuts. Other plants—wheat and corn, for example—have thin cotyledons that function primarily to help the young plant digest and absorb food stored in the endosperm. (See Chapter 37 for a discussion of seed germination and early growth.)



James Mauseth, University of Texas

Figure 36-11 Seed structure

A bean seed has been dissected—its seed coat and one of its two cotyledons were removed—to show the radicle, hypocotyl, remaining cotyledon, and plumule with its foliage leaf at the shoot apex. This particular seed had begun germinating, so its radicle is larger than in an ungerminated seed.

Fruits are mature, ripened ovaries

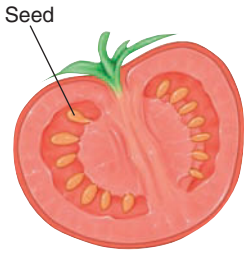
After double fertilization takes place within the ovule, the ovule develops into a seed, and the ovary surrounding it develops into a **fruit.** For example, a pea pod is a fruit, and the peas within it are seeds. A fruit may contain one or more seeds; some orchid fruits contain several thousand to a few million seeds! Fruits provide protection for the enclosed seeds and sometimes aid in their dispersal.

There are several types of fruits; their differences result from variations in the structure or arrangement of the flowers from which they were formed. The four basic types of fruits—simple fruits, aggregate fruits, multiple fruits, and accessory fruits—are summarized in Figure 36-12.

Most fruits are simple fruits. A **simple fruit** develops from a single ovary, which may consist of a single carpel or several fused carpels. At maturity, simple fruits may be fleshy or dry. Two examples of simple, fleshy fruits are berries and drupes. A **berry** is a fleshy fruit that has soft tissues throughout and contains few to many seeds; a blueberry is a berry, as are grapes, cranberries, bananas, and tomatoes. Many so-called berries do not fit the botanical definition. Strawberries, raspberries, and mulberries, for example, are not berries; these three fruits are discussed shortly.

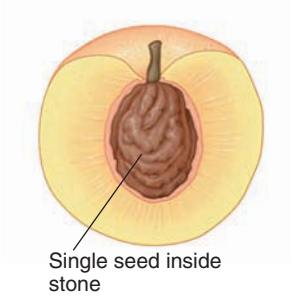
A **drupe** is a simple, fleshy or fibrous fruit that contains a hard stone (pit) surrounding a single seed. Examples of drupes include peaches, plums, olives, avocados, and almonds. The almond shell is actually the stone, which remains after the rest of the fruit has been removed.

Many simple fruits are dry at maturity; some of these split open, usually along seams, called *sutures,* to release their seeds. A



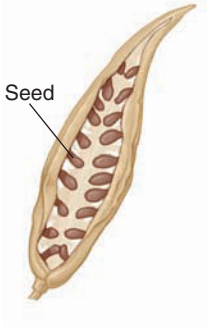
Berry (simple fruit)
A simple, fleshy fruit in which the fruit wall is soft throughout.

Tomato (*Lycopersicon lycopersicum*)



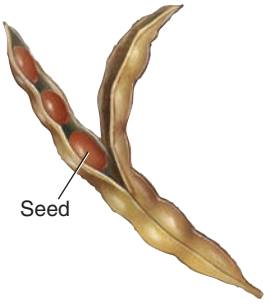
Drupe (simple fruit)
A simple, fleshy fruit in which the inner wall of the fruit is a hard stone.

Peach (*Prunus persica*)



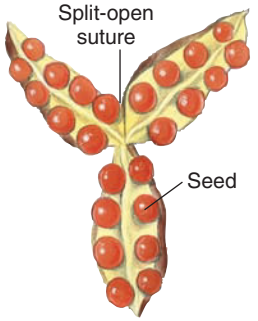
Follicle (simple fruit)
A simple, dry fruit that splits open along one suture to release its seeds; fruit is formed from ovary that consists of a single carpel.

Milkweed (*Asclepias syriaca*)



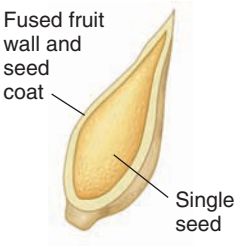
Legume (simple fruit)
A simple, dry fruit that splits open along two sutures to release its seeds; fruit is formed from ovary that consists of a single carpel.

Green bean (*Phaseolus vulgaris*)



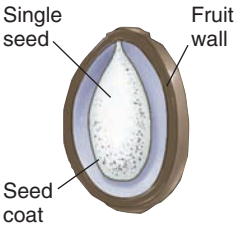
Capsule (simple fruit)
A simple, dry fruit that splits open along two or more sutures or pores to release its seeds; fruit is formed from ovary that consists of two or more carpels.

Iris (*Iris*)



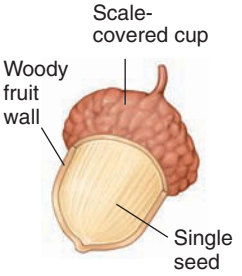
Caryopsis (simple fruit)
A simple, dry fruit in which the fruit wall is fused to the seed coat.

Wheat (*Triticum*)



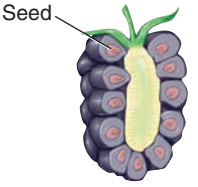
Achene (simple fruit)
A simple, dry fruit in which the fruit wall is separate from the seed coat.

Sunflower (*Helianthus annuus*)



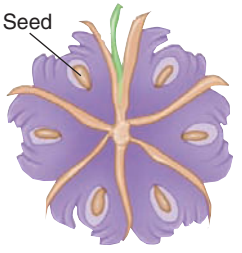
Nut (simple fruit)
A simple, dry fruit that has a stony wall, is usually large, and does not split open at maturity.

Oak (*Quercus*)



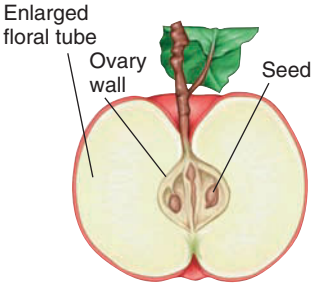
Aggregate fruit
A fruit that develops from a single flower with several to many pistils (i.e., carpels are not fused into a single pistil).

Blackberry (*Rubus*)



Multiple fruit
A fruit that develops from the ovaries of a group of flowers.

Mulberry (*Morus*)



Accessory fruit
A fruit composed primarily of nonovarian tissue (such as the receptacle or floral tube).

Apple (*Malus sylvestris*)

Figure 36-12 ***Animated*** Fruit types

Fruits are botanically classified into four groups—simple, aggregate, multiple, and accessory—based on their structure and mechanism of seed dispersal.

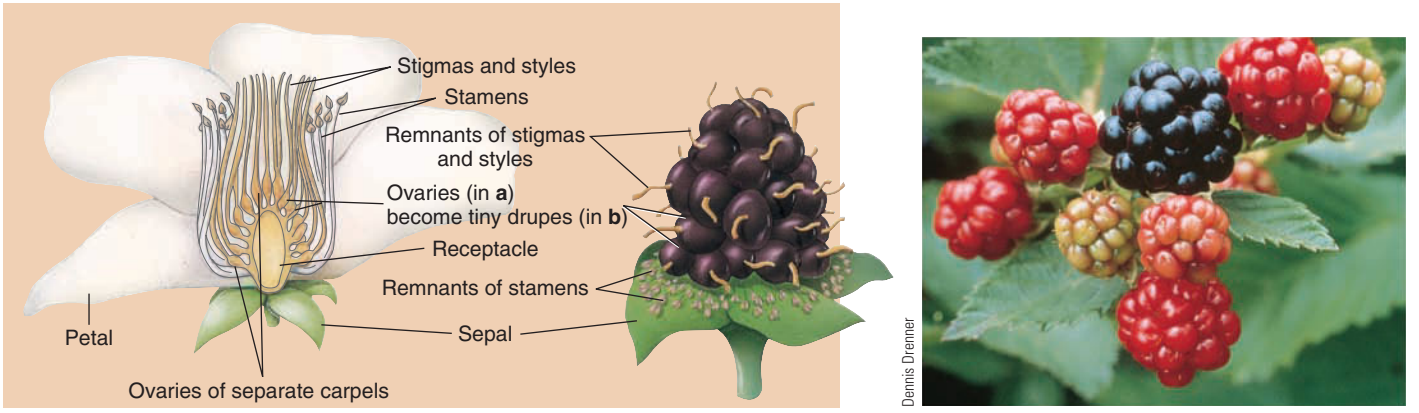


Figure 36-13 An aggregate fruit

(a) Cutaway view of a blackberry (*Rubus*) flower, showing the many separate carpels in the center of the flower. **(b)** A developing blackberry fruit is an aggregate of tiny drupes. The little "hairs" on the blackberry are remnants of stigmas and styles. **(c)** Developing blackberry fruits at various stages of maturity.

milkweed pod is an example of a **follicle,** a simple, dry fruit that develops from a single carpel and splits open along one suture to release its seeds. A **legume** is a simple, dry fruit that develops from a single carpel and splits open along two sutures. Pea pods are legumes, as are green beans, although both are generally harvested before the fruit has dried out and split open. Pea seeds are usually removed from the fruit and consumed, whereas in green beans the entire fruit and seeds are eaten. A **capsule** is a simple, dry fruit that develops from two or more fused carpels and splits open along two or more sutures or pores. Iris, poppy, and cotton fruits are capsules.

Other simple, dry fruits, such as **caryopses** (sing., *caryopsis*), or **grains,** do not split open at maturity. Each caryopsis contains a single seed. Because the seed coat is fused to the fruit wall, a caryopsis looks like a seed rather than a fruit. Kernels of corn and wheat are fruits of this type.

An **achene** is similar to a caryopsis in that it is simple and dry, does not split open at maturity, and contains a single seed. However, the seed coat of an achene is not fused to the fruit wall. Instead, the single seed is attached to the fruit wall at one point only, permitting an achene to be separated from its seed. The sunflower fruit is an example of an achene. One can peel off the fruit wall (the shell) to reveal the sunflower seed within.

Nuts are simple, dry fruits that have a stony wall and do not split open at maturity. Unlike achenes, nuts are usually large, single seeded, and often derived from a compound ovary. Examples of nuts include chestnuts, acorns, and hazelnuts. Many so-called nuts do not fit the botanical definition. Peanuts and Brazil nuts, for example, are seeds, not nuts.

Aggregate fruits are a second main type of fruit. An **aggregate fruit** is formed from a single flower that contains several to many separate (free) carpels (Fig. 36-13). After fertilization, each ovary from each individual carpel enlarges. As they enlarge, the ovaries may fuse to form a single fruit. Raspberries, blackberries, and magnolia fruits are examples of aggregate fruits.

A third type is the **multiple fruit,** formed from the ovaries of many flowers that grow in proximity on a common floral stalk. The ovary from each flower fuses with nearby ovaries as it develops and enlarges after fertilization. Pineapples, figs, and mulberries are multiple fruits (Fig. 36-14).

Accessory fruits are the fourth type. They differ from other fruits in that plant tissues in addition to ovary tissue make up the fruit. For example, the edible portion of a strawberry is the red,

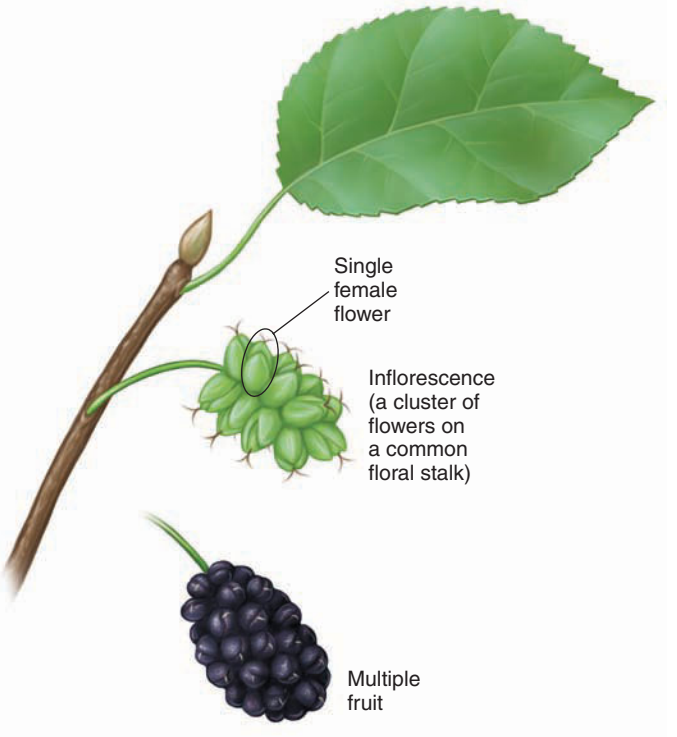

Figure 36-14 A multiple fruit

Mulberry (*Morus*) is formed from the ovaries and fleshy tepals (petals and sepals) of many flowers that fused to become a multiple fruit. Mulberry flowers are imperfect and contain either stamens or carpels. Also shown is an enlarged inflorescence of female flowers from which the mulberry fruit develops.

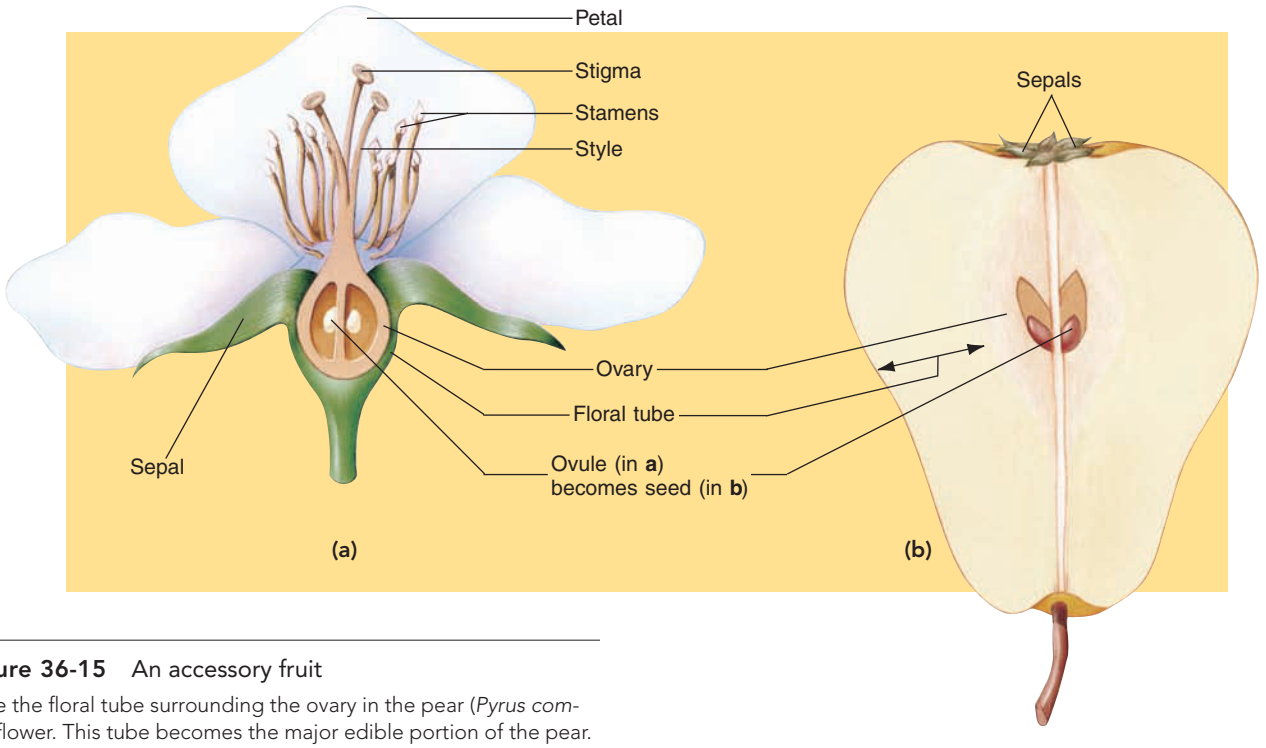

Figure 36-15 An accessory fruit

(a) Note the floral tube surrounding the ovary in the pear (*Pyrus communis*) flower. This tube becomes the major edible portion of the pear. **(b)** Longitudinal section through a pear showing the fruit tissue, which derives from both the floral tube and the ovary.

fleshy receptacle. Apples and pears are also accessory fruits; the outer part of each of these fruits is an enlarged *floral tube,* consisting of receptacle tissue along with portions of the calyx, that surrounds the ovary (Fig. 36-15).

Seed dispersal is highly varied

Wind, animals, water, and explosive dehiscence disperse the various seeds and fruits of flowering plants. Effective methods of seed dispersal have made it possible for certain plants to expand their geographic range. In some cases the seed is the actual agent of dispersal, whereas in others the fruit performs this role. In tumbleweeds, such as Russian thistle, the entire plant is the agent of dispersal because it detaches and blows across the ground, scattering seeds as it bumps along. Tumbleweeds are lightweight and are sometimes blown many kilometers by the wind.

Wind is responsible for seed dispersal in many plants. Plants such as maple trees have winged fruits adapted for wind dispersal. Light, feathery plumes enable other seeds or fruits to be transported by wind, often for considerable distances. Both dandelion fruits and milkweed seeds have this type of adaptation (Fig. 36-16a).

Some plants have special structures that aid in dispersal of their seeds and fruits by animals. The spines and barbs of burdock burs and similar fruits catch in animal fur and fall off as the animal moves about (Fig. 36-16b).

Fleshy, edible fruits are also adapted for animal dispersal. Birds, bats, primates, grazing ruminants, and ants are common dispersal agents. These animals are attracted to the fruit by its color, location, odor, and taste. As the animal eats these fruits, it either discards or swallows the seeds. Many seeds that are swallowed have thick seed coats and are not digested; instead, they pass through the digestive tract and are deposited in the animal's feces some distance from the parent plant. In fact, some seeds do not germinate unless they have passed through an animal's digestive tract; the animal's digestive juices probably aid germination by helping break down the seed coat. Some edible fruits apparently contain chemicals that function as laxatives to speed seeds through an animal's digestive tract; the less time these seeds spend in the gut, the more likely they are to germinate.

Animals such as squirrels and many bird species also help disperse acorns and other fruits and seeds by burying them for winter use. Many buried seeds are never used by the animal and germinate the following spring. Ants collect the seeds of many plants and take them underground to their nests. Ants disperse and bury seeds for hundreds of plant species in almost every terrestrial environment, from northern coniferous forests to tropical rain forests to deserts.

Both ants and flowering plants benefit from their association. The ants ensure the reproductive success of the plants whose seeds they bury, and the plants supply food to the ants. A seed that is collected and taken underground by ants often contains a special structure called an *elaiosome,* or *oil body,* that protrudes from the seed (Fig. 36-17). Elaiosomes are a nutritious food for ants, which carry seeds underground before removing the elaiosome. Once an elaiosome is removed from a seed, the ants discard the undamaged seed in an underground refuse pile, which happens to be rich in organic material (such as ant droppings and dead ants) and minerals (inorganic nutrients) required by young seedlings. Thus, ants not only bury the seeds away from animals

that might eat them but also place the seeds in rich soil that is ideal for germination and seedling growth.

The coconut is an example of a fruit adapted for dispersal by water. The coconut has air spaces that make it buoyant and capable of being carried by ocean currents for thousands of kilometers. When it washes ashore, the seed may germinate and grow into a coconut palm tree.

Some seeds are not dispersed by wind, animals, or water. Such seeds are found in fruits that use *explosive dehiscence*, in which the fruit bursts open suddenly and quite often violently, forcibly discharging its seeds (Fig. 36-18). These fruits burst open due to pressure caused by differences in *turgor* (hydrostatic pressure) as the cells in the fruit dry out. The fruits of plants such as touch-me-not and bitter cress split open so explosively that seeds are scattered a meter or more.

GERMINATION AND EARLY GROWTH

Learning Objective

9 Summarize the influence of internal and environmental factors on the germination of seeds.

Pollination and fertilization are followed by seed and fruit development in flowering plants. Each seed develops from an ovule and contains an embryonic plant and food to provide nourishment for the embryo during germination. **Germination**—the process of a seed sprouting—and the growth of young seedlings into mature plants are aspects of growth and development. Within a given species, the precise requirements for seed germination represent evolutionary adaptations that protect the young seedlings from adverse environmental conditions. Environmental cues, such as the presence of water and oxygen, proper temperature, and sometimes the presence of light penetrating the soil surface, influence whether or not a seed germinates.

No seed germinates unless it has absorbed water. The embryo in a mature seed is dehydrated, and a watery environment is necessary for active metabolism. When a seed germinates, its metabolic machinery is turned on, and numerous materials are synthesized and others degraded. Therefore, water is an absolute requirement for germination. The absorption of water by a dry seed is **imbibition.** As a seed imbibes water, it often swells to several times its original, dry size (Fig. 36-19). Cells imbibe water by adhesion of water onto and into materials such as cellulose, pectin, and starches within the seed.

Germination and subsequent growth require a great deal of energy. Because young plants obtain this energy by converting the energy of food molecules stored in the seed's endosperm or cotyledons to ATP during aerobic respiration, much oxygen is usually needed during germination. (Some plants, such as rice, grow in flooded soil where oxygen is absent and carry out *alcohol fermentation* during the early stages of germination and seedling growth.)

Temperature is another environmental factor that affects germination. Each species has an optimal, or ideal, temperature at which the germination percentage is highest. For most plants, the optimal germination temperature is between 25°C and 30°C (77°F and 86°F). Some seeds, such as those of apples, require prolonged exposure to low temperatures before their seeds break dormancy and germinate. Some of the environmental factors needed for germination help ensure the survival of the young plant. The requirement of a prolonged low-temperature period ensures that seeds adapted to temperate climates germinate in the spring rather than the fall.

Some plants, especially those with tiny seeds, such as lettuce, require light for germination. A light requirement ensures that a tiny seed germinates only if it is close to the soil surface. If such a seed were to germinate several centimeters below the soil surface, it might not have enough food reserves to grow to the surface. But if this light-dependent seed remains dormant until the soil is disturbed and it is brought to the surface, it has a much greater likelihood of survival.

Marion Lobstein

Figure 36-19 Imbibition

Pinto bean (*Phaseolus vulgaris*) seeds before imbibition (*left*) and after (*right*). Dry seeds imbibe water before they germinate.

Some seeds do not germinate immediately

A mature seed is often dormant and may not germinate immediately even if growing conditions are ideal. In certain seeds, internal factors, which are under genetic control, prevent germination even when all external conditions are favorable. Many seeds are dormant because certain chemicals are present or absent or because the seed coat restricts germination. For example, the seeds of many desert plants contain high concentrations of *abscisic acid* (discussed in Chapter 37), which inhibits germination under unfavorable conditions. Abscisic acid is washed out only when rainfall is sufficient to support the plant's growth after the seed germinates.

Some seeds, such as certain legumes, have extremely hard, thick seed coats that prevent water and oxygen from entering, thereby inducing dormancy. *Scarification,* the process of scratching or scarring the seed coat (physically with a knife or chemically with an acid) before sowing it, induces germination in these plants. Scarification in nature occurs, for example, when these seeds pass through the digestive tracts of animals or when the seed coats are partially digested by soil bacteria.

Eudicots and monocots exhibit characteristic patterns of early growth

Once conditions are right for germination, the first part of the plant to emerge from the seed is the radicle, or embryonic root. As the root grows and forces its way through the soil, it encounters considerable friction from soil particles. A root cap protects the delicate apical meristem of the root tip.

The shoot (the stem with its leaves and reproductive structures) is next to emerge from the seed. Stem tips are not protected by a structure comparable to a root cap, but plants have ways to protect the delicate stem tip as it grows through the soil to the surface. The stem of a bean seedling (a eudicot), for instance, curves over to form a hook so that the stem tip and

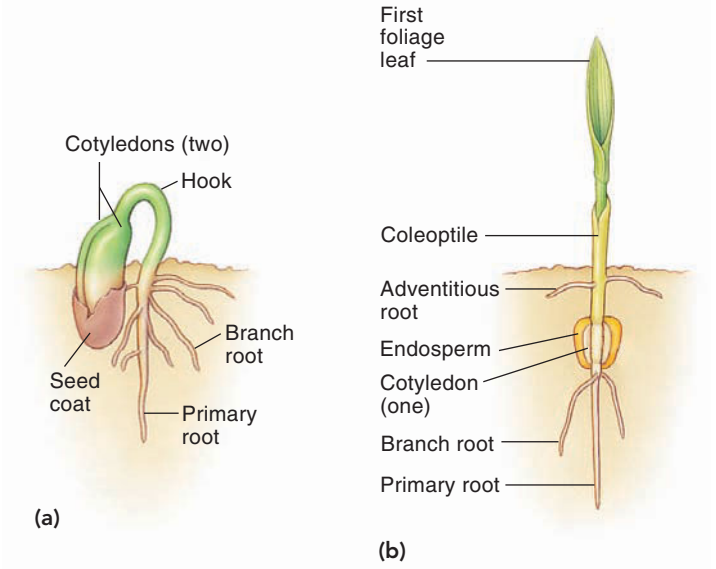

Figure 36-20 ***Animated*** Germination and seedling growth

(a) Common bean, a eudicot. The hook in the stem protects the delicate stem tip as it grows through the soil. Once the shoot emerges from the soil, the hook straightens. **(b)** Corn, a monocot. The coleoptile, a sheath of cells, emerges first from the soil. The shoot and leaves grow through the middle of the coleoptile. (From Cecie Starr and Ralph Taggart, *Biology, Unity and Diversity of Life,* 9th ed., p. 547. Art by Raychel Ciemma.)

cotyledons are actually *pulled up* through the soil (Fig. 36-20a). Corn and other grasses (monocots) have a special sheath of cells called a **coleoptile** that surrounds and protects the young shoot (Fig. 36-20b). First, the coleoptile pushes up through the soil, and then the leaves and stem grow through the tip of the coleoptile.

Review

- What factors influence the germination of seeds?
- Why are plant growth and development so sensitive to environmental cues?

ASEXUAL REPRODUCTION IN FLOWERING PLANTS

Learning Objectives

10 Explain how the following structures may be used to propagate plants asexually: rhizomes, tubers, bulbs, corms, stolons, plantlets, and suckers.

11 Define *apomixis.*

Flowering plants have many kinds of asexual reproduction, several of which involve modified stems: rhizomes, tubers, bulbs, corms, and stolons. A **rhizome** is a horizontal underground stem that may or may not be fleshy. Fleshiness indicates that the rhizome is used for storing food materials, such as starch (Fig. 36-21a). Although rhizomes resemble roots, they are really stems, as indicated by the presence of scalelike leaves, buds, nodes, and internodes. (Roots have none of these features.) Rhizomes frequently branch in different directions. Over time, the old portion of the rhizome dies, and the two branches eventually separate to become distinct plants. Irises, bamboos, ginger, and many grasses are examples of plants that reproduce asexually by forming rhizomes.

Some rhizomes produce greatly thickened ends called **tubers,** which are fleshy underground stems enlarged for food storage. When the attachment between a tuber and its parent plant breaks, often as a result of the death of the parent plant, the tuber grows into a separate plant. Potatoes and elephant's ear (*Caladium*) are examples of plants that produce tubers (Fig. 36-21b). The "eyes" of a potato are axillary buds, evidence that the tuber is an underground stem rather than a storage root such as a sweet potato or carrot.

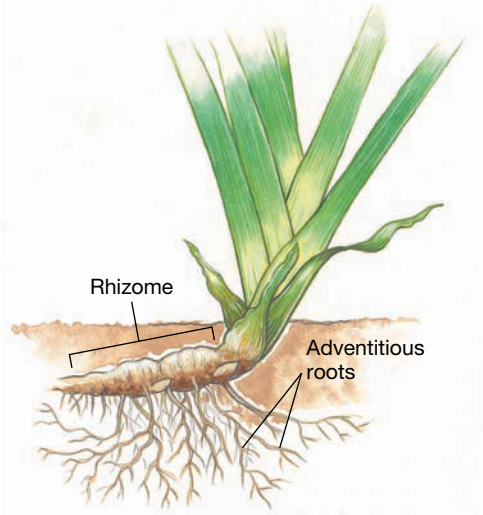
A **bulb** is a modified underground bud in which fleshy storage leaves are attached to a short stem (Fig. 36-21c). A bulb is globose (round) and covered by paperlike bulb scales, which are modified leaves. It frequently forms axillary buds that develop into small daughter bulbs (bulblets). These new bulbs are initially attached to the parent bulb, but when the parent bulb dies and rots away, each daughter bulb can become established as a separate plant. Lilies, tulips, onions, and daffodils are some plants that form bulbs.

A **corm** is a very short, erect underground stem that superficially resembles a bulb (Fig. 36-21d). Unlike the bulb, whose food is stored in underground leaves, the corm's storage organ is a thickened underground stem covered by papery scales (modified leaves). Axillary buds frequently give rise to new corms; the death of the parent corm separates these daughter corms, which then become established as separate plants. Familiar garden plants that produce corms include crocus, gladiolus, and cyclamen.

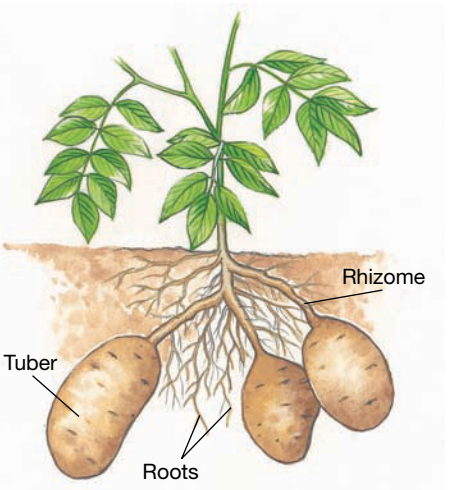
Stolons, or **runners,** are horizontal, aboveground stems that grow along the surface and have long internodes (Fig. 36-21e). Buds develop along the stolon, and each bud gives rise to a new shoot that roots in the ground. When the stolon dies, the daughter plants live separately. The strawberry plant produces stolons.

Some plants form detachable **plantlets** (small plants) in notches along their leaf margins. *Kalanchoe,* whose common name is "mother of thousands," has meristematic tissue that gives rise to an individual plantlet at each notch in the leaf (Fig. 36-22). When these plantlets reach a certain size, they drop to the ground, root, and grow.

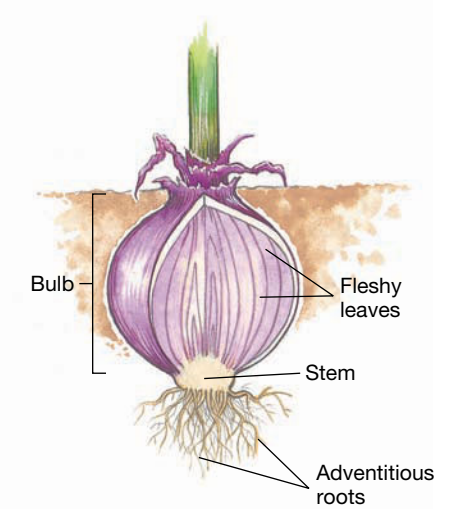
Some plants reproduce asexually by producing **suckers,** aboveground shoots that develop from adventitious buds on roots (Fig. 36-23). Each sucker grows additional roots and becomes an independent plant when the parent plant dies. Examples of plants that form suckers include black locust, pear, apple, cherry, blackberry, and aspen. A quaking aspen (*Populus tremuloides*) colony in the Wasatch Mountains of Utah contains at least 47,000 tree trunks formed from suckers that can be traced back to a single individual; this massive "organism" occupies almost 43 hectares (106 acres). Some weeds, such as field bindweed, produce many suckers. These plants are difficult to control, because



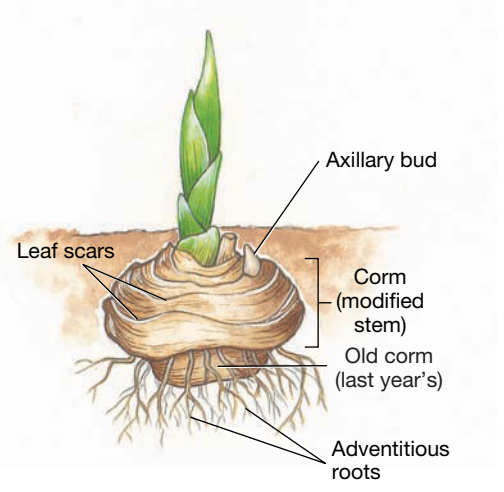
(a) Rhizome. Irises have horizontal underground stems called rhizomes. New aerial shoots arise from buds that develop on the rhizome.



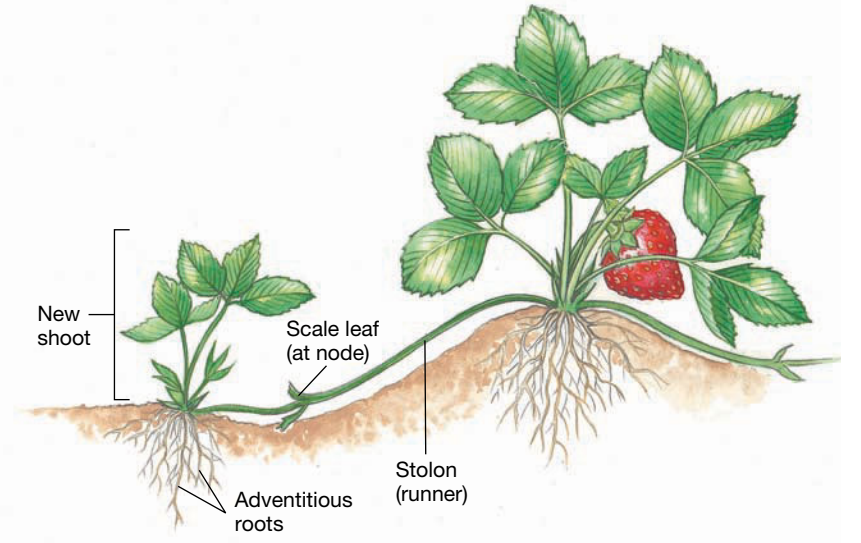
(b) Tuber. Potato plants form rhizomes, which enlarge into tubers (the potatoes) at the ends.



(c) Bulb. A bulb is a short underground stem to which overlapping, fleshy leaves are attached; most of the bulb consists of leaves.



(d) Corm. A corm is an underground stem that is almost entirely stem tissue surrounded by a few papery scales.



(e) Stolon. Strawberries reproduce asexually by forming stolons, or runners. New plants (shoots and roots) are produced at every other node.

Figure 36-21 Modified stems

pulling the plant out of the soil seldom removes all the roots, which can grow as deep as 3 m (10 ft). In fact, in response to wounding, the roots produce additional suckers, which can be a considerable nuisance to humans.

Apomixis is the production of seeds without the sexual process

Some flowering plants produce embryos in seeds without meiosis and the fusion of gametes. This asexual process is **apomixis.** For example, an embryo may develop from a diploid cell in the ovule rather than from a diploid zygote that forms from the union of two haploid gametes. Seed production by apomixis is a form of asexual reproduction. Because there is no fusion of gametes, the embryo is virtually genetically identical to the maternal genotype. However, the advantage of apomixis over other methods of asexual reproduction is that the seeds and fruits produced by apomixis can be dispersed by methods associated with sexual reproduction.

Apomixis, which occurs in various species of more than 40 angiosperm families, is often found in plants that are polyploid with varying degrees of sterility. Apomixis allows these sterile plants to reproduce and therefore survive. Examples of plants

Jerome Wexler/Photo Researchers, Inc.

Figure 36-22 Plantlets

The "mother of thousands" (*Kalanchoe*) produces detachable plantlets along the margins of its leaves. The young plantlets drop off and root in the ground.

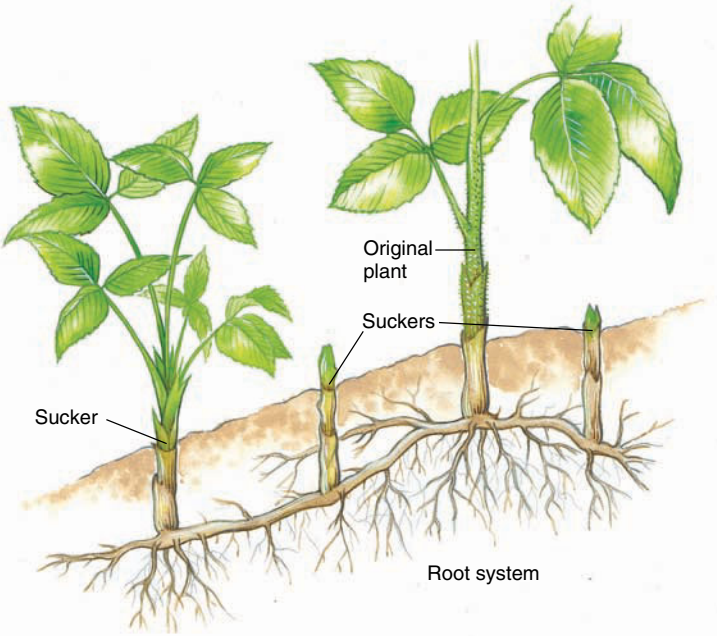


Figure 36-23 Suckers in various stages of development

All the suckers are connected to one another through the root system.

that can reproduce by apomixis include dandelions, citrus trees, mango, blackberries, garlic, and certain grasses.

Plant biologists are actively engaged in identifying the genes involved in asexual reproduction by apomixis. If researchers can transfer these genes to crop plants that possess superior traits such as high yield, they may be able to develop apomictic crop plants whose traits do not get lost or diluted during the genetic shuffling of sexual reproduction.

Review

- How are rhizomes and tubers involved in asexual reproduction?
- How are corms and bulbs similar? How are they different?
- What is apomixis? How is the ability to reproduce by apomixis advantageous?

A COMPARISON OF SEXUAL AND ASEXUAL REPRODUCTION

Learning Objective

12 State the differences between sexual reproduction and asexual reproduction, and discuss the evolutionary advantages and disadvantages of each.

Sexual reproduction and asexual reproduction are suited for different environmental circumstances. As you know, sexual reproduction results in offspring that are genetically different from the parents; that is, the parental genotypes are not preserved in the offspring. This genetic diversity of offspring may be selectively advantageous, particularly in an unstable, or changing, environment. (We define *environment* broadly to include all external conditions, both living and nonliving, that affect an organism.) If a plant species that reproduces sexually (and is therefore genetically diverse) is exposed to increasing annual temperatures as a result of global warming, for example, some of the individuals may be more fit than either the parents or other offspring. The genetic diversity from sexual reproduction may also let the individuals of a species exploit new environments, thereby expanding their range.

You have seen that asexual reproduction results in offspring that are virtually genetically identical to the parent; that is, the parental genotype is preserved. Assuming the parent is well adapted to its environment (that is, the parent has a favorable combination of alleles), this genetic similarity may be selectively advantageous if the environment remains stable (unchanging) for several generations. None of the offspring of asexual reproduction is more fit than the parent, but neither is any of them less fit.

Despite the apparent advantages of asexual reproduction, most plant species whose reproduction is primarily asexual occasionally reproduce sexually. Even in what appears a stable environment, plants are exposed to changing selective pressures, such as changes in the number and kinds of predators and parasites, the availability of food, competition from other species, and climate. Sexual reproduction permits species whose reproduction is primarily asexual to increase their genetic variability so at least some individuals are adapted to the changing selective pressures in a stable environment.

Sexual reproduction has some disadvantages

Although the genetic diversity produced by sexual reproduction is advantageous to a species' long-term survival, sexual reproduction is a "costly" form of reproduction. Sexual reproduction requires both male and female gametes, which must meet for reproduction to occur. The many adaptations of flowers for different modes of pollination represent one cost of sexual reproduction.

Sexual reproduction produces some individuals with genotypes that are well adapted to the environment, but it also produces some individuals that are less well adapted. Therefore, sexual reproduction is usually accompanied by high death rates among offspring, particularly when selective pressures are strong. As discussed in Chapter 18, however, this aspect of sexual reproduction is an important part of evolution by natural selection.

Every biological process involves trade-offs, and sexual reproduction is no exception. Although sexual reproduction has its costs, the adaptive advantages of sexual reproduction clearly outweigh any disadvantages.

Review

- How does sexual reproduction in plants differ from asexual reproduction?
- What is an adaptive advantage of sexual reproduction? Why is sexual reproduction considered costly?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Describe the functions of each part of a flower (page 768).
- **Sepals** cover and protect the flower parts when the flower is a bud. **Petals** play an important role in attracting animal pollinators to the flower.
- **Stamens** produce pollen grains. Each stamen consists of a thin stalk (the **filament**) attached to a saclike structure (the **anther**).
- The **carpel** is the female reproductive unit. A **pistil** may consist of a single carpel or a group of fused carpels. Each pistil has three sections: a **stigma,** on which the pollen grains land; a **style,** through which the pollen tube grows; and an **ovary** that contains one or more **ovules.**

ThomsonNOW™ **Learn more about flower structure by clicking on the figure in ThomsonNOW.**

2 Identify where eggs and pollen grains are formed within the flower (page 768).
- Pollen forms within pollen sacs in the anther. Each **pollen grain** contains two cells. One generates two sperm cells, and the other produces a **pollen tube** through which the sperm cells reach the ovule.
- An egg and two **polar nuclei,** along with several other nuclei, are formed in the ovule. Both egg and polar nuclei participate directly in fertilization.

ThomsonNOW™ **Watch plant reproduction unfold by clicking on the figure in ThomsonNOW.**

3 Compare the evolutionary adaptations that characterize flowers pollinated in different ways (by insects, birds, bats, and wind) (page 771).
- Flowers pollinated by insects are often yellow or blue and have a scent. Bird-pollinated flowers are often yellow, orange, or red and do not have a strong scent. Bat-pollinated flowers often have dusky white petals and are scented. Plants pollinated by wind often have smaller petals or lack petals altogether and do not produce a scent or nectar; wind-pollinated flowers make large amounts of pollen.

4 Define *coevolution,* and give examples of ways that plants and their animal pollinators have affected one another's evolution (page 771).
- **Coevolution** is reciprocal adaptation caused by two different species (such as flowering plants and their animal pollinators) forming an interdependent relationship and affecting the course of one another's evolution. For example, flowers with large, showy petals and scent have evolved in some plants, whereas hairy bodies that catch and hold sticky pollen grains have evolved in bees.

5 Distinguish between pollination and fertilization (page 775).
- **Pollination** is the transfer of pollen grains from anther to stigma. After pollination, **fertilization,** the fusion of gametes, occurs.
- Flowering plants undergo **double fertilization.** In the ovule, the egg fuses with one sperm cell, forming a zygote (fertilized egg) that eventually develops into a multicellular embryo in the **seed.** The two polar nuclei fuse with the second sperm cell, forming a triploid nutritive tissue called **endosperm.**

ThomsonNOW™ **Learn more about double fertilization by clicking on the figures in ThomsonNOW.**

6 Trace the stages of embryo development in flowering plants, and list and define the main parts of seeds (page 775).
- A eudicot embryo develops in the seed in an orderly fashion, from proembryo to globular embryo to the heart stage to the torpedo stage.
- A mature seed contains both a young plant embryo and nutritive tissue—stored in the endosperm or in the **cotyledons** (seed leaves)—for use during germination. A tough, protective **seed coat** surrounds the seed.

ThomsonNOW™ **Watch embryonic development in flowering plants by clicking on the figure in ThomsonNOW.**

7 Explain the relationships among the following: ovules, ovaries, seeds, and fruits (page 775).
- Ovules are structures with the potential to develop into seeds, whereas ovaries are structures with the potential to develop into fruits. Seeds are enclosed within **fruits,** which are mature, ripened ovaries.

8 Distinguish among simple, aggregate, multiple, and accessory fruits (page 775).
- **Simple fruits** develop from a single ovary that consists of one carpel or several fused carpels. **Aggregate fruits** develop from a single flower with many separate ovaries. **Multiple fruits** develop from the ovaries of many flowers growing in close proximity on a common axis. In **accessory fruits,** the major part of the fruit consists of tissue other than ovary tissue.

9 Summarize the influence of internal and environmental factors on the germination of seeds (page 782).
- **Germination** is the process of seed sprouting. Internal factors affecting whether a seed germinates include the maturity of the embryo; the presence or absence of chemical inhibitors; and the presence or absence of hard, thick seed coats.

- External environmental factors that may affect germination include requirements for oxygen, water, temperature, and light. For example, before germinating, dry seeds absorb water by **imbibition.**

ThomsonNOW™ Learn more about germination and seedling growth by clicking on the figure in ThomsonNOW.

10 Explain how the following structures may be used to propagate plants asexually: rhizomes, tubers, bulbs, corms, stolons, plantlets, and suckers (page 783).
- Rhizomes, tubers, bulbs, corms, and stolons are stems specialized for asexual reproduction. A **rhizome** is a horizontal underground stem. A **tuber** is a fleshy underground stem enlarged for food storage. A **bulb** is a modified underground bud with fleshy storage leaves attached to a short stem. A **corm** is a short, erect underground stem covered by papery scales. A **stolon** is a horizontal aboveground stem with long internodes.
- Some leaves have meristematic tissue along their margins and give rise to detachable **plantlets.**
- Roots may develop adventitious buds that develop into **suckers.** Suckers produce additional roots and may give rise to new plants.

11 Define *apomixis* (page 783).
- **Apomixis** is the production of seeds and fruits without sexual reproduction.

12 State the differences between sexual reproduction and asexual reproduction, and discuss the evolutionary advantages and disadvantages of each (page 785).
- Sexual reproduction involves the union of two gametes; the offspring produced by sexual reproduction are genetically variable. Asexual reproduction involves the formation of offspring without the fusion of gametes; the offspring are virtually genetically identical to the single parent.
- The parental genotypes are not preserved in the offspring of sexual reproduction. Genetic diversity among offspring produced by sexual reproduction may let individuals survive in a changing environment or exploit new environments. Sexual reproduction is costly, because both male and female gametes must be produced and must meet.
- The parental genotype is preserved in asexual reproduction. Genetic similarity may be advantageous if the environment is stable. Most plant species whose reproduction is primarily asexual occasionally reproduce sexually, thereby increasing their genetic variability.

TEST YOUR UNDERSTANDING

1. In flowering plants, the _____ is/are large (multicellular) and nutritionally independent. (a) gametes (b) microspores (c) megaspores (d) mature gametophyte (e) mature sporophyte
2. The normal order of whorls from the flower's periphery to the center is (a) sepals ⟶ petals ⟶ carpels ⟶ stamens (b) stamens ⟶ carpels ⟶ sepals ⟶ petals (c) sepals ⟶ petals ⟶ stamens ⟶ carpels (d) petals ⟶ carpels ⟶ stamens ⟶ sepals (e) carpels ⟶ stamens ⟶ petals ⟶ sepals
3. A pistil consists of (a) stigma, style, and stamen (b) anther and filament (c) sepal and petal (d) stigma, style, and ovary (e) radicle, hypocotyl, and plumule
4. The petals of a flower are collectively called a (a) calyx (b) capsule (c) carpel (d) cotyledon (e) corolla
5. The transfer of pollen grains from anther to stigma is (a) fertilization (b) double fertilization (c) pollination (d) germination (e) apomixis
6. The observation that insects with long mouthparts pollinate long, tubular flowers and insects with short mouthparts pollinate flowers with short corollas is explained by (a) coevolution (b) germination (c) double fertilization (d) apomixis (e) explosive dehiscence
7. The process of _____ in flowering plants involves one sperm cell fusing with an egg cell and one sperm cell fusing with two polar nuclei. (a) coevolution (b) germination (c) double fertilization (d) apomixis (e) pollination
8. The nutritive tissue in the seeds of flowering plants that is formed from the union of a sperm cell and two polar nuclei is called the (a) plumule (b) endosperm (c) cotyledon (d) hypocotyl (e) radicle
9. The _____ is a multicellular structure that anchors the embryo and aids in nutrient uptake from the endosperm. (a) proembryo (b) ovule (c) suspensor (d) cotyledon (e) pollen tube
10. After fertilization, the ovule develops into a _____ and the ovary develops into a _____. (a) fruit; seed (b) seed; fruit (c) calyx; corolla (d) corolla; calyx (e) follicle; legume
11. In plants that lack endosperm in their mature seeds, the cotyledons function to (a) enclose and protect the seed (b) aid in seed dispersal (c) serve as an absorptive embryonic root (d) store food reserves (e) attach the embryo within the ovule
12. _____ fruits develop from many ovaries of a single flower, whereas _____ fruits develop from the ovaries of many separate flowers. (a) multiple; accessory (b) simple; accessory (c) aggregate; multiple (d) accessory; aggregate (e) simple; multiple
13. Apples, strawberries, and pears are examples of what kind of fruit? (a) accessory (b) simple (c) multiple (d) aggregate (e) legume
14. A horizontal underground stem that may or may not be fleshy and that is often specialized for asexual reproduction is called a (a) stolon (b) bulb (c) corm (d) rhizome (e) tuber
15. Place the following events in the correct order.

    1. pollen tube grows into ovule 2. insect lands on flower to drink nectar 3. embryo develops within the seed 4. fertilization occurs 5. pollen carried by insect contacts stigma

    (a) 2, 5, 1, 4, 3 (b) 1, 4, 2, 5, 3 (c) 3, 2, 5, 1, 4 (d) 5, 1, 3, 4, 2 (e) 2, 5, 4, 3, 1

CRITICAL THINKING

1. Sketch the kinds of flowers that form simple, aggregate, multiple, and accessory fruits.
2. Using what you have learned in this chapter, speculate whether it is more likely that offspring of asexual reproduction develop in close proximity to or widely dispersed from the parent plant. Explain your reasoning. How could you design an experiment to test your hypothesis?
3. Which type of reproduction, sexual or asexual, might be more beneficial in the following circumstances, and why: (a) a perennial (plant that lives more than two years) in a stable environment; (b) an annual (plant that lives one year) in a rapidly changing environment; and (c) a plant adapted to an extremely narrow climate range?
4. Using what you have learned in this chapter, offer an explanation of why telephone poles and wires strung across grassy fields or plains often have tree seedlings growing under them.
5. **Evolution Link.** Is seed dispersal by ants an example of coevolution? Why or why not?

Plant Growth and Development

Dwight R. Kuhn

Black-eyed Susan. This plant (*Rudbeckia hirta*), which grows to 0.9 m (3 ft), produces flowers in response to the shortening nights of spring and early summer.

KEY CONCEPTS

Growth and development are influenced by a plant's internal conditions and signals from its external environment.

A plant may respond to an external stimulus, such as light, gravity, or touch, by a directional growth response, or tropism. Study of tropisms has helped biologists elucidate links between the external environment and internal signals such as hormones.

Hormones are chemical signals responsible for coordinating and regulating many aspects of plant development.

Although there are many plant hormones, five have been well-characterized: auxins, gibberellins, cytokinins, ethylene, and abscisic acid.

Plants have different receptors that detect various colors of light. Phytochrome detects red and far-red light, which affect several aspects of development, including the timing of flowering.

The ultimate control of plant growth and development, which includes all the changes that take place during the entire life of an individual, is genetic. If the genes required for development of a particular trait, such as the shape of a leaf, the color of a flower, or the type of root system, are not present, that characteristic does not develop. When a particular gene is present, its expression—that is, how it exhibits itself as an observable feature of an organism—is determined by several factors, including signals from other genes and from the environment. The location of a cell in the young plant body also has a profound effect on gene expression during development. Chemical signals from adjacent cells help a cell "perceive" its location within the plant body. Each cell's spatial environment helps determine what that cell ultimately becomes.

Growth and development, including a plant's responses to various changes in its environment, are controlled by plant *hormones*, organic compounds that are present in very low concentrations in plant tissues and that act as chemical signals between cells. Environmental cues, such as changing day length and variations in precipitation and temperature, exert an important influence on gene expression and hormone production, as they do on all aspects of plant growth and development.

For example, the initiation of sexual reproduction is often under environmental control, particularly in temperate latitudes, and plants switch to reproductive growth after receiving appropriate signals from the environment. Many flowering plants are sensitive to changes in the relative amounts of daylight and darkness that accompany the changing seasons, and these plants flower in re-

sponse to those changes (see photograph on page 789). Other plants have temperature requirements that induce sexual reproduction. Thus, plants continually perceive information from the environment and use this information to help regulate normal growth and development. We consider all of these aspects of growth and development in this chapter. ■

TROPISMS

Learning Objective

1 Describe phototropism, gravitropism, and thigmotropism.

Plants exhibit movements in response to environmental stimuli such as light, gravity, and touch. A plant may respond to such an external stimulus by directional growth—that is, the direction of growth depends on the direction of the stimulus. Such a directional growth response, called a **tropism,** results in a change in the position of a plant part. Tropisms are irreversible and may be positive or negative, depending on whether the plant grows toward the stimulus (a positive tropism) or away from it (a negative tropism). Tropisms are under hormonal control, which is discussed later in the chapter.

Phototropism is the directional growth of a plant caused by light (Fig. 37-1). Most growing shoot tips exhibit positive phototropism by bending (growing) toward light, something you may have observed if you place houseplants near a sunny window. This growth response increases the likelihood that stems and leaves receive adequate light for photosynthesis. The bending response of phototropism is triggered by blue light with wavelengths less than 500 nm. (You may recall from Chapter 33 that blue light also induces stomata to open.)

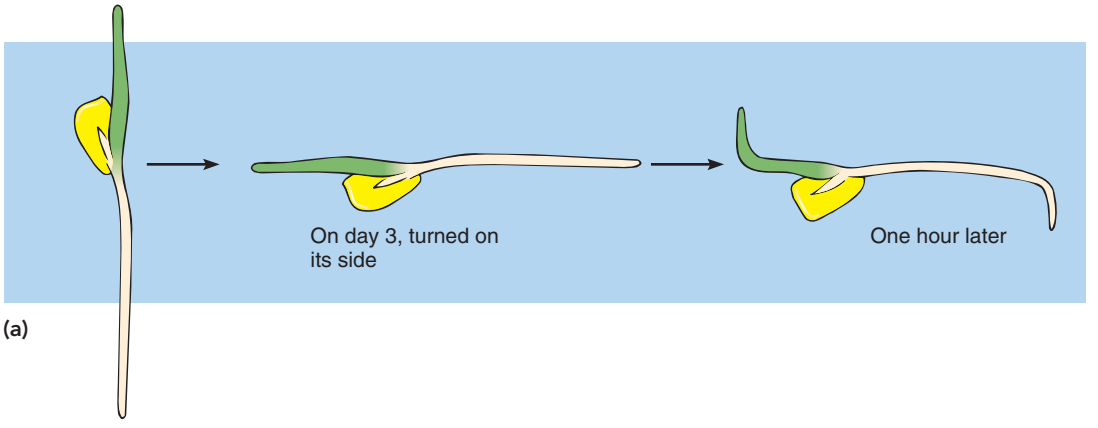
For a plant or any organism to have a biological response to light, it must contain a light-sensitive substance, called a *photoreceptor,* to absorb the light. The photoreceptor that absorbs blue light and triggers the phototropic response and other blue-light responses (such as stomatal opening) is a family of yellow pigments called **phototropins.** Phototropins are light-activated **kinases,** enzymes that transfer phosphate groups. There is evidence that phototropins become phosphorylated—that is, a phosphate group is added—in response to blue light. Thus, phosphorylation is an early step in the blue light–signaling pathway.

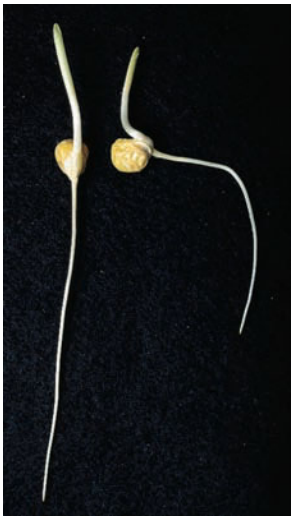
Runk/Schoenberger/Grant Heilman

Figure 37-1 ***Animated*** Phototropism

Stems of corn (*Zea mays*) seedlings grow in the direction of light and therefore exhibit positive phototropism. The bending is caused by greater elongation on the shaded side of a stem than on the lighted side.

Growth in response to the direction of gravity is called **gravitropism.** Most stem tips exhibit negative gravitropism by growing away from Earth's center, whereas most root tips exhibit positive gravitropism (Fig. 37-2). The root cap is the site of gravity perception in roots; when the root cap is removed, the root con-





Dennis Drenner

(b)

Figure 37-2 ***Animated*** Gravitropism

(a) A corn (*Zea mays*) seedling was turned on its side 3 days after germinating. In 1 hour the root and shoot tips had curved. **(b)** In 24 hours (*seedling on the right*), the new root growth was downward (positive gravitropism) and the new shoot growth was upward (negative gravitropism). A control seedling germinated at the same time is on the left.

tinues to grow, but it loses any ability to perceive gravity. Special cells in the root cap possess starch-containing **amyloplasts** that collect toward the bottom of the cells in response to gravity, and these amyloplasts may initiate at least some of the gravitropic response. If the root is put in a different position, as when a potted plant is laid on its side, the amyloplasts tumble to a new position, always settling in the direction of gravity. The gravitropic response (bending) occurs shortly thereafter and involves the hormone *auxin* (discussed later in the chapter). Despite the movement of amyloplasts in response to gravity, researchers question their role in gravitropism. A mutant *Arabidopsis* plant that lacks amyloplasts in its root cap cells still responds gravitropically when placed on its side, indicating that roots do not necessarily need amyloplasts to respond to gravity. Ongoing research may clarify how roots perceive gravity.

Thigmotropism is growth in response to a mechanical stimulus, such as contact with a solid object. The twining or curling growth of tendrils or stems, which helps attach a climbing plant such as a vine to some type of support, is an example of thigmotropism (see Fig. 33-13b).

Review

- What is phototropism? How does blue light trigger the phototropic response?
- How do phototropism and gravitropism differ?

PLANT HORMONES AND DEVELOPMENT

Learning Objectives

2 Describe a general mechanism of action for plant hormones, using auxin as your example.

3 Describe early auxin experiments involving phototropism.

4 List several ways that each of these hormones affects plant growth and development: auxins, gibberellins, cytokinins, ethylene, and abscisic acid.

5 Summarize the activities of these plant hormones and hormone-like signaling molecules: brassinosteroids, jasmonates, salicylic acid, systemin, and oligosaccharins.

A plant **hormone** is an organic compound that acts as a chemical signal eliciting a variety of responses that regulate growth and development. The study of plant hormones is challenging because hormones are effective in extremely small concentrations (less than 10^{-6} mol/L). In addition, the effects of different plant hormones overlap, and it is difficult to determine which hormone, if any, is the primary cause of a particular response. Plant hormones may also stimulate a response at one concentration and inhibit that same response at a different concentration.

Plant hormones are different from animal hormones in several ways. For example, most plant hormones are not produced in one part of the plant and transported over long distances to another part, where they cause a particular response; instead, the effects of plant hormones often occur close to where hormones are produced. Also, plant hormones are generally small molecules, not large, complex molecules like many animal hormones.

For many years, biologists studied five major classes of plant hormones: auxins, gibberellins, cytokinins, ethylene, and abscisic acid. More recently, researchers have uncovered compelling evidence for a variety of signaling molecules, such as brassinosteroids, jasmonates, salicylic acid, systemin, and oligosaccharins. (Table 37-1 summarizes plant hormones and hormone-like signaling molecules discussed in this chapter.)

Plant hormones act by signal transduction

Researchers have used molecular genetic techniques to better understand the biology of plant hormones. *Arabidopsis* mutants are particularly useful. For example, different mutants have defects

TABLE 37-1

Plant Hormones and Signaling Molecules

Hormone	Site of Production	Principal Actions
Auxins (e.g., IAA)	Shoot apical meristem, young leaves, seeds	Stem elongation, apical dominance, root initiation, fruit development
Gibberellins (e.g., GA_3)	Young leaves and shoot apical meristems, embryo in seed	Seed germination, stem elongation, flowering, fruit development
Cytokinins (e.g., zeatin)	Roots	Cell division, delay of leaf senescence, inhibition of apical dominance, flower development, embryo development, seed germination
Ethylene	Stem nodes, ripening fruit, damaged or senescing tissue	Fruit ripening, responses to environmental stressors, seed germination, maintenance of apical hook on seedlings, root initiation, senescence and abscission in leaves and flowers
Abscisic acid	Almost all cells that contain plastids (leaves, stems, roots)	Seed dormancy, responses to water stress
Brassinosteroids (e.g., brassinolide)	Shoots (leaves and flower buds), seeds, fruits	Light-mediated gene expression, cell division, cell elongation, seed germination, vascular development
Jasmonates (e.g., jasmonic acid)	Leaves? Probably many tissues	Initiation of defenses against predators or disease organisms
Salicylic acid	Wound (site of infection)	Resistance to disease organisms
Systemin	Wound (site of herbivore or pathogen attack)	Initiation of defenses against predators (herbivores) or disease organisms
Oligosaccharins	Unknown	May function in normal cell growth and development; defense responses to disease organisms

Key Point

Many plant hormones activate genes through a signal cascade involving a series of enzymes.

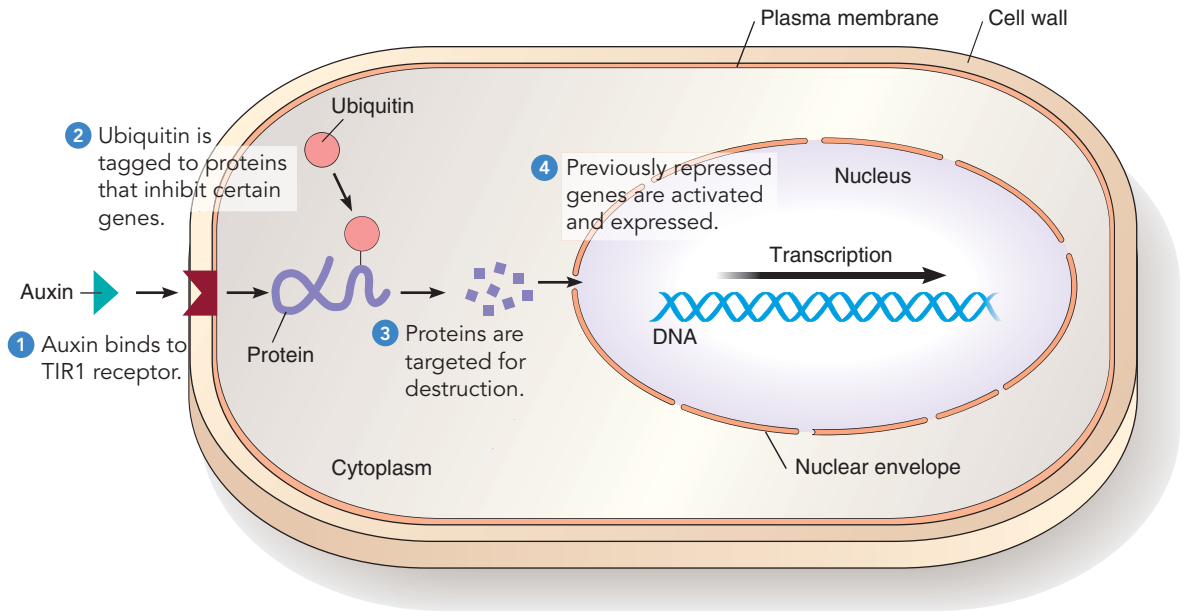


Figure 37-3 General mechanism of action for the hormone auxin

The numbered steps are explained in the text.

in hormone synthesis, hormone transport, signal reception, or signal transduction. In **signal transduction,** a receptor converts an extracellular signal into an intracellular signal that causes some change in the cell. Such mutants enable plant biologists to identify and clone genes involved in these aspects of hormone biology. Studying the mutant phenotypes helps plant biologists establish connections between the mutant genes and specific physiological activities involved in growth and development.

Using this research, biologists are elucidating the general mechanism of plant hormone action. It appears that many plant hormones bind to **enzyme-linked receptors** located in the plasma membrane; the hormone binds to the receptor, where it triggers an enzymatic reaction of some sort.

Let us consider a specific example that involves the plant hormone *auxin,* which is known to cause rapid changes in gene expression (Fig. 37-3). As shown in step 1, the receptor for auxin is located in the plasma membrane and has a three-dimensional shape that binds to the auxin molecule. The binding of auxin to its receptor catalyzes the attachment of the molecule *ubiquitin* to repressor proteins that inhibit certain genes (step 2). Whenever ubiquitin is attached to protein molecules, the cell targets those molecules for destruction (step 3). As a result, the genes that were repressed by those repressor proteins are now activated, resulting in changes in cell growth and development (step 4).

The identification of the receptor for auxin was reported in 2005 by two groups working independently. This receptor, called *transport inhibitor response 1 (TIR1)* protein, is an **F-box protein.** The *F-box* is a short sequence of amino acids found in molecules that catalyze the addition of ubiquitin tags to proteins targeted for destruction. Interestingly, all animals, plants, and fungi examined to date use ubiquitin to target proteins for destruction, but bacteria do not. This suggests that the use of ubiquitin tags evolved early in eukaryote evolution and was conserved as the various groups of eukaryotes diversified. Plants have about 700 F-box proteins, but not much is known about most of them. Future research may identify other plant hormones and signaling molecules that use F-box proteins as receptors.

Auxins promote cell elongation

Charles Darwin, the British naturalist best known for developing the theory of natural selection to explain evolution, also provided the first evidence for the existence of auxins. The experiments that Darwin and his son Francis performed in the 1870s involved positive phototropism, the directional growth of plants toward light. The plants they used were newly germinated canary grass seedlings. As in all grasses, the first part of a canary grass seedling to emerge from the soil is the coleoptile, a protective sheath that encircles the stem. When coleoptiles are exposed to light from only one direction, they bend toward the light. The bending occurs below the tip of the coleoptile.

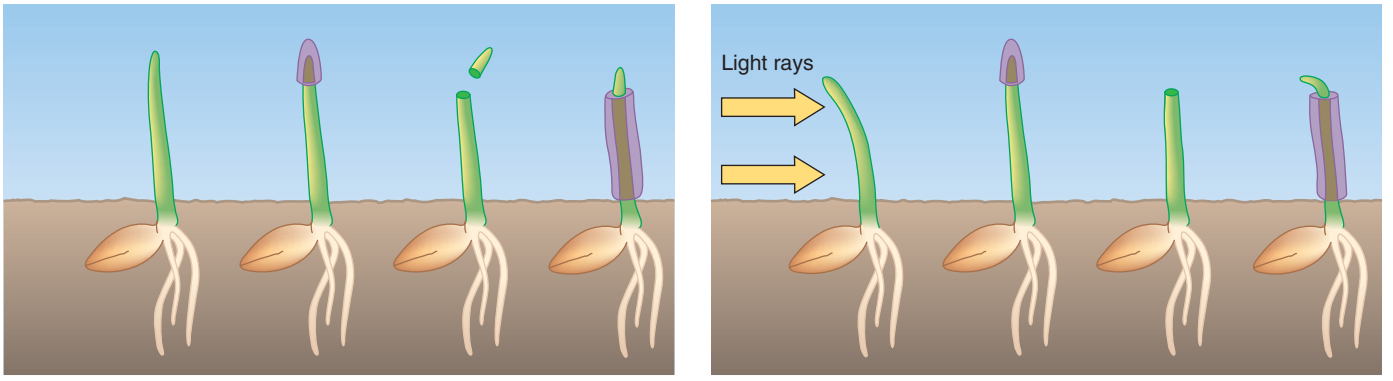
The Darwins tried to influence this bending in several ways (Fig. 37-4). For example, they covered the tip of the coleoptile as soon as it emerged from the soil. When they covered that part of the coleoptile above where the bend would be expected

Key Experiment

QUESTION: What part of the grass coleoptile depends on light for phototropic growth?

HYPOTHESIS: The coleoptile tip is required for the growth (bending) of the coleoptile shaft that accompanies exposure to light coming from one direction.

EXPERIMENT: Some canary grass coleoptiles were uncovered, some were covered only at the tip, some had the tip removed, and some were covered everywhere but at the tip (left). The covers were impervious to light.



RESULTS AND CONCLUSION: After exposure to light coming from one direction, the uncovered plants and the plants with uncovered tips grew toward the light (right). The plants with tips covered or removed did not bend toward light. The Darwins concluded that some substance was produced in the tip and transmitted to the lower part, causing it to bend.

Figure 37-4 The Darwins' phototropism experiments

to occur, the plants did not bend. On other plants, they removed the coleoptile tip and found bending did not occur. When the bottom of the coleoptile where the curvature would occur was shielded from the light, the coleoptile bent toward light. From these experiments, the Darwins concluded that "some influence is transmitted from the upper to the lower part, causing it to bend."

In the 1920s, Frits Went, a young Dutch scientist, isolated the phototropic hormone from oat coleoptiles. He removed the coleoptile tips and placed them on tiny blocks of agar for a period of time. When he put one of these agar blocks squarely on a decapitated coleoptile, normal growth resumed. When he placed one of these agar blocks to one side of the tip of a decapitated coleoptile in the dark, bending occurred (Fig. 37-5). The results indicated that the substance had diffused from the coleoptile tip into the agar and, later, from the agar into the decapitated coleoptile. Went named this substance **auxin** (from the Greek *aux,* "enlarge" or "increase"). The purification and elucidation of the primary auxin's chemical structure were accomplished in the mid-1930s by a research team led by U.S. biologist Kenneth Thimann at the California Institute of Technology.

Auxin is a group of several natural (and artificial) plant hormones; the most common and physiologically important auxin is **indoleacetic acid (IAA).** The movement of auxin in the plant is said to be *polar,* or unidirectional. Auxin moves downward along the shoot–root axis from its site of production, usually the shoot apical meristem. Young leaves and seeds are also sites of auxin production.

Auxin's most characteristic action is promotion of cell elongation in stems and coleoptiles. This effect, apparently exerted by acidification of cell walls, increases their plasticity and thus enables them to expand under the force of the cell's internal turgor pressure. Auxin's effect on cell elongation also provides an explanation for phototropism. When a plant is exposed to a light from only one direction, some of the auxin migrates laterally to the shaded side of the stem before moving down the stem by polar transport. Because of the greater auxin concentration on the shaded side of the stem, the cells there elongate more than the cells on the light side, and the stem bends toward the light (Fig. 37-6). Auxin is also involved in gravitropism and thigmotropism.

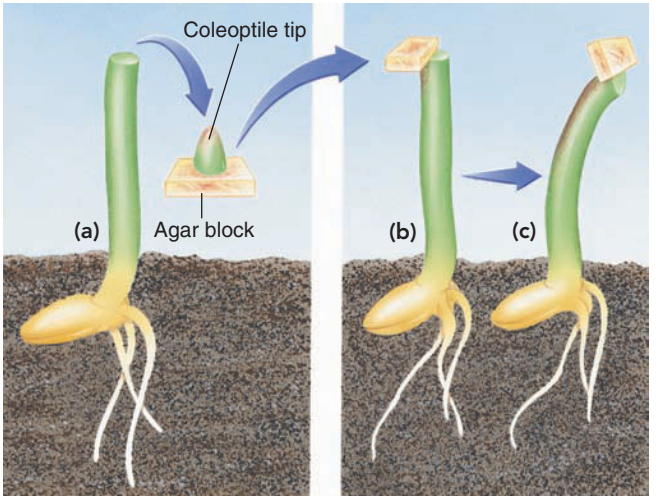
Auxin exerts other effects on plants. For example, some plants tend to branch out very little when they grow. Growth in these plants occurs almost exclusively from the apical meristem rather than from axillary buds, which do not develop as long as the terminal bud is present. Such plants are said to exhibit **apical dominance,** the inhibition of axillary bud growth by the apical meristem. In plants with strong apical dominance, auxin produced in the apical meristem inhibits axillary buds near the apical meristem from developing into actively growing shoots. When the apical meristem is pinched off, the auxin source is removed and axillary buds grow to form branches. Apical dominance is

Key Experiment

QUESTION: Is there a chemical substance responsible for elongation of coleoptiles, and can it be isolated?

HYPOTHESIS: The factor responsible for coleoptile growth is a diffusible chemical that can be isolated from coleoptile tips.

EXPERIMENT: Coleoptile tips were placed on agar blocks for a period of time **(a).** The agar block was transferred to a decapitated coleoptile. It was placed off-center, and the coleoptile was left in darkness **(b).**



RESULTS AND CONCLUSION: The coleoptile bent **(c),** indicating that a chemical moved from the original coleoptile tip to the agar block and from there to the same side of the decapitated coleoptile, causing that side to elongate.

Figure 37-5 ***Animated*** Isolating auxin from coleoptiles

often quickly re-established, however, as one branch begins to inhibit the growth of others. Other hormones (ethylene and cytokinin, both discussed later) are also involved in apical dominance. As with many physiological activities, the changing ratios of these hormones may be the factor responsible for apical dominance.

Auxin produced by developing seeds stimulates the development of the fruit. When auxin is applied to certain flowers in which fertilization has not occurred (and, therefore, in which seeds are not developing), the ovary enlarges and develops into a seedless fruit. Seedless tomatoes are produced in this manner.[1] Auxin is not the only hormone involved in fruit development, however.

Some manufactured, or synthetic, auxins have structures similar to that of IAA. The synthetic auxin naphthalene acetic acid stimulates root development on stem cuttings and is used

[1]Not all seedless fruits are produced by treatment with auxin. In Thompson seedless grapes, fertilization occurs but the embryos abort, and therefore the seeds fail to develop. Thompson seedless grapes are sprayed with the hormone gibberellin to increase berry size.

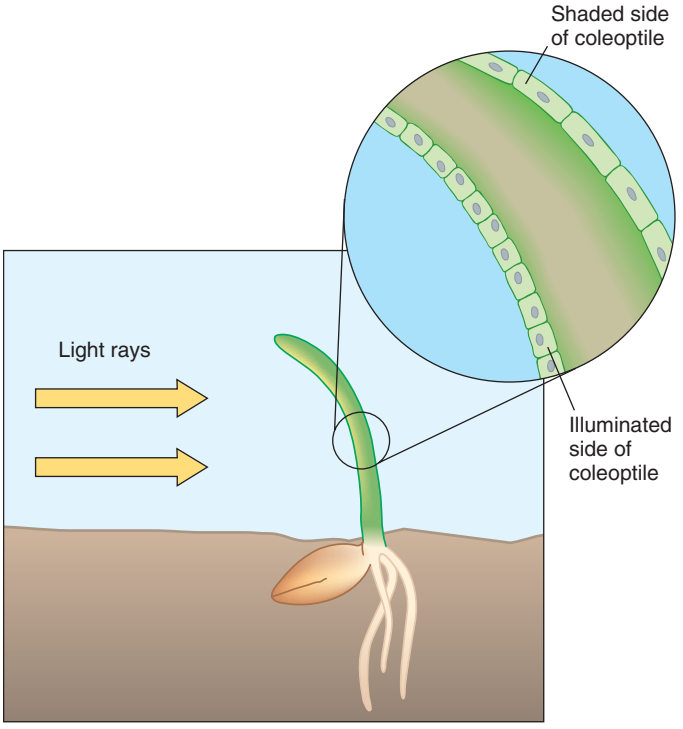


Figure 37-6 Phototropism and the unequal distribution of auxin

Auxin travels down the side of the stem or coleoptile *away* from the light, causing cells on the shaded side to elongate. Therefore, the stem or coleoptile bends toward light.

for asexual propagation, particularly of woody plants with horticultural importance (Fig. 37-7). The synthetic auxins 2,4-D and 2,4,5-T have been used as selective herbicides (weed killers). These compounds kill plants with broad leaves but, for reasons not completely understood, do not kill grasses. Both herbicides are similar in structure to IAA and disrupt the plants' normal growth processes. Because many of the world's most important crops are grasses (such as wheat, corn, and rice), 2,4-D and 2,4,5-T can kill broadleaf weeds that compete with these crops. The use of 2,4,5-T is no longer allowed in the United States, however, because of its association with dioxins, a group of mildly to very toxic compounds formed as by-products during the manufacture of 2,4,5-T.

Gibberellins promote stem elongation

In the 1920s, a Japanese biologist was studying a disease of rice in which the young rice seedlings grew extremely tall and spindly, fell over, and died. The cause of the disease was a fungus (*Gibberella fujikuroi*) that produces a chemical substance named **gibberellin.** Not until after World War II did scientists in Europe and North America learn of the work done by the Japanese scientists. During the 1950s and 1960s, studies in the United States and Great Britain showed that gibberellins are produced by healthy plants as well as by the fungus.

Figure 37-7 Auxin and root development on stem cuttings

(*Left*) Many adventitious roots developed on a honeysuckle (*Lonicera fragrantissima*) cutting placed in a solution with a high concentration of synthetic auxin. (*Middle*) Fewer roots developed in a lower auxin concentration. (*Right*) The cutting placed in water (no auxin) served as a control and did not form roots in the same period.

Robert Lyons/Visuals Unlimited

Figure 37-8 Gibberellin and stem elongation

Like many biennials, Indian blanket (*Gaillardia pulchella*) grows as a rosette, which is a circular cluster of leaves close to the ground, during its first year (*left*). It then bolts when it initiates flowering in the second year (*right*). The plant in bloom grows to 0.6 m (2 ft).

Gibberellins are hormones involved in many normal plant functions. The symptoms of the seedling disease are caused by an abnormally high gibberellin concentration in the plant tissue (because both plant and fungus produce gibberellin). Currently, dozens of naturally occurring gibberellins are known, although many are probably inactive precursors; there are no synthetic gibberellins.

Gibberellins promote stem elongation in many plants. When gibberellin is applied to a plant, particularly certain dwarf varieties, this elongation may be spectacular. Some corn and pea plants that are dwarfs as a result of one or more mutations grow to a normal height when treated with gibberellin. Short-stemmed, high-yielding varieties of wheat have short stems because they have a reduced response to gibberellin. These varieties put less of their resources into stem height and more resources into grain production. Gibberellins are also involved in **bolting,** the rapid elongation of a floral stalk that occurs naturally in many plants when they initiate flowering (Fig. 37-8).

Gibberellins cause stem elongation by stimulating cells to divide as well as to elongate. The actual mechanism of cell elongation differs from that caused by auxin, however. Recall that IAA-induced cell elongation involves the acidification of the cell wall. In gibberellin-induced cell elongation, cell wall acidification does not occur; biologists do not yet know how gibberellins modify cell wall properties to cause cell elongation.

Gibberellins affect several reproductive processes in plants. They stimulate flowering, particularly in long-day plants (discussed later in the chapter). In addition, gibberellins substitute for the low temperature that biennials require before they begin flowering. If gibberellins are applied to biennials during their first year of growth, flowering occurs without exposure to a period of low temperature. Gibberellins, like auxin, affect fruit development. Agriculturalists apply gibberellins to several varieties of grapes to produce larger fruits.

Gibberellins are also involved in seed germination in certain plants. In a classic experiment involving barley seed germination, researchers showed that the release of gibberellin from the embryo triggers the synthesis of α-amylase, an enzyme that digests starch in the endosperm. As a result, glucose becomes available for absorption by the embryo. Although enzymes mobilize starch reserves in many types of seeds, gibberellin control of seed enzymes appears restricted to cereals and other grasses. In addition to mobilizing food reserves in newly germinated grass seeds, application of gibberellins substitutes for low-temperature or light requirements for germination in seeds of plants such as lettuce, oats, and tobacco.

Cytokinins promote cell division

During the 1940s and 1950s, researchers were trying to find substances that might induce plant cells to divide in **tissue culture,** a technique in which cells are isolated from plants and grown in a nutrient medium (see *Focus On: Cell and Tissue Culture*). They discovered that cells would not divide without a substance found in coconut milk. Because coconut milk has a complex chemical composition, investigators did not chemically identify the division-inducing substance for some time. Finally, researchers isolated an active substance from a different source, aged DNA from herring sperm. They called it **cytokinin** because it induces cytokinesis, or cytoplasmic division. In 1963, researchers identified the first plant cytokinin, zeatin, in corn. Since then, similar molecules have been identified in other plants. Biologists have also synthesized several cytokinins. Cytokinins are structurally similar to adenine, a purine base that is part of DNA and RNA molecules.

focus on

CELL AND TISSUE CULTURE

Cells can be isolated from certain plants and grown in a chemically defined, sterile nutrient medium. In initial experiments with such cultures, plant cells could be kept alive, but they did not divide. Researchers later discovered that adding certain natural materials, such as the liquid endosperm of coconut, also known as coconut milk, induced cells to divide in culture. By the late 1950s, plant cells from a variety of sources could be cultured successfully, dividing to produce a mass of disorganized, relatively undifferentiated cells, or callus.

In 1958, F. C. Steward, a plant physiologist at Cornell University, succeeded in generating an entire carrot plant from a single callus cell derived from a carrot root (see Fig. 17-2). This demonstrated that each plant cell contains a genetic blueprint for all features of an entire organism. His work also showed that an entire plant can be grown from a single cell, provided the proper genes are expressed at the appropriate times.

Since Steward's pioneering work, biologists have successfully cultured many plants by using a variety of cell sources. Plants have been regenerated from different tissues, organ explants (excised organs or parts such as root apical meristems), and single cells. Cell and tissue culture techniques help answer many fundamental questions involving growth and development in plants. These techniques also have great practical potential. Using tissue culture, researchers can regenerate many genetically identical plants from the cells of a single, genetically superior plant. Many kinds of plants—from orchids and African violets to coastal redwoods—have been cultured in this way.

It is also possible to alter the genetic composition of a cell while it is in culture and then have these changes expressed in the whole plant following regeneration. Thus, tissue culture provides a valuable tool to genetic engineers who wish to introduce desirable new traits, such as better nutritional properties, into crop species such as rice (see Fig. 15-17b).

Cytokinins promote cell division and differentiation of young, relatively unspecialized cells into mature, more specialized cells in intact plants. They are a required ingredient in any plant tissue culture medium and must be present for cells to divide. In tissue culture, cytokinins interact with auxin during the formation of plant organs such as roots and stems (Fig. 37-9). For example, in tobacco tissue culture a high ratio of auxin to cytokinin induces root formation, whereas a low ratio of auxin to cytokinin induces shoot formation.

Cytokinins and auxin also interact in the control of apical dominance. Here their relationship is antagonistic: auxin inhibits the growth of axillary buds, and cytokinin promotes their growth.

One effect of cytokinins on plant cells is to delay the aging process. Plant cells, like all living cells, go through a natural aging process known as **senescence.** Senescence is accelerated in cells of plant parts that are cut, such as flower stems. Botanists think that plants must have a continual supply of cytokinins from the roots. Cut stems, of course, lose their source of cytokinins and therefore age rapidly. When cytokinins are sprayed on leaves of a cut stem of many species, they remain green, whereas unsprayed leaves turn yellow and die.

Despite their involvement in regulating many aspects of plant growth and development, cytokinins currently have few commercial applications other than plant tissue culture. However, in 1995, molecular biologists at the University of Wisconsin combined a promoter from a gene activated during normal senescence with a gene that encodes an enzyme involved in cytokinin synthesis. (Recall from Chapter 13 that the **promoter** is the nucleotide sequence in DNA to which RNA polymerase attaches to begin transcription.) The leaves of transgenic tobacco plants that contained this recombinant DNA produced more cytokinin and therefore lived longer and continued to photosynthesize

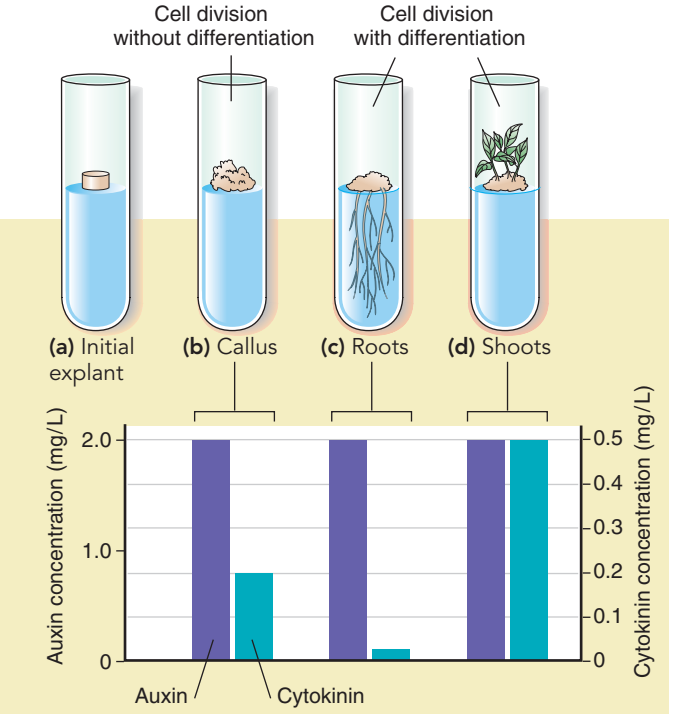

Figure 37-9 Auxin–cytokinin interactions in tissue culture

Varying amounts of auxin and cytokinin in the culture media produce different growth responses. **(a)** The initial explant is a small piece of sterile tissue from the pith of a tobacco stem, which is placed on nutrient agar. **(b)** Nutrient agar containing 2.0 mg/L of auxin and 0.2 mg/L of cytokinin causes cells to divide and form a clump of undifferentiated tissue called a callus. **(c)** Agar with 2.0 mg/L of auxin and 0.02 mg/L of cytokinin (high ratio of auxin to cytokinin) stimulates root growth. **(d)** Agar with 2.0 mg/L of auxin and 0.5 mg/L of cytokinin (low ratio of auxin to cytokinin) stimulates shoot growth.

Figure 37-10 Cytokinin synthesis and delay of senescence

The tobacco (*Nicotiana tabacum*) plant on the left was genetically engineered to produce additional cytokinin as it aged, whereas the tobacco plant of the same age on the right served as a control. Note the extensive senescence and death of older leaves on the control plant. Depending on the variety, tobacco grows 0.9 to 3 m (3 to 10 ft) tall.

(Fig. 37-10). This molecular technology has the potential to increase the longevity and productivity of certain crops.

Ethylene promotes abscission and fruit ripening

During the early 20th century, scientists observed that the gas **ethylene** (C_2H_4) has several effects on plant growth, but not until 1934 did they demonstrate that plants produce ethylene. This natural hormone influences many plant processes. Ethylene inhibits cell elongation, promotes seed germination, promotes apical dominance, and is involved in plant responses to wounding or invasion by disease-causing microorganisms.

Ethylene also has a major role in many aspects of senescence, including fruit ripening. As a fruit ripens, it produces ethylene, which triggers an acceleration of the ripening process. This induces the fruit to produce more ethylene, which further accelerates ripening. The expression "one rotten apple spoils the barrel" is true. A rotten apple is one that is overripe and produces large amounts of ethylene, which diffuses and triggers the ripening process in nearby apples. Humans use ethylene commercially to uniformly ripen bananas and tomatoes. These fruits are picked while green and shipped to their destination, where they are exposed to ethylene before they are delivered to grocery stores (Fig. 37-11).

Plants growing in a natural environment encounter rain, hail, wind, and contact with passing animals. All these mechanical stressors alter their growth and development, making them shorter and stockier than plants grown in a greenhouse. Ethylene regulates such developmental responses to mechanical stimuli, known as **thigmomorphogenesis.** Plants that are mechanically disturbed produce additional ethylene, which in turn inhibits stem elongation and enhances cell wall thickening in supporting cells (collenchyma and sclerenchyma). These changes are adaptive because shorter, thicker stems are less likely to be damaged by mechanical stressors.

Ethylene is involved in leaf abscission, which is actually influenced by two antagonistic hormones, ethylene and auxin. As a leaf ages (as autumn approaches, for deciduous trees in temperate climates), the level of auxin in the leaf decreases. Concurrently, cells in the abscission layer at the base of the petiole (where the leaf will break away from the stem) begin producing ethylene.

Abscisic acid promotes seed dormancy

In 1963, two different research teams discovered **abscisic acid.** Despite its name, abscisic acid does not induce abscission in most plants. Instead, abscisic acid is involved in a plant's response to stress and in seed **dormancy,** a temporary state of arrested physiological activity. As an environmental stress hormone, abscisic acid particularly promotes changes in plant tissues that are water stressed. (Recall that ethylene also affects plant responses to certain stressors, such as mechanical stressors and wounding.)

Figure 37-12 Abscisic acid and seed germination

In a corn (*Zea mays*) mutant that does not produce abscisic acid, some of the kernels have germinated while still on the ear, producing roots (*arrows*).

Botanists best understand the effect of abscisic acid on plants suffering from water stress. The level of abscisic acid increases dramatically in the leaves of plants exposed to severe drought conditions. The high level of abscisic acid in the leaves activates a signal transduction process that leads to the closing of stomata. The closing of stomata saves the water that the plant would normally lose by transpiration, thereby increasing the plant's likelihood of survival. As knowledge of abscisic acid signaling in guard cells increases, botanists hope to use this information to engineer crops and horticultural plants that are resistant to drought.

The onset of winter is also a type of stress on plants. A winter adaptation that involves abscisic acid is dormancy in seeds. Many seeds have high levels of abscisic acid in their tissues and do not germinate until the abscisic acid washes out. In a corn mutant unable to synthesize abscisic acid, the seeds germinate as soon as the embryos are mature, even while attached to the ear (Fig. 37-12).

Abscisic acid is not the only hormone involved in seed dormancy. For example, addition of gibberellin reverses the effects of dormancy. In seeds, the level of abscisic acid decreases during the winter, and the level of gibberellin increases. Cytokinins are also implicated in breaking dormancy. Once again, you see that a single physiological activity such as seed dormancy may be controlled in plants by the interaction of several hormones. The plant's actual response may result from changing ratios of hormones rather than the effect of each individual hormone.

Additional signaling molecules affect growth and development, including plant defenses

Biologists continue to discover new plant hormones and hormone-like signaling molecules. Many of these signaling molecules are involved in defensive responses of plants to disease organisms and insects. Here we briefly consider five groups—the brassinosteroids, jasmonates, salicylic acid, systemin, and oligosaccharins.

Brassinosteroids are steroid hormones found in plants

Although steroid hormones have crucial roles in animals, biologists are just beginning to understand the roles of these hormones in plants. The **brassinosteroids** (**BRs**) are a group of steroids that function as plant hormones. BRs are involved in several aspects of growth and development. *Arabidopsis* mutants that cannot synthesize BRs are dwarf plants with reduced fertility. Researchers reverse this defect by applying BR. Studies of these mutants suggest that the brassinosteroids are involved in multiple developmental processes, such as cell division, cell elongation, light-induced differentiation, seed germination, and vascular development.

Parts of the BR signaling pathway have been characterized. BRs bind to receptors in the plant plasma membrane (unlike steroid hormones in animals, which enter the cell and bind to receptors in the cytoplasm or nucleus). The binding of BR to its receptor triggers a signaling cascade that alters gene expression in the cell.

Jasmonates are derivatives of fatty acids

Jasmonates affect several plant processes, such as pollen development, root growth, fruit ripening, and senescence. These lipid-derived plant hormones, which are structurally similar to *prostaglandins* in animals, are also produced in response to the presence of insect pests and disease-causing organisms.

Jasmonates trigger the production of enzymes that confer an increased resistance against herbivorous (plant-eating) insects. For example, caterpillar-infested tomato plants release volatile jasmonates into the air that attract natural caterpillar enemies, such as parasitic wasps that lay their eggs on the caterpillar's bodies. When the eggs hatch, the wasp larvae consume, and ultimately kill, the host insects. In one study, treating plants with jasmonic acid increased parasitism on caterpillar pests twofold over control fields in which the plants did not have jasmonic acid applications. Jasmonates may be of practical value in controlling certain insect pests without the use of chemical pesticides.

About 20 different jasmonates have been identified and characterized. Biologists have made progress in identifying key aspects of the jasmonate signaling pathway, although important steps are not yet known. Interestingly, the jasmonate signaling pathway includes ubiquitin, which was discussed earlier in the chapter in relation to auxin (see Fig. 37-3). As in the auxin signaling pathway, the ubiquitin tags in the jasmonate signaling pathway may cause degradation of as-yet-unidentified transcription repressors, thereby altering gene expression.

Salicylic acid is a phenolic compound

For centuries people chewed willow (*Salix*) bark to treat headaches and other types of pain. **Salicylic acid** was first extracted from willow bark and is chemically related to aspirin (acetylsalicylic acid). More recently, biologists have shown that salicylic acid is a signaling molecule that helps plants defend against insect pests and pathogens such as viruses. When a plant is under attack, the concentration of salicylic acid increases, and it spreads systemically throughout the plant. Biologists think that salicylic acid binds to a cell receptor, triggering a signal transduction pathway that switches on genes. These genes code for proteins that establish **systemic acquired resistance** to fight infection and promote wound healing.

Plants also use salicylic acid to signal nearby plants. Tobacco plants infected with tobacco mosaic virus release into the air a volatile form of salicylic acid known as *methyl salicylate,* or *oil of wintergreen.* When nearby healthy plants receive the airborne chemical signal, they begin synthesizing antiviral proteins that enhance their resistance to the virus.

Systemin is a small polypeptide

Although many animal hormones are polypeptides, the first plant polypeptide with hormonal properties was not isolated until 1991. This polypeptide, **systemin,** consists of 18 amino acids and is transported systemically throughout the plant in response to wounding by insects. Systemin may stimulate natural defense mechanisms at extremely low concentrations, as low as one part per trillion. Systemin may trigger the plant to activate genes that produce *protease inhibitors,* molecules that disrupt insect digestion, curbing leaf damage done by caterpillars and other herbivorous insects. The discovery of systemin in tomato leaves prompted a flurry of research in search of polypeptide regulators and resulted in the discovery of additional polypeptides in other plants.

Oligosaccharins are composed of sugar residues

Oligosaccharins are carbohydrate fragments that consist of short, branched chains of sugar molecules. They are present in extremely small quantities in cells and active at much lower concentrations (100 to 1000 times as low) than hormones such as auxin. Different oligosaccharins may have distinct functions. Some trigger the production of **phytoalexins** (from the Greek *phyto,* "plant," and *alexi,* "to ward off"), antimicrobial compounds that limit the spread of plant pathogens such as fungi. Other oligosaccharins inhibit flowering and induce vegetative growth.

Progress is being made in identifying the elusive flower-promoting signal

Experiments in which different tobacco species are grafted together indicate that unidentified flower-promoting and flower-inhibiting substances may exist. *Nicotiana silvestris* is a *long-day* tobacco plant (it requires a short night to flower); a variety of *N. tabacum* is a *day-neutral* tobacco plant (seasonal changes do not affect when it flowers). When a long-day tobacco is grafted to a day-neutral tobacco and exposed to short nights, both plants flower (Fig. 37-13). The day-neutral tobacco plant flowers sooner than it normally would.

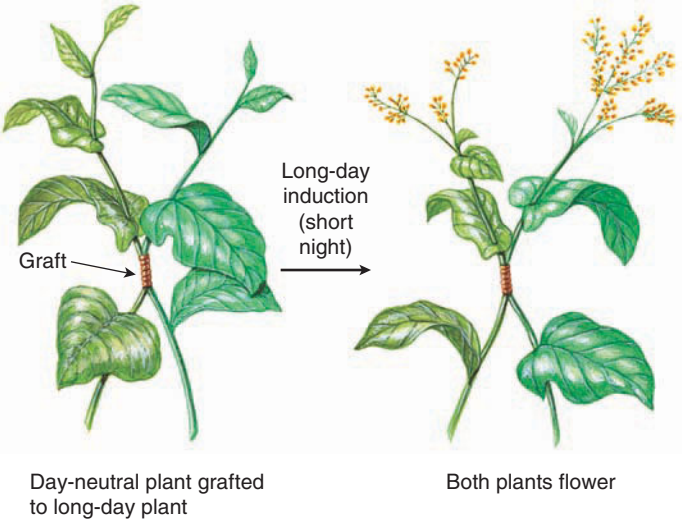

Figure 37-13 Evidence for the existence of a flower-promoting substance

When a long-day tobacco plant (*Nicotiana silvestris*) is grafted to a day-neutral tobacco plant (*N. tabacum*) and both plants are exposed to a long-day–short-night regimen, they both flower. The day-neutral plant flowers sooner than it normally would, presumably because a flower-promoting substance passes from the long-day plant to the day-neutral one through the graft.

Biologists hypothesize that a flower-promoting substance, **florigen,** may be induced in the long-day plant and transported to the day-neutral plant through the graft union, causing the day-neutral tobacco plant to flower sooner than expected. An intact plant may produce florigen in the leaves and transport it in the phloem to the shoot apical meristem. There, it induces a transition from vegetative to reproductive development—that is, to a meristem that produces flowers.

When a botanist grafts a long-day tobacco to a day-neutral tobacco and exposes them to long nights, neither plant flowers. As long as these conditions continue, the day-neutral plants do not flower even when they would normally do so. In this case, the long-day tobacco may produce a flower-inhibiting substance that is transported to the day-neutral tobacco through the graft union. This substance prevents the day-neutral tobacco from flowering.

Biologists have not yet isolated and chemically characterized all flower promoters (florigen) or flower inhibitors. In 2005, however, plant biologists working with the model plant *Arabidopsis* reported the identification of an important component of the florigen signal. A gene known as *Flowering Locus T (FT)* is activated in *Arabidopsis* leaves, and the mRNA transcript is expressed. This *FT* mRNA travels in the phloem from the leaf to the shoot apical meristem, where it is translated into FT protein. The FT pro-

tein interacts with **transcription factors** to alter gene expression, thereby initiating flower development at the shoot apex.

Review

- How are signal reception, signal transduction, and altered cell activity part of the general mechanism of action for auxin?
- How is auxin involved in phototropism?
- Which hormones are involved in each of the following physiological processes: (1) seed germination, (2) stem elongation, (3) fruit ripening, (4) leaf abscission, and (5) seed dormancy?
- How does salicylic acid help plants defend against insects and viruses?

LIGHT SIGNALS AND PLANT DEVELOPMENT

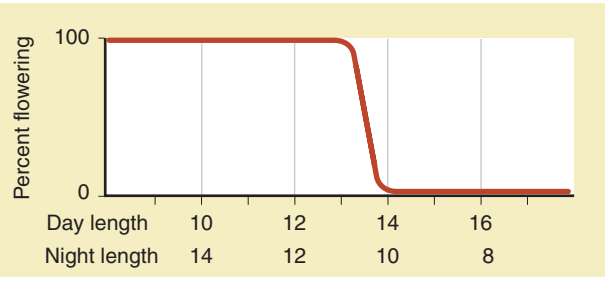
Learning Objectives

6 Explain how varying amounts of light and darkness induce flowering.
7 Describe the role of phytochrome in flowering, including a brief discussion of phytochrome signal transduction.
8 Define *circadian rhythm,* and give an example.
9 Distinguish between phytochrome and cryptochrome.

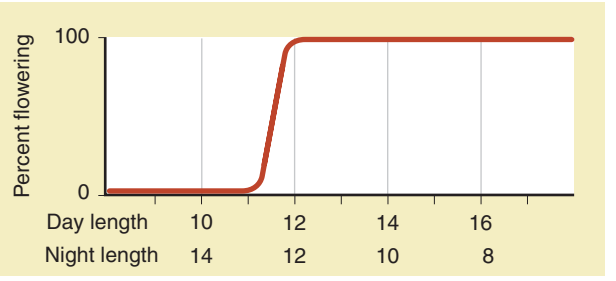
Photoperiodism is any response of a plant to the relative lengths of daylight and darkness. Initiation of flowering at the shoot apical meristem is one of several physiological activities that are photoperiodic in many plants. Plants are classified into four main groups—short-day, long-day, intermediate-day, and day-neutral—on the basis of how photoperiodism affects their transition from vegetative growth to flowering.

Short-day plants (also called **long-night plants**) flower when the night length is equal to or greater than some critical period (Fig. 37-14a). Thus, short-day plants detect the lengthening nights of late summer or fall. There are two kinds of short-day plants: qualitative and quantitative. In *qualitative short-day plants,* flowering occurs only in short days; in *quantitative short-day plants,* flowering is accelerated by short days. The initiation of flowering in short-day plants is not due to the shorter period of daylight but to the long, uninterrupted period of darkness. The minimum critical night length varies considerably from one plant species to another but falls between 12 and 14 hours for many. Examples of short-day plants are florist's chrysanthemum, cocklebur, and poinsettia, which typically flower in late summer or fall. Poinsettias, for example, typically initiate flower buds in early October in the Northern Hemisphere and flower about 8 to 10 weeks later; hence, their traditional association with Christmas.

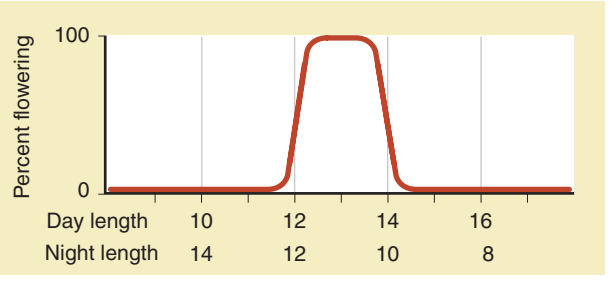
Long-day plants (also called **short-night plants**) flower when the night length is equal to or less than some critical period (Fig. 37-14b). In *qualitative long-day plants,* flowering occurs only in long days; in *quantitative long-day plants,* long days accelerate flowering. Long-day plants, such as spinach, black-eyed Susan (see photograph in chapter introduction) and the model research plant *Arabidopsis thaliana,* flower when they detect the shortening nights of spring and early summer.



(a) Short-day plants flower when the night length is equal to or exceeds a certain critical length in a 24-hour period.



(b) Long-day plants flower when the night length is equal to or less than a certain critical length in a 24-hour period. The critical length varies among different species; short-day plants may require a shorter night length than long-day plants, as shown.



(c) Intermediate-day plants have a narrow night-length requirement.

Figure 37-14 Generalized photoperiodic responses in short-day, long-day, and intermediate-day plants

Intermediate-day plants do not flower when night length is either too long or too short (Fig. 37-14c). Sugarcane and coleus are intermediate-day plants. These plants flower when exposed to days and nights of intermediate length.

Some plants, called **day-neutral plants,** do not initiate flowering in response to seasonal changes in the period of daylight and darkness but instead respond to some other type of stimulus, external or internal. Cucumber, sunflower, corn, and onion are examples of day-neutral plants. Many of these plants originated in the tropics, where day length does not vary appreciably during the year. In contrast, short-day, long-day, and intermediate-day plants are temperate or subtropical (midlatitude species).

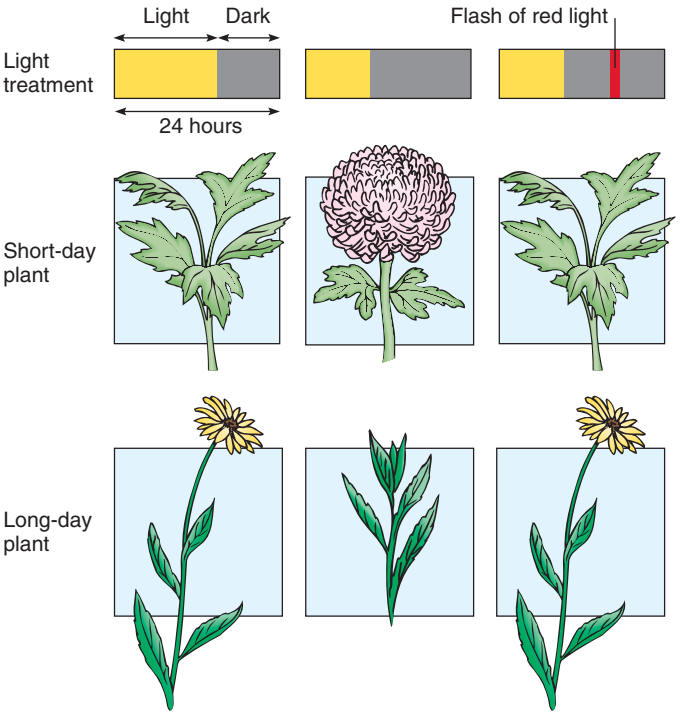


Figure 37-15 ***Animated*** Photoperiodic responses of short-day and long-day plants

A short-day plant flowers when it is grown under long-night conditions (*top middle*), but it does not flower when exposed to a long night interrupted with a brief flash of red light (*top right*). A long-day plant does not flower when grown under long-night conditions (*bottom middle*) unless the long night is interrupted with a brief flash of red light (*bottom right*).

Plant biologists have experimented with the effects of various light regimens on flowering. Figure 37-15 shows how flowering in long-day and short-day plants is affected by different light treatments, including a short-day–long-night regimen with a *night break,* a short burst of light in the middle of the night.

Phytochrome detects day length

The main photoreceptor for photoperiodism and many other light-initiated plant responses (such as germination and seedling establishment) is **phytochrome,** a family of about five blue-green pigment proteins, each of which is coded for by a different gene. A mixture of phytochrome proteins is present in cells of all vascular plants examined so far. For example, five members of the phytochrome family, designated phyA, phyB, phyC, phyD, and phyE, occur in *A. thaliana.*

Much of the current knowledge of phytochrome in *Arabidopsis* is based on various mutant plants that do not express a specific phytochrome gene, such as the gene that codes for phyA. By studying the physiological response of plants that do not produce an individual phytochrome, biologists have concluded that the individual forms of phytochrome have both unique and overlapping functions. PhyB appears to exert its influence at all stages of the plant life cycle, whereas the other forms of phytochrome have narrower functions at specific stages in the life cycle.

PhyA and phyB may have antagonistic (opposite) effects on flowering. In long-day plants, phyB may inhibit flowering and phyA may induce flowering. Flowering occurs more rapidly in long-day plants with mutations in the gene that codes for phyB; such mutations reduce or eliminate the production of phyB. In contrast, flowering is delayed or prevented in long-day plants with mutations in the gene that codes for phyA.

Each member of the phytochrome family exists in two forms and readily converts from one form to the other after absorption of light of specific wavelengths. One form, designated **Pr** (for *r*ed-absorbing *p*hytochrome), strongly absorbs light with a relatively short red wavelength (660 nm). In the process, the shape of the molecule changes to the second form of phytochrome, **Pfr,** so designated because it absorbs *f*ar-*r*ed light, which is light with a relatively long red wavelength (730 nm) (Fig. 37-16). When it absorbs far-red light, Pfr reverts to the original form, Pr. Pfr is the active form of phytochrome, triggering or inhibiting physiological responses such as flowering.

What does a pigment that absorbs red light and far-red light have to do with daylight and darkness? Sunlight consists of various amounts of the entire spectrum of visible light, in addition to ultraviolet and infrared radiation. Because sunlight contains more

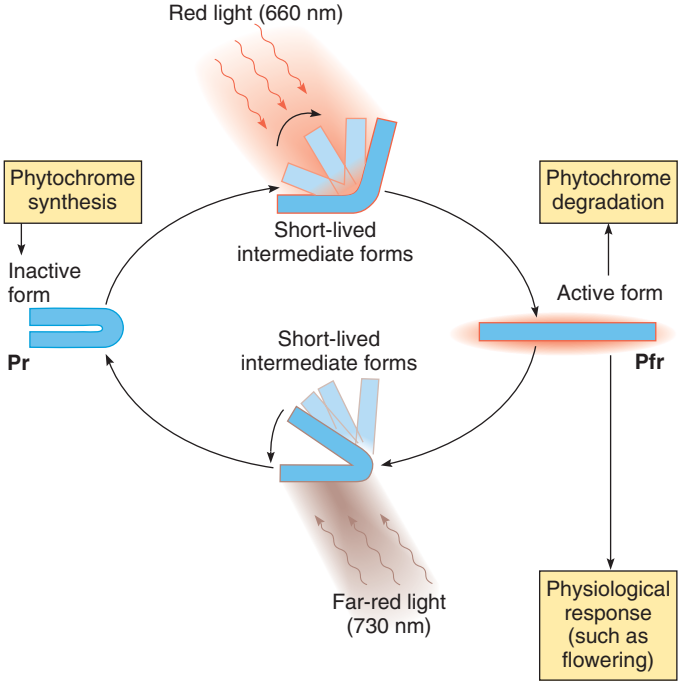

Figure 37-16 ***Animated*** Phytochrome

Each member of the phytochrome family occurs in two forms, designated Pr and Pfr, and readily converts from one form to the other. Red light (660 nm) converts Pr to Pfr, and far-red light (730 nm) converts Pfr to Pr.

red than far-red light, however, when a plant is exposed to sunlight, the level of Pfr increases. During the night, the level of Pfr slowly decreases as Pfr, which is less stable than Pr, is degraded.

The importance of phytochrome to plants cannot be overemphasized. Timing of day length and darkness is the most reliable way for plants to measure the change from one season to the next. This measurement, which synchronizes the stages of plant development, is crucial for survival, particularly in environments where the climate has an annual pattern of favorable and unfavorable seasons.

Competition for sunlight among shade-avoiding plants involves phytochrome

Plants sense the proximity of nearby plants, which are potential competitors, and react by changing the way they grow and develop. Many plants, from small herbs to large trees, compete for light, a response known as **shade avoidance,** in which plants tend to grow taller when closely surrounded by other plants. If successful, the shade-avoiding plant projects its new growth into direct sunlight and thereby increases its chances of survival.

Since the 1970s, botanists have recognized the environmental factor that triggers shade avoidance: plants perceive changes in the ratio of red to far-red light that result from the presence of nearby plants. The leaves of neighboring plants absorb much more red light than far-red light. (The green pigment chlorophyll strongly absorbs red light during photosynthesis.) In a densely plant-populated area, the ratio of red light to far-red light (r/fr) decreases, affecting the equilibrium between the Pr and Pfr forms, particularly of phyB. This signal triggers a series of responses that cause the shade-avoiding plant, which is adapted to full-light environments, to grow taller or flower earlier. Figure 37-17 shows an interesting application of additional (reflected) far-red light without the reduction in incoming sunlight that occurs in shade avoidance.

When a plant is using many of its resources for stem elongation, it has fewer resources for new leaves and branches, storage tissues, and reproductive tissues. However, for a shade-avoiding plant that is shaded by its neighbors, a rapid increase in stem length is advantageous, because once this plant is taller than its neighbors, it obtains a larger share of unfiltered sunlight.

Phytochrome is involved in other responses to light, including germination

Phytochrome is involved in the light requirement that some seeds have for germination. Seeds with a light requirement must be exposed to light containing red wavelengths. Exposure to red light converts Pr to Pfr, and germination occurs. Many temperate forest species with small seeds require light for germination. (Larger seeds generally do not have a light requirement.) This adaptation enables the seeds to germinate at the optimal time. During early spring, sunlight, including red light, penetrates the bare branches of overlying deciduous trees and reaches the soil between the trees. As spring temperatures warm, the seeds on the soil absorb red light and germinate. During their early growth, the newly germinated seedlings do not have to compete with the taller trees for sunlight.

Other physiological functions under the influence of phytochrome include sleep movements in leaves (discussed later); shoot dormancy; leaf abscission; and pigment formation in flowers, fruits, and leaves.

Cary Wolinsky

Figure 37-17 Colored mulches and plant growth processes

The red mulch reflects far-red light from the ground to the tomato plants. The plants, absorbing the extra far-red light, react as if nearby plants are present. Their aboveground growth is greater, and their fruits ripen earlier. Manipulating mulch colors also modifies yield, flavor, and nutrient content.

Phytochrome acts by signal transduction

Some phytochrome-induced responses are very rapid and short-term, whereas others are slower and long-term. The rapid responses probably involve reversible changes in the properties of membranes, altering cell ionic balances. Red light, for example, causes potassium ion (K^+) channels to open in cell membranes involved in plant movements caused by changes in turgor. Exposure to far-red light causes the K^+ channels to close. Slower phytochrome-induced responses involve the selective regulation of transcription of numerous genes. For example, phytochrome activates transcription of the gene for the small subunit of *rubisco*, an enzyme involved in photosynthesis.

Key Point

The active form of phytochrome moves from the cytoplasm into the nucleus, where it affects gene expression by interacting with transcription factors such as PIF3.

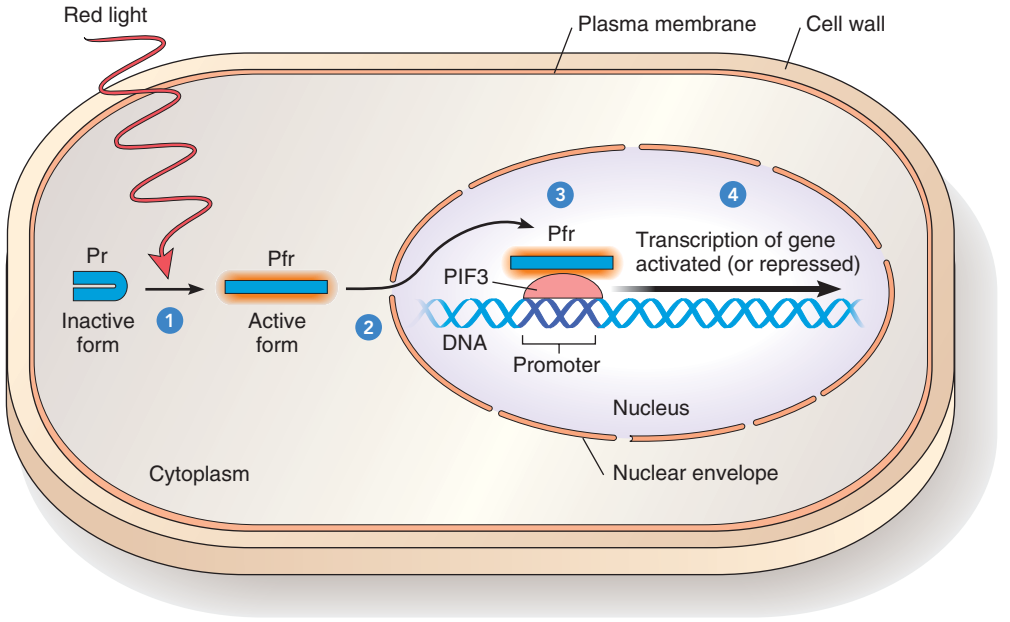

Figure 37-18 Phytochrome signal transduction

The numbered steps are explained in the text.

Each phytochrome molecule consists of a protein attached to a light-absorbing photoreceptor. Biologists hypothesize that the absorption of light by the photoreceptor portion of phytochrome elicits a change in the shape of the larger protein component. This change, in turn, triggers one or more signal transduction pathways.

One important research tool in studying phytochrome signal transduction is mutant plants that respond as if they were exposed to a particular light stimulus even if they were not. Research indicates that the active form of phytochrome moves from the cytoplasm into the nucleus, where it affects gene expression by activating a transcription factor. When activated, the transcription factor, which binds to the promoter of a gene, either turns on or represses transcription that leads to protein synthesis. Biologists have identified **phytochrome-interacting factor (PIF-3),** a transcription factor involved in phytochrome signaling.

The pathway in phytochrome signal transduction with PIF-3 is relatively simple (Fig. 37-18). In step 1, inactive phytochrome (Pr) in the cytoplasm absorbs red light and is converted into the active form, Pfr, which (step 2) moves into the nucleus. There, phytochrome (step 3) binds to the transcription factor PIF3 (which is already bound to the promoter) and (step 4) activates (or represses) the transcription of light-responsive genes.

The signal transduction pathway is shut down by far-red light, which is absorbed by the Pfr in the Pfr–PIF3 complex in the nucleus. When Pfr is converted to Pr, it dissociates from PIF3.

The signal transduction pathway just described is not the end of the story. Biologists think that there are probably other pathways by which phytochrome regulates light-responsive gene expression.

Light influences circadian rhythms

Almost all organisms, including plants, animals, fungi, eukaryotic microorganisms, and many prokaryotes, appear to have an internal timer, or biological clock, that approximates a 24-hour cycle, the time it takes for Earth to rotate around its own axis. These internal cycles are known as **circadian rhythms** (from the Latin *circum,* "around," and *diurn,* "daily"). Circadian rhythms help an organism detect the time of day, whereas photoperiodism enables a plant to detect the time of year.

Why do plants and other organisms exhibit circadian rhythms? Predictable environmental changes, such as sunrise and sunset, occur during the course of each 24-hour period. These predictable changes may be important to an individual organism, causing it to change its physiological activities or its behavior (in the case of animals). Researchers think that circadian rhythms help an organism synchronize repeated daily activities so that they occur at the appropriate time each day. If, for example, an insect-pollinated flower does not open at the time of day that pollinating insects are foraging for food, reproduction will be unsuccessful.

Dennis Drenner

(a) Leaf position at noon in a bean (*Phaseolus vulgaris*) seedling.

Dennis Drenner

(b) Leaf position at midnight.

Figure 37-19 Sleep movements

Circadian rhythms in plants affect such biological events as gene expression, the timing of photoperiodism (that is, of seasonal reproduction), the rate of photosynthesis, and the opening and closing of stomata. **Sleep movements** observed in the common bean and other plants are another example of a circadian rhythm (Fig. 37-19). During the day, bean leaves are horizontal, possibly for optimal light absorption, but at night the leaves fold down or up, a movement that orients them perpendicular to their daytime position. The biological significance of sleep movements is unknown at this time.

When constant environmental conditions are maintained, circadian rhythms such as sleep movements repeat every 20 to 30 hours, at least for several days. In nature, the rising and setting of the sun reset the biological clock so that the cycle repeats every 24 hours. What happens if a plant's circadian clock is mutated so that it is not resynchronized by the day–night cycle? In 2005, biologists at the University of Cambridge in England reported the identification of mutants of the model plant *Arabidopsis* in which the circadian clock is not synchronized to match the external day–night cycle. The mutant plants were found to contain less chlorophyll, fix less carbon by photosynthesis, grow more slowly, and have less of a competitive advantage than *Arabidopsis* plants with a normal circadian clock.

For many plants, two photoreceptors—the red light–absorbing phytochrome and the blue/ultraviolet-A light–absorbing **cryptochrome**—are implicated in resetting the biological clock. Certain amino acid sequences of the protein portion of phytochrome are homologous with amino acid sequences of clock proteins in fruit flies, fungi, mammals, and bacteria; this molecular evidence strongly supports the circadian-clock role of phytochrome. The evidence for cryptochrome as a clock protein is also convincing. First discovered in plants, cryptochrome counterparts are found in the fruit fly and mouse biological-clock proteins. Possibly both photoreceptors are involved in resetting the biological clock in plants; researchers have evidence that phytochrome and cryptochrome sometimes interact to regulate similar responses.

Review

- What is phytochrome? What are two roles of phytochrome?
- What are the steps in phytochrome signal transduction?
- In what process is cryptochrome involved?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Describe phototropism, gravitropism, and thigmotropism (page 790).

- **Tropisms** are directional growth responses. **Phototropism** is growth in response to the direction of light. **Gravitropism** is growth in response to the influence of gravity. **Thigmotropism** is growth in response to contact with a solid object.

ThomsonNOW™ **Learn more about phototropism and gravitropism by clicking on the figures in ThomsonNOW.**

2 Describe a general mechanism of action for plant hormones, using auxin as your example (page 791).

- Plants produce and respond to **hormones,** organic compounds that act as highly specific chemical signals to elicit a variety of responses that regulate growth and development.
- Many plant hormones bind to **enzyme-linked receptors** located in the plasma membrane; the hormone binds to the receptor, triggering an enzymatic reaction of some sort. The receptor for auxin, which is located in the plasma membrane, binds to auxin. This catalyzes the attachment of ubiquitin to repressor proteins, targeting those molecules for destruction. When genes repressed by those proteins are then activated, changes in cell growth and development result.

3 Describe early auxin experiments involving phototropism (page 791).

- Darwin and his son performed phototropism experiments in the 1870s on grass seedlings. When they covered the

coleoptile tip, the plant did not bend. When they removed the coleoptile tip, bending did not occur. When the bottom of the coleoptile was shielded from the light, the coleoptile bent. The Darwins concluded that some substance is transmitted from the upper to the lower part that causes the plant to bend.

- In the 1920s, Frits Went isolated the phototropic hormone from oat coleoptiles by removing the coleoptile tips and placing them on agar blocks. Normal growth resumed when he put one of these agar blocks squarely on a decapitated coleoptile; the substance had diffused from the coleoptile tip into the agar and, later, from the agar into the decapitated coleoptile. Went named this substance auxin.

ThomsonNOW™ See the auxin experiments in action by clicking on the figure in ThomsonNOW.

4 List several ways that each of these hormones affects plant growth and development: auxins, gibberellins, cytokinins, ethylene, and abscisic acid (page 791).

- **Auxin** is involved in cell elongation; tropisms; **apical dominance,** the inhibition of axillary buds by the apical meristem; and fruit development. Auxin also stimulates root development on stem cuttings.
- **Gibberellins** are involved in stem elongation, flowering, and germination.
- **Cytokinins** promote cell division and differentiation; delay **senescence,** the natural aging process; and interact with auxin and ethylene in apical dominance. Cytokinins induce cell division in **tissue culture,** a technique in which cells are isolated from plants and grown in a nutrient medium.
- **Ethylene** plays a role in ripening fruits; apical dominance; leaf abscission; wound response; **thigmomorphogenesis,** a developmental response to mechanical stressors such as wind; and senescence.
- **Abscisic acid** is an environmental stress hormone involved in stomatal closure caused by water stress and in seed **dormancy,** a temporary state of reduced physiological activity.

5 Summarize the activities of these plant hormones and hormone-like signaling molecules: brassinosteroids, jasmonates, salicylic acid, systemin, and oligosaccharins (page 791).

- Plant steroids known as **brassinosteroids** are involved in several aspects of plant growth and development, such as cell division, cell elongation, light-induced differentiation, seed germination, and vascular development.
- **Jasmonates** affect several plant processes, such as pollen development, root growth, fruit ripening, and senescence. They are also produced in response to the presence of insect pests and disease-causing organisms.
- **Salicylic acid** triggers **systemic acquired resistance** that helps defend plants against pathogens and insect pests.
- **Systemin,** a polypeptide with hormonal properties, stimulates a natural defense mechanism in which the plant produces molecules that disrupt insect digestion.
- **Oligosaccharins,** short branched chains of sugar molecules, inhibit flowering and stimulate vegetative growth.

6 Explain how varying amounts of light and darkness induce flowering (page 800).

- **Photoperiodism** is any response of plants to the duration and timing of light and dark. Flowering is a photoperiodic response in many plants. **Short-day plants** detect the lengthening nights of late summer or fall and flower at that time. **Long-day plants** detect the shortening nights of spring and early summer and flower at that time. **Intermediate-day plants** flower when exposed to days and nights of intermediate length.

ThomsonNOW™ Learn more about photoperiodism by clicking on the figure in ThomsonNOW.

7 Describe the role of phytochrome in flowering, including a brief discussion of phytochrome signal transduction (page 800).

- The photoreceptor in photoperiodism is **phytochrome,** a family of about five blue-green pigments. Each type of phytochrome has two forms, **Pr** and **Pfr,** named by the wavelength of light they absorb. Pfr is the active form, triggering or inhibiting physiological responses such as flowering, **shade avoidance,** and a light requirement for germination.
- The pathway in phytochrome **signal transduction** begins when inactive phytochrome in the cytoplasm absorbs red light and is converted into the active form, Pfr, which moves into the nucleus. There, phytochrome binds to the transcription factor PIF3 (phytochrome-interacting factor) and activates or represses the transcription of light-responsive genes.

ThomsonNOW™ Learn more about phytochrome by clicking on the figure in ThomsonNOW.

8 Define *circadian rhythm,* and give an example (page 800).

- A **circadian rhythm** is a regular period in an organism's growth or activities that approximates the 24-hour day and is reset by the rising and setting of the sun. Two examples of circadian rhythms are the opening and closing of stomata and **sleep movements.**

9 Distinguish between phytochrome and cryptochrome (page 800).

- Both phytochrome and **cryptochrome** are photoreceptors that sometimes interact to regulate similar responses, such as resetting the biological clock. Phytochrome strongly absorbs red light, whereas cryptochrome absorbs blue and ultraviolet-A light.

TEST YOUR UNDERSTANDING

1. In the signal transduction process for the hormone auxin, the molecule ubiquitin (a) absorbs blue light (b) becomes phosphorylated (c) tags certain proteins for destruction (d) interacts antagonistically with gibberellins (e) binds to a receptor in the plant cell's plasma membrane

2. When you prune shrubs to make them "bushier"—that is, to prevent apical dominance—you are affecting the distribution and action of which plant hormone? (a) auxin (b) jasmonic acid (c) systemin (d) ethylene (e) abscisic acid

3. A synthetic _____ known as 2,4-D is used as a selective herbicide. (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
4. Research on a fungal disease of rice provided the first clues about the plant hormone (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
5. This plant hormone interacts with auxin during the formation of plant organs in tissue culture. (a) florigen (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
6. The plant hormone _____ delays senescence, whereas the plant hormone _____ promotes senescence. (a) cytokinin; auxin (b) auxin; cytokinin (c) cytokinin; ethylene (d) abscisic acid; ethylene (e) gibberellin; auxin
7. The stress hormone that helps plants respond to drought is (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
8. This hormone promotes seed dormancy. (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
9. Which signaling molecule triggers the release of volatile substances that attract parasitic wasps to plant-eating caterpillars? (a) brassinosteroid (b) jasmonic acid (c) systemin (d) salicylic acid (e) oligosaccharin
10. The three classes of photoreceptors that enable plants to sense the presence and duration of light are (a) phytochrome, cryptochrome, and circadian rhythms (b) chlorophyll, photosynthesis, and photoperiodism (c) phytochrome, photoperiodism, and chlorophyll (d) phytochrome, cryptochrome, and phototropin (e) phototropin, photosynthesis, and photoperiodism
11. A plant's response to the relative amounts of daylight and darkness is (a) apical dominance (b) bolting (c) gravitropism (d) photoperiodism (e) phototropism
12. Pfr, the active state of _____, forms when red light is absorbed. (a) photosystem I (b) phytochrome (c) far-red light (d) phototropin (e) cryptochrome
13. Which of the following represents the correct order in the phytochrome signal transduction pathway?

    1. red light 2. light-responsive gene is switched on (or off) 3. movement of Pfr to nucleus 4. conversion of Pr to Pfr 5. formation of PFr–PIF3 complex that is bound to promoter region

    (a) 1, 3, 5, 4, 2 (b) 1, 5, 3, 2, 4 (c) 1, 2, 3, 4, 5 (d) 1, 4, 3, 2, 5 (e) 1, 4, 3, 5, 2
14. Which of the following statements about phytochrome is *incorrect?* (a) phytochrome is the main photoreceptor for photoperiodism (b) phytochrome is a family of about five blue-green pigment proteins, each coded by a different gene (c) most of our knowledge of phytochrome function is based on mutant corn (*Zea mays*) plants (d) each member of the phytochrome family exists in two forms: Pr and Pfr (e) phytochrome helps plants sense the presence of nearby plants with which they must compete for light
15. Which photoreceptor(s) is/are implicated in resetting the biological clock? (a) phytochrome only (b) cryptochrome only (c) phototropin only (d) cryptochrome and gibberellin (e) phytochrome and cryptochrome
16. The orientation of the growth of a plant according to the direction of light is called _____, whereas the twining of tendrils is an example of _____. (a) thigmomorphogenesis; gravitropism (b) photoperiodism; thigmomorphogenesis (c) phototropism; gravitropism (d) phototropism; thigmotropism (e) photoperiodism; thigmotropism

CRITICAL THINKING

1. Predict whether flowering in a short-day plant with a minimum critical night length of 14 hours would be expected to occur in the following situations. Explain each answer. (a) The plant is exposed to 15 hours of daylight and 9 hours of uninterrupted darkness. (b) The plant is exposed to 9 hours of daylight and 15 hours of darkness. (c) The plant is exposed to 9 hours of daylight and 15 hours of darkness, with a 10-minute exposure to red light in the middle of the night.
2. If you transplanted the short-day plant discussed in question 1 to the tropics, would it flower? Explain your answer.
3. **Evolution Link.** What adaptive advantages are conferred on a plant whose stems are positively phototropic and whose roots are positively gravitropic?
4. **Evolution Link.** Explain why a plant with a mutation in one of its phytochrome genes that affects flowering time would be at an evolutionary disadvantage.
5. **Analyzing Data.** Examine Figure 37-14a. When the day length is 10 hours and the night length is 14 hours, what percent of the plants flower? When the day length is 16 hours and the night length is 8 hours, what percent of the plants flower? What is the critical night length for this plant?

Animal Structure and Function: An Introduction

Fritz Polking/Dembinsky Photo Associates

Larger body size does not mean bigger cells. The cells of the Yacare caiman (*Caiman yacare*) and the flambeau butterfly (*Dryas julia*) on its head are all about the same size. The caiman is larger because its genes specify that its body should consist of a larger number of cells.

KEY CONCEPTS

Structure and function are closely linked at every level of organization.

The main types of tissues in a complex animal are epithelial, connective, muscle, and nervous.

Tissues and organs form the 11 main organ systems of a complex animal.

Homeostatic mechanisms are responsible for the body's automatic tendency to maintain a relatively stable internal environment.

Thermoregulation contributes to homeostasis.

Animal groups are dramatically diverse with radically different body structures. For example, consider how different the caiman and the butterfly are, not only in size but also in body form and lifestyle (see photograph). Despite their differences, animal groups share many characteristics. One of these characteristics is their relatively large size.

Why *are* most animals larger than bacteria, protists, and fungi? The answer may be related to *ecological niches*, which are the functional roles of a species within a community. By the time animals evolved, bacteria, protists, and fungi already occupied most available ecological niches. For new species to succeed, they had to displace others from a niche or adapt to a new one. Success in a new niche required a new body plan, and new body plans often involved larger size. Increased size provided more opportunity for capturing food. Predators are typically larger than their prey.

To grow larger than their bacterial and protist competitors, animals had to be multicellular. Recall that the size of a single cell is limited by the ratio of its surface area (plasma membrane) to its volume (see Chapter 4). The plasma membrane needs to be large enough relative to the cell's volume to permit passage of materials into and out of the cell so that the conditions necessary for life can be maintained. In a multicellular animal, each cell has a large enough surface area–to-volume ratio to effectively regulate its internal environment. Individual cells live and die and are replaced while the organism continues to maintain itself and thrive. The number of cells, not their individual sizes, is mainly responsible for the size of an animal.

In unicellular organisms, such as bacteria and many protists, the single cell carries on all the activities necessary for life. Recall that unicellular and small, flat organisms depend on diffusion for many life processes, including gas exchange and disposal of metabolic wastes. One reason they can be small is that they do not require complex organ systems.

In Chapter 1 we discussed the levels of organization of multicellular organisms. Recall that cells organize to form *tissues,* and tissues associate to form *organs* such as the heart or stomach. Groups of tissues and organs form the *organ systems* of a complex *organism.* Billions of cells may be organized to form the tissues, organs, and organ systems of a complex animal. **Anatomy** is the study of an organism's structure. **Physiology** is the study of how the body functions. Structure and function are closely linked at every level of organization.

Cells, tissues, organs, and organ systems work together to maintain appropriate conditions in the body. The tendency to maintain a relatively constant internal environment is called *homeostasis,* and the processes that accomplish the task are *homeostatic mechanisms.* For example, in mammals, nervous, endocrine, and cardiovascular systems work together to regulate body temperature.

In this chapter we focus on the basic form and function of animals. We describe the types and functions of tissues as well as organ systems. We discuss the important concept of homeostasis, using regulation of body temperature as an example. In the following chapters, we discuss how animals carry out life processes and how organ systems work together to maintain homeostasis of the animal as a whole. ■

TISSUES

Learning Objectives

1. Compare the structure and function of the four main kinds of animal tissues: epithelial, connective, muscle, and nervous.
2. Compare the structure and function of the main types of epithelial tissue.
3. Compare the main types of connective tissue, and summarize their functions.
4. Contrast the three types of muscle tissue and their functions.
5. Relate the structure of the neuron to its function.

In a multicellular organism, cells specialize to perform specific tasks. A **tissue** consists of a group of closely associated, similar cells that carry out specific functions. Biologists classify animal tissues as epithelial, connective, muscle, or nervous. Classification of tissues depends on their structure and origin. Each kind of tissue is composed of cells with characteristic sizes, shapes, and arrangements; and each type of tissue is specialized to perform a specific function or group of functions. For example, some tissues are specialized to transport materials, whereas others contract, enabling the animal to move. Still others secrete hormones that regulate metabolic processes. As we discuss each tissue type, notice the relationship between its form and its function.

Epithelial tissues cover the body and line its cavities

Epithelial tissue (also called **epithelium**) consists of cells fitted tightly together to form a continuous layer, or sheet, of cells. One surface of the sheet is typically exposed because it covers the body (outer layer of the skin) or lines a cavity, such as the *lumen* (the cavity in a hollow organ) of the intestine. The other surface of an epithelial layer attaches to the underlying tissue by a noncellular **basement membrane** consisting of tiny fibers and nonliving polysaccharide material that the epithelial cells produce.

Epithelial tissue forms the outer layer of the skin and the linings of the digestive, respiratory, excretory, and reproductive tracts. As a result, everything that enters or leaves the body must cross at least one layer of epithelium. Food taken into the mouth and swallowed is not really "inside" the body until it is absorbed through the epithelium of the gut and enters the blood. To a large extent, the permeabilities of the various epithelial tissues regulate the exchange of substances between the different parts of the body, as well as between the animal and the external environment.

Epithelial tissues perform many functions, including protection, absorption, secretion, and sensation. The epithelial layer of the skin, the **epidermis,** covers the entire body and protects it from mechanical injury, chemicals, bacteria, and fluid loss. The epithelial tissue lining the digestive tract absorbs nutrients and water into the body. Some epithelial cells form **glands** that secrete cell products such as hormones, enzymes, or sweat. Other epithelial cells are sensory receptors that receive information from the environment. For example, epithelial cells in taste buds and in the nose specialize as chemical receptors.

Table 38-1 illustrates the main types of epithelial tissue, indicates their locations in the body, and describes their functions. We can distinguish three types of epithelial cells on the basis of shape. **Squamous** epithelial cells are thin, flat cells shaped like flagstones. **Cuboidal** epithelial cells are short cylinders that from the side appear cube shaped, like dice. Actually, each cuboidal cell is typically hexagonal in cross section, making it an eight-sided polyhedron.

Columnar epithelial cells look like columns or cylinders when viewed from the side. The nucleus is usually located near the base of the cell. Viewed from above or in cross section, these cells often appear hexagonal. On its free surface, a columnar epithelial cell may have cilia that beat in a coordinated way, moving materials over the tissue surface. Most of the upper respiratory tract is lined

with ciliated columnar epithelium that moves particles of dust and other foreign material away from the lungs.

Epithelial tissue is also classified by the number of layers. **Simple epithelium** is composed of one layer of cells. It is usually located where substances are secreted, excreted, or absorbed or where materials diffuse between compartments. For example, simple squamous epithelium lines the air sacs in the lungs. The structure of this thin tissue is wonderfully suited to permit diffusion of gases in and out of air sacs.

Stratified epithelium, which has two or more layers, is found where protection is required. Stratified squamous epithelium, which makes up the outer layer of your skin, continuously regenerates as it is sloughed off during normal wear and tear. The cells of **pseudostratified epithelium** falsely appear layered. Although all its cells rest on a basement membrane, not every cell extends to the exposed surface of the tissue. This arrangement gives the impression of two or more cell layers. Some of the respiratory passageways are lined with pseudostratified epithelium equipped with cilia.

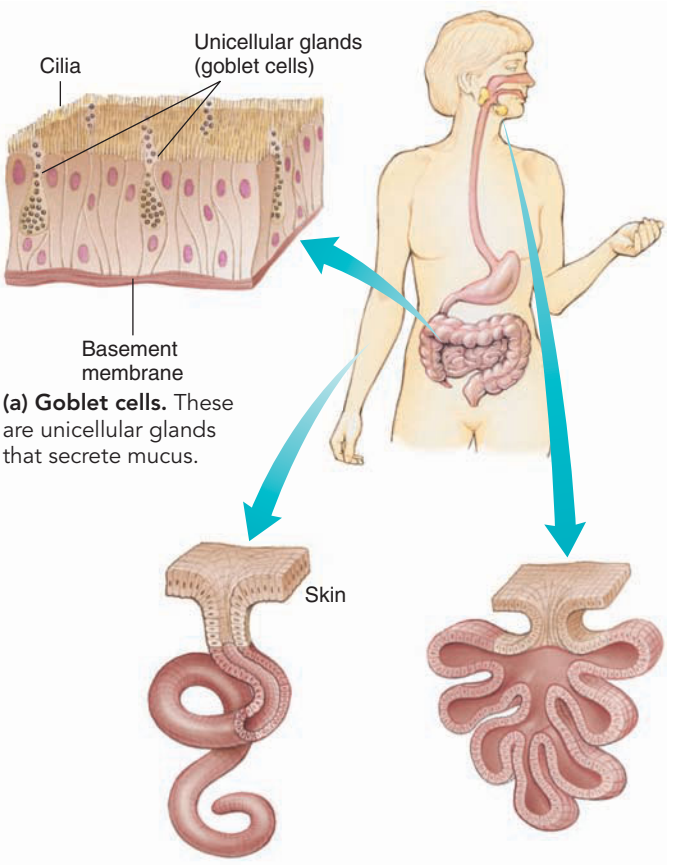
The lining of blood and lymph vessels is called **endothelium.** Endothelial cells have a different embryonic origin from "true" epithelium. However, these cells are structurally similar to squamous epithelial cells and can be included in that category.

A gland consists of one or more epithelial cells specialized to produce and secrete a product such as sweat, milk, mucus, wax, saliva, hormones, or enzymes (Fig. 38-1). Epithelial tissue lining the cavities and passageways of the body typically has some specialized mucus-secreting cells called **goblet cells.** The mucus lubricates these surfaces, offers protection, and facilitates the movement of materials.

Glands are classified as exocrine or endocrine. **Exocrine glands,** like goblet cells and sweat glands, secrete their products onto a free epithelial surface, typically through a duct (tube). **Endocrine glands** lack ducts. These glands release their products, called **hormones,** into the **interstitial fluid** (tissue fluid) or blood; hormones are typically transported by the cardiovascular system. (Endocrine glands are discussed in Chapter 48.)

An **epithelial membrane** consists of a sheet of epithelial tissue and a layer of underlying connective tissue. Types of epithelial membranes include mucous membranes and serous membranes. A **mucous membrane,** or mucosa, lines a body cavity that opens to the outside of the body, such as the digestive or respiratory tract. The epithelial layer secretes mucus that lubricates the tissue and protects it from drying.

A **serous membrane** lines a body cavity that does not open to the outside of the body. It consists of simple squamous epithelium over a thin layer of loose connective tissue. This type of membrane secretes fluid into the cavity it lines. Examples of serous membranes are the pleural membranes lining the pleural cavities around the lungs and the pericardial membranes lining the pericardial cavity around the heart.



(a) Goblet cells. These are unicellular glands that secrete mucus.

(b) Sweat gland. Sweat glands are simple glands consisting of coiled tubes. Their walls are constructed of simple cuboidal epithelium.

(c) Parotid salivary gland. Compound glands, like the parotid, have branched ducts.

Figure 38-1 Glands

A gland consists of one or more epithelial cells.

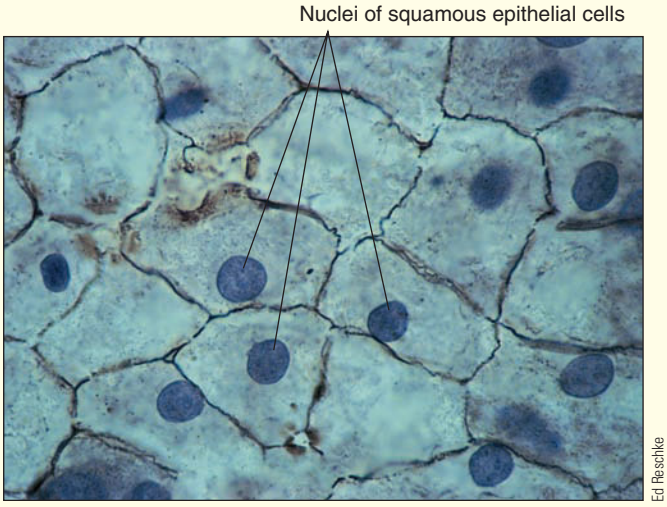
Connective tissues support other body structures

Almost every organ in the body has a framework of **connective tissue** that supports and cushions it. Typically, connective tissues contain relatively few cells. Its cells are embedded in an extensive **intercellular substance** consisting of threadlike, microscopic **fibers** scattered throughout a **matrix,** a thin gel of polysaccharides that the cells secrete. The nature and function of each kind of connective tissue are determined in part by the structure and properties of the intercellular substance.

Connective tissue typically contains three types of fibers: collagen, elastic, and reticular. **Collagen fibers,** the most numerous type, are made of **collagens,** a group of fibrous proteins found in all animals (see Fig. 3-22b). Collagens are the most abundant proteins in mammals, accounting for about 25% of their total protein mass. Collagen is very tough (meat is tough because of its collagen content). The tensile strength (ability to stretch without tearing) of collagen fibers is comparable to that of steel. Collagen

TABLE 38-1

Epithelial Tissues



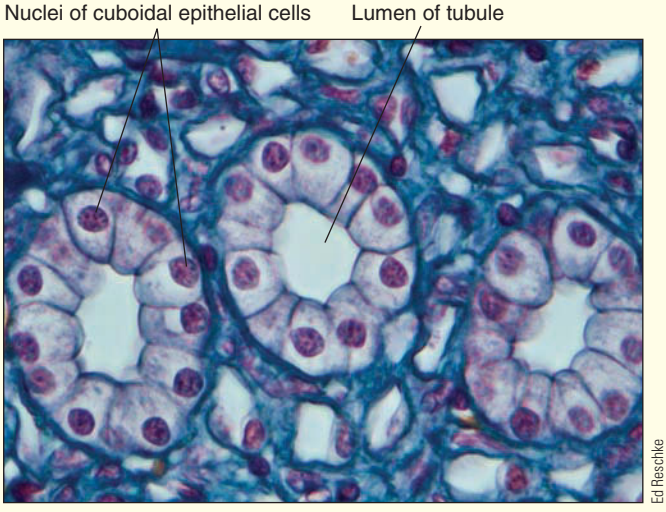
LM of simple squamous epithelium.

Simple Squamous Epithelium

Main Locations
Air sacs of lungs; lining of blood vessels

Functions
Passage of materials where little or no protection is needed and where diffusion is major form of transport

Description and Comments
Cells are flat and arranged as single layer



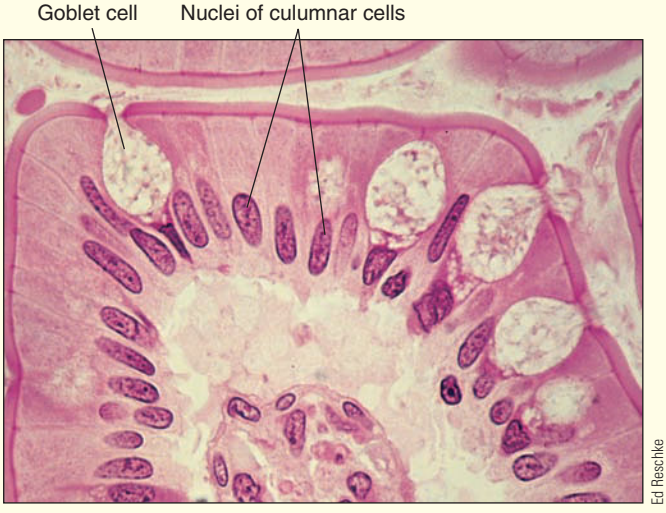
LM of simple cuboidal epithelium.

Simple Cuboidal Epithelium

Main Locations
Linings of kidney tubules; gland ducts

Functions
Secretion and absorption

Description and Comments
Single layer of cells; LM shows cross section through tubules; from the side each cell looks like a short cylinder; some have microvilli for absorption



LM of simple columnar epithelium.

Simple Columnar Epithelium

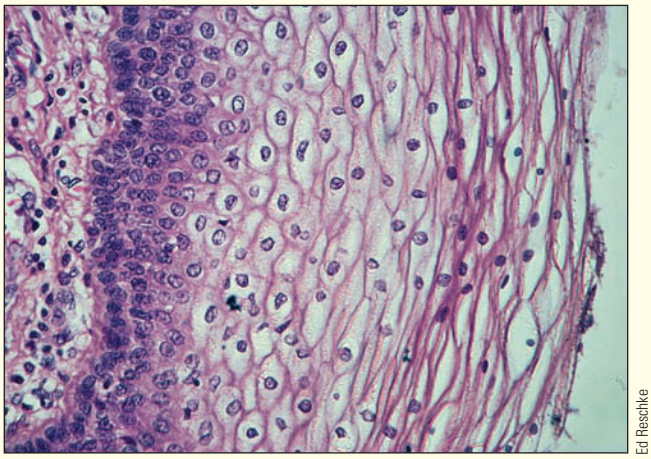
Main Locations
Linings of much of digestive tract and upper part of respiratory tract

Functions
Secretion, especially of mucus; absorption; protection; movement of layer of mucus

Description and Comments
Single layer of columnar cells; sometimes with enclosed secretory vesicles (in goblet cells); highly developed Golgi complex; often ciliated

TABLE 38-1

Continued



LM of stratified squamous epithelium.

Stratified Squamous Epithelium

Main Locations
Skin; mouth lining; vaginal lining

Functions
Protection only; little or no absorption or transit of materials; outer layer continuously sloughed off and replaced from below

Description and Comments
Several layers of cells, with only the lower ones columnar and metabolically active; division of lower cells causes older ones to be pushed upward toward surface, becoming flatter as they move

LM of pseudostratified columnar epithelium, ciliated.

Pseudostratified Epithelium

Main Locations
Some respiratory passages; ducts of many glands

Functions
Secretion; protection; movement of mucus

Description and Comments
Ciliated, mucus-secreting, or with microvilli; comparable in many ways to columnar epithelium except that not all cells are the same height; so, though all cells contact the same basement membrane, the tissue appears stratified

fibers are wavy and flexible, allowing them to remain intact when tissue is stretched.

Elastic fibers branch and fuse to form networks. They can be stretched by a force and then (like a stretched rubber band) return to their original size and shape when the force is removed. Elastic fibers, composed of the protein elastin, are an important component of structures that must stretch.

Reticular fibers are very thin, branched fibers that form delicate networks joining connective tissues to neighboring tissues. Reticular fibers consist of collagen and some glycoprotein.

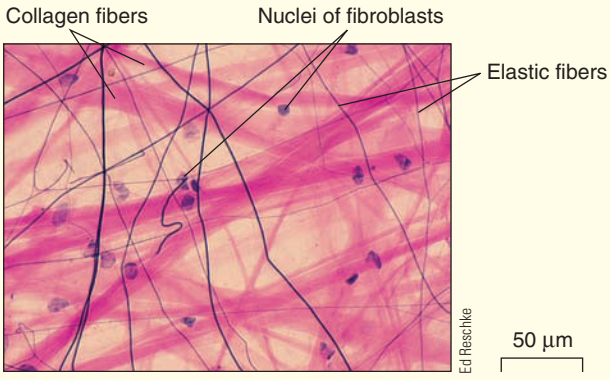
The cells of different kinds of connective tissues differ in their shapes and structures and in the kinds of fibers and matrices they secrete. **Fibroblasts** are connective tissue cells that produce the fibers, as well as the protein and carbohydrate complexes, of the matrix. Fibroblasts release protein components that become arranged to form the characteristic fibers. These cells are especially active in developing tissues and are important in healing wounds. As tissues mature, the number of fibroblasts decreases and they become less active. **Macrophages,** the body's scavenger cells, commonly wander through connective tissues, cleaning up cell debris and phagocytosing foreign matter, including bacteria.

Some of the main types of connective tissue are (1) loose and dense connective tissues; (2) elastic connective tissue; (3) reticular connective tissue; (4) adipose tissue; (5) cartilage; (6) bone; and (7) blood, lymph, and tissues that produce blood cells. These tissues vary widely in their structural details and in the functions they perform (▮ Table 38-2).

Loose connective tissue is the most widely distributed connective tissue in the vertebrate body. This thin filling between body parts serves as a reservoir for fluid and salts. Nerves, blood vessels, and muscles are wrapped in this tissue. Together with adipose tissue, loose connective tissue forms the subcutaneous (below the skin) layer that attaches skin to the muscles and other structures beneath. Loose connective tissue consists of fibers

TABLE 38-2

Connective Tissues



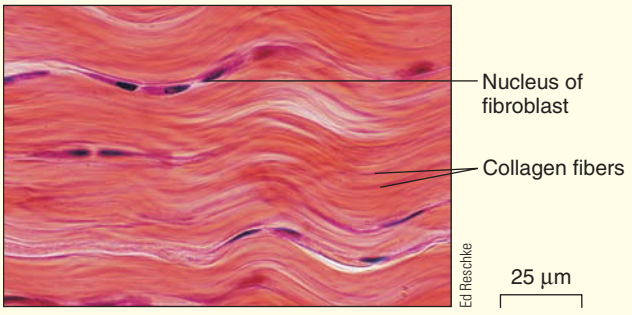
LM of loose connective tissue.

Loose Connective Tissue

Main Locations
Everywhere that support must be combined with elasticity, such as subcutaneous tissue (the layer of tissue beneath the dermis of the skin)

Functions
Support; reservoir for fluid and salts

Description and Comments
Fibers produced by fibroblast cells embedded in semifluid matrix and mixed with miscellaneous other cells



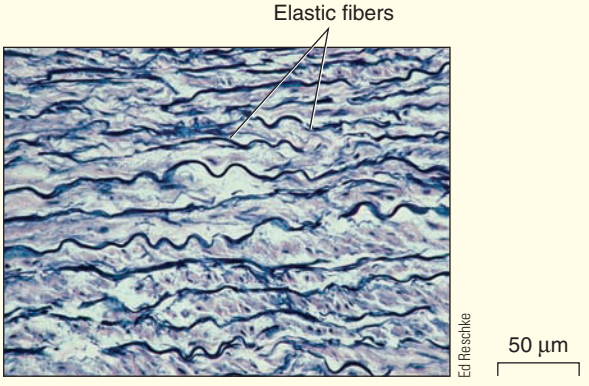
LM of dense connective tissue.

Dense Connective Tissue

Main Locations
Tendons; many ligaments; dermis of skin

Functions
Support; transmission of mechanical forces

Description and Comments
Collagen fibers may be regularly or irregularly arranged



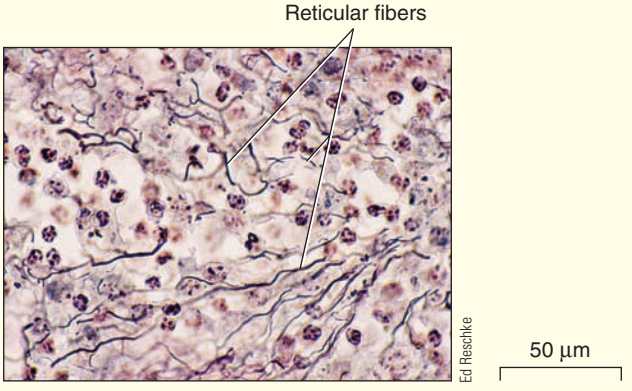
LM of elastic connective tissue.

Elastic Connective Tissue

Main Locations
Structures that must both expand and return to their original size, such as lung tissue and large arteries

Function
Confers elasticity

Description and Comments
Branching elastic fibers interspersed with fibroblasts



LM of reticular connective tissue.

Reticular Connective Tissue

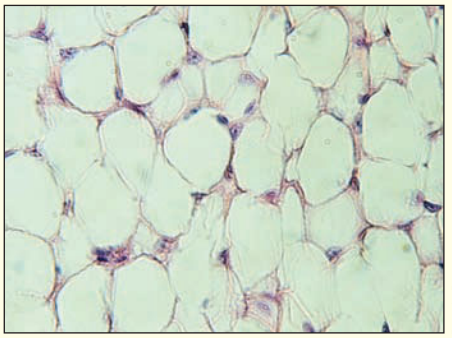
Main Locations
Framework of liver; lymph nodes; spleen

Function
Support

Description and Comments
Consists of interlacing reticular fibers

TABLE 38-2

Continued



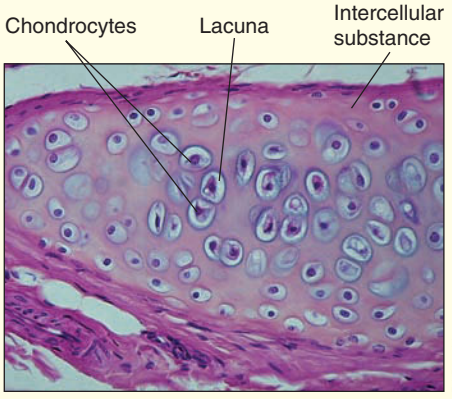
LM of adipose tissue.

Adipose Tissue

Main Locations
Subcutaneous layer; pads around certain internal organs

Functions
Food storage; insulation; support of such organs as mammary glands, kidneys

Description and Comments
Fat cells are star shaped at first; fat droplets accumulate until typical ring-shaped cells are produced



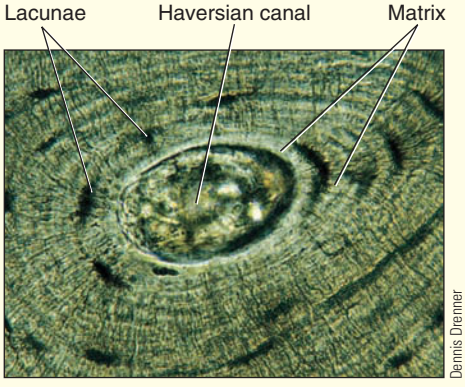
LM of cartilage.

Cartilage

Main Locations
Supporting skeletons in sharks and rays; ends of bones in mammals and some other vertebrates; supporting rings in walls of some respiratory tubes; tip of nose; external ear

Function
Flexible support

Description and Comments
Cells (chondrocytes) separated from one another by intercellular substance; cells occupy lacunae



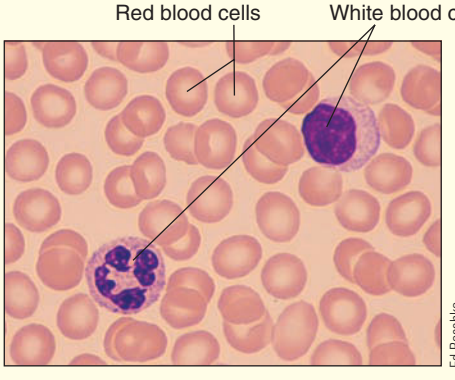
LM of bone.

Bone

Main Locations
Forms skeletal structure in most vertebrates

Functions
Support and protection of internal organs; calcium reservoir; skeletal muscles attach to bones

Description and Comments
Osteocytes in lacunae; in compact bone, lacunae embedded in lamellae, concentric circles of matrix surrounding Haversian canals



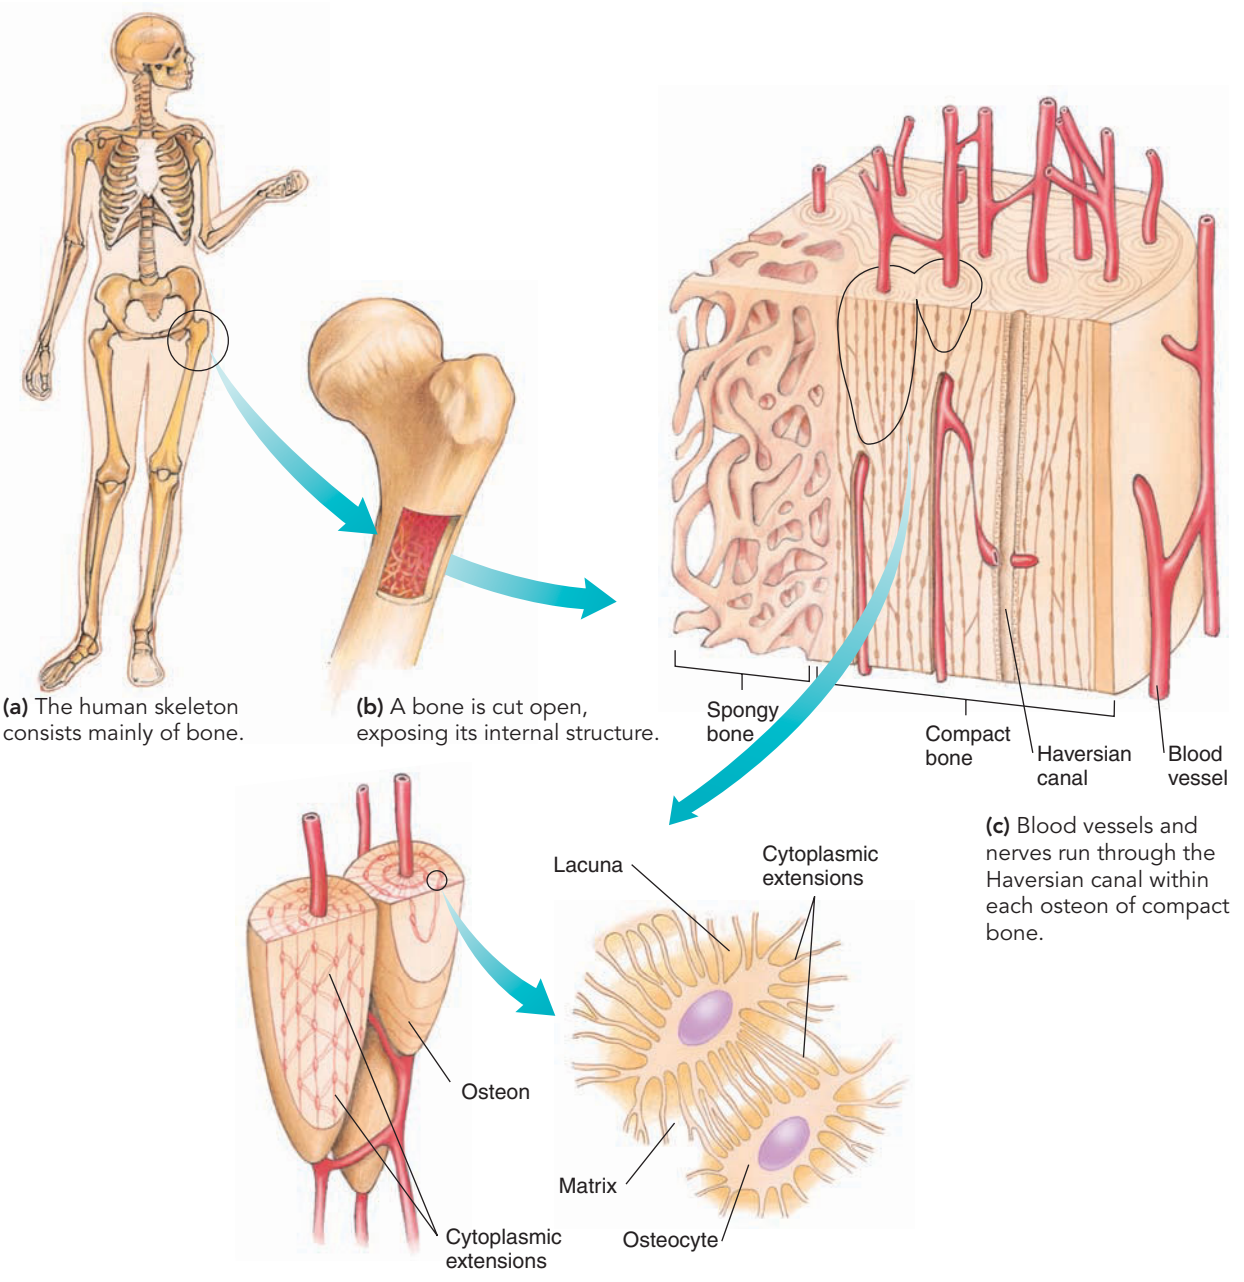
LM of blood.

Blood

Main Locations
Within heart and blood vessels of circulatory system

Functions
Transports oxygen, nutrients, wastes, and other materials

Description and Comments
Consists of cells dispersed in fluid intercellular substance (plasma)



(a) The human skeleton consists mainly of bone.

(b) A bone is cut open, exposing its internal structure.

(c) Blood vessels and nerves run through the Haversian canal within each osteon of compact bone.

(d) The bone matrix is rigid and hard. Osteocytes become trapped within lacunae but communicate with one another by way of cytoplasmic extensions that extend through tiny canals.

Figure 38-2 Bone

running in all directions through a semifluid matrix. Its flexibility permits the parts it connects to move.

Dense connective tissue, found in the dermis (lower layer) of the skin, is very strong, though somewhat less flexible than loose connective tissue. Collagen fibers predominate. **Tendons,** the cords that connect muscles to bones, and **ligaments,** the cables that connect bones to one another, consist of dense connective tissue in which collagen bundles are arranged in a definite pattern.

Elastic connective tissue consists mainly of bundles of parallel elastic fibers. This tissue is found in structures that must expand and then return to their original size, such as lung tissue and the walls of large arteries.

Reticular connective tissue is composed mainly of interlacing reticular fibers. It forms a supporting internal framework in many organs, including the liver, spleen, and lymph nodes.

The cells of **adipose tissue** store fat and release it when fuel is needed for cellular respiration. Adipose tissue is found in the subcutaneous layer and in tissue that cushions internal organs.

The supporting skeleton of a vertebrate is made of cartilage, or of both cartilage and bone. **Cartilage** is the supporting skeleton in the embryonic stages of all vertebrates. In most vertebrates,

bone replaces cartilage during development. However, cartilage remains in some supporting structures. For example, in humans cartilage is found in the external ear, the supporting rings in the walls of the respiratory passageways, the tip of the nose, the ends of some bones, and the discs that serve as cushions between the vertebrae.

Cartilage is firm yet elastic. Its cells, called **chondrocytes,** secrete a hard, rubbery matrix around themselves and also secrete collagen fibers, which become embedded in the matrix and strengthen it. Chondrocytes eventually come to lie, singly or in groups of two or four, in small cavities in the matrix called **lacunae.** These cells remain alive and are nourished by nutrients and oxygen that diffuse through the matrix. Cartilage tissue lacks nerves, lymph vessels, and blood vessels.

Bone, the main vertebrate skeletal tissue, is like cartilage in that it consists mostly of matrix material. The bone cells, called **osteocytes,** are contained within lacunae. Osteocytes secrete and maintain the matrix (Fig. 38-2). Unlike cartilage, however, bone is a highly vascular tissue, with a substantial blood supply. Osteocytes communicate with one another and with capillaries by tiny channels (*canaliculi*) that contain long cytoplasmic extensions of the osteocytes.

A typical bone has an outer layer of *compact bone* surrounding a filling of *spongy bone.* Compact bone consists of spindle-shaped units called **osteons.** Within each osteon, osteocytes are arranged in concentric layers of matrix called *lamellae.* In turn, the lamellae surround central microscopic channels known as **Haversian canals,** through which capillaries and nerves pass.

Bones are amazingly light and strong. Calcium salts of bone render the matrix very hard, and collagen prevents the bony matrix from being overly brittle. Most bones have a large, central **marrow cavity** that contains a spongy tissue called *marrow.* Yellow marrow consists mainly of fat. Red marrow is the connective tissue in which blood cells are produced. We discuss bone in more detail in Chapter 39.

Blood and **lymph** are circulating tissues that help other parts of the body communicate and interact. Like other connective tissues, they consist of specialized cells dispersed in an intercellular substance. In mammals, blood consists of **red blood cells, white blood cells,** and **platelets,** all suspended within **plasma,** the liquid, noncellular part of the blood. In humans and other vertebrates, red blood cells contain the respiratory pigment that transports oxygen. White blood cells defend the body against disease-causing microorganisms (see Chapter 44). Platelets, small fragments broken off from large cells in the bone marrow, play a key role in blood clotting. Plasma consists of water, proteins, salts, and a variety of soluble chemical messengers such as hormones that it transports from one part of the body to another. We discuss blood in Chapter 43.

Muscle tissue is specialized to contract

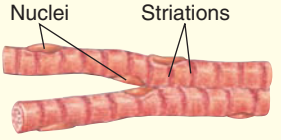
Most animals move by contracting the long, cylindrical or spindle-shaped cells of **muscle tissue.** Each muscle cell is called a **muscle fiber** because of its length. A muscle fiber contains many thin, longitudinal, parallel contractile units called **myofibrils.** Two proteins, **myosin** and **actin,** are the chief components of myofibrils and play a key role in contraction of muscle fibers.

Some invertebrates have skeletal and smooth muscle. Vertebrates have three types of muscle tissue: skeletal, cardiac, and smooth (Table 38-3). **Skeletal muscle** makes up the large muscle masses attached to the bones of the body. Skeletal muscle fibers are very long, and each fiber has many nuclei. The nuclei of skeletal muscle fibers are also unusual in their position. They lie just under the plasma membrane, which frees the entire central part of the skeletal muscle fiber for the myofibrils. This adaptation appears to increase the efficiency of contraction. When skeletal muscles contract, they move parts of the body. Whereas skeletal muscle fibers are generally under voluntary control, you

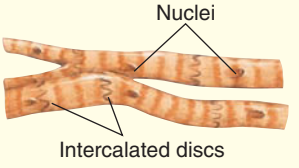
TABLE 38-3

Muscle Tissues

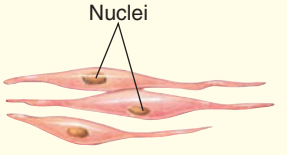
	Skeletal	Cardiac	Smooth
Location	Attached to skeleton	Walls of heart	Walls of stomach, intestines, etc.
Type of control	Voluntary	Involuntary	Involuntary
Shape of fibers	Elongated, cylindrical, blunt ends	Elongated, cylindrical, fibers that branch and fuse	Elongated, spindle shaped, pointed ends
Striations	Present	Present	Absent
Number of nuclei per fiber	Many	One or two	One
Position of nuclei	Peripheral	Central	Central
Speed of contraction	Most rapid	Intermediate (varies)	Slowest
Resistance to fatigue (with repetitive contraction)	Least	Intermediate	Greatest



Skeletal muscle fibers



Cardiac muscle fibers



Smooth muscle fibers

UNWELCOME TISSUES: CANCERS

A neoplasm ("new growth"), or **tumor,** is an abnormal mass of cells. A neoplasm may be benign or malignant (cancerous). A **benign** ("kind") tumor tends to grow slowly, and its cells stay together. Because benign tumors form masses with distinct borders, they can usually be removed surgically.

A **malignant** ("wicked") **neoplasm,** or **cancer,** usually grows much more rapidly and invasively than a benign tumor. In fact, two basic defects in behavior that characterize most cancer cells are rapid multiplication and abnormal relations with neighboring cells. Unlike normal cells, which respect one another's boundaries and form tissues in an orderly, organized manner, cancer cells grow helter-skelter on one another and infiltrate normal tissues. They apparently no longer receive or respond appropriately to signals from surrounding cells; communication is lacking (see figure).

In Chapter 17 you learned that cancer results from abnormal expression of specific genes critical for cell division. When a cancer cell multiplies, all the cells derived from it are also abnormal. Unlike the cells of benign tumors, cancer cells do not retain normal structural features. Cancers that develop from connective tissues or muscle are referred to as **sarcomas.** Those that originate in epithelial tissue are called **carcinomas.** Most human cancers are epithelial.

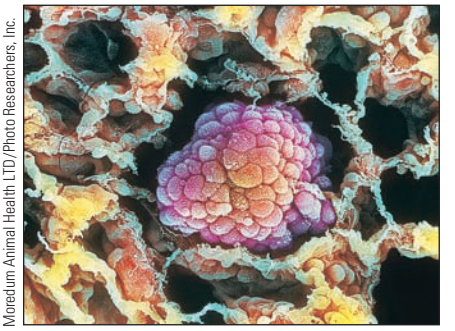
Death from cancer results from **metastasis,** a migration of cancer cells through blood or lymph channels to other parts of the body. Once there, cancer cells multiply, forming new malignant neoplasms that interfere with the normal functions of the tissues being invaded. Cancer often spreads so rapidly and extensively that surgeons cannot locate or remove all the malignant masses.

Some neoplasms grow to several millimeters in diameter and then enter a dormant stage, which may last for months or even years. Solid tumors, which account for more than 85% of cancer deaths, require blood vessels to ensure delivery of nourishment and oxygen. Eventually, cancer cells release a chemical substance that stimulates nearby blood vessels to develop new capillaries. These blood vessels grow into the abnormal mass of cells. Nourished by its new blood supply, the neoplasm begins to grow rapidly. Newly formed blood vessels have leaky walls that provide a route for metastasis. Malignant cells enter the blood through these walls and are transported to new sites.

Cancer is the second leading cause of death in the United States. One in three people in the United States develops cancer at some time in his or her life. Currently, the key to survival is early diagnosis and treatment with some combination of surgery, hormonal treatment, radiation therapy, and **chemotherapy,** which may include drugs that suppress mitosis. Many new treatments are under investigation, including agents that inhibit the development of new blood vessels. A recently discovered molecular link between chronic inflammation and cancer is also inspiring new approaches to cancer treatment. Cancer is actually a large family of closely related diseases (there are hundreds of distinct varieties), so treatment must be tailored to the particular type of cancer.

Alleles of some genes appear to affect an individual's level of tolerance to **carcinogens,** cancer-producing agents. More than 80% of cancer cases are thought to be triggered by carcinogens in the environment. You can decrease risk of developing cancer by following these recommendations:

1. Do not smoke or use tobacco. Smoking is responsible for more than 80% of lung cancer cases, and it increases the risk for many other cancers.
2. Avoid prolonged exposure to the sun. When in the sun, use sunscreen or sunblock. Exposure to the sun is responsible for almost all the 400,000 cases of skin cancer reported each year in the United States.
3. Eat a healthy diet, including fruits and vegetables. Although research results are not clear, it appears prudent to increase the fiber content of your diet and avoid high-fat, smoked, salt-cured, and nitrite-cured foods.
4. Avoid unnecessary exposure to X-rays.
5. Women should examine their breasts each month, have regular mammograms, and obtain annual Papanicolaou (Pap) and human papilloma virus (HPV) tests. Certain HPV strains can cause cervical cancer; vaccines are now available.
6. Men should regularly examine their testes and have prostate examinations yearly after age 50. They should also have the prostate-specific antigen (PSA) blood test. These routine tests detect cancer at an early, more treatable stage.
7. Beginning at age 50, both men and women should be screened for colorectal cancer. Detection and removal of polyps (benign growths that can become malignant) can prevent cancer.



Lung cancer
When the cancer cells shown in this color-enhanced SEM of human lung tissue multiply rapidly and invade normal tissues, they interfere with normal function. A mass of malignant cells (*pink*) occupies the air sac in the center, and cancer cells that have separated from the main tumor can be seen in other air sacs. Microvilli on the surface of the cancer cells give them a fuzzy appearance.

do not normally contract your cardiac and smooth muscle fibers at will.

Light microscopy shows that both skeletal and cardiac fibers have alternating light and dark transverse stripes, or **striations,** that change their relative sizes during contraction. Striated muscle fibers contract rapidly but cannot remain contracted for a long period. They must relax and rest momentarily before contracting again. (Muscle contraction is discussed in Chapter 39.)

Cardiac muscle is the main tissue of the heart. When this muscle contracts, the heart pumps the blood. The fibers of car-

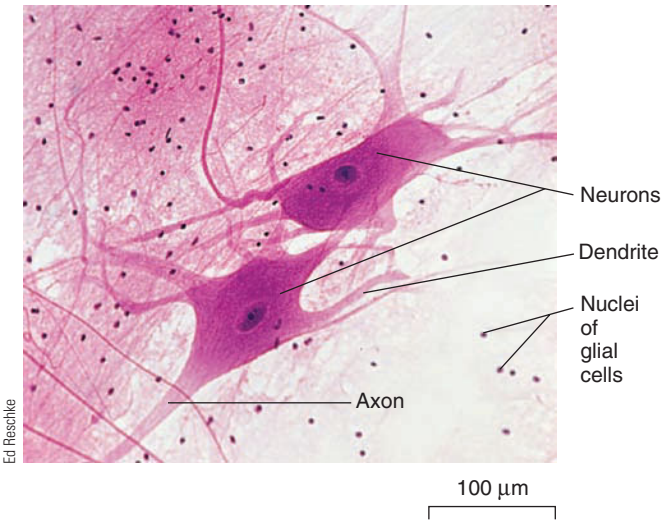


Figure 38-3 LM of nervous tissue

Neurons transmit impulses. Glial cells support and nourish neurons.

diac muscle join end to end, and they branch and rejoin to form complex networks. One or two nuclei lie within each fiber. A characteristic feature of cardiac muscle tissue is the presence of *intercalated discs,* specialized junctions where the fibers join.

Smooth muscle occurs in the walls of the digestive tract, uterus, blood vessels, and many other internal organs. Contraction of smooth muscle allows an organ to perform some function. When smooth muscle in the wall of the digestive tract contracts, food is moved through the digestive tract. When smooth muscle in the walls of arterioles (small arteries) contract, the blood vessel constricts, raising blood pressure. Each spindle-shaped smooth muscle fiber contains a single, central nucleus.

Nervous tissue controls muscles and glands

Nervous tissue consists of neurons and glial cells. **Neurons** are specialized for receiving and transmitting signals. **Glial cells** support and nourish the neurons (Fig. 38-3).

A typical neuron has a **cell body** containing the nucleus as well as two types of cytoplasmic extensions (discussed in Chapter 40). **Dendrites** are cytoplasmic extensions specialized for receiving signals and transmitting them to the cell body. The single **axon** transmits signals, called *nerve impulses,* away from the cell body. Axons range in length from 1 or 2 mm to more than a meter. Those extending from the spinal cord down the arm or leg in a human, for example, may be a meter or more in length.

Certain neurons receive signals from the external or internal environment and transmit them to the spinal cord and brain. Other neurons relay, process, or store information. Still others transmit signals from the brain and spinal cord to the muscles and glands. Neurons communicate at junctions called **synapses.** A **nerve** consists of a great many neurons bound together by connective tissue.

In this chapter, we have focused on normal tissues. For a discussion of some abnormal tissues, see *Focus On: Unwelcome Tissues: Cancers.*

Review

- What are the main differences in structure and function between epithelial tissue and connective tissue?
- What type of tissue lines the air sacs of the lungs? How is its structure adapted to its function?
- How is the structure of adipose tissue adapted to its function? Where is it found in the body?
- What are some differences between the three types of muscle tissue? How is the structure of each type adapted for its function?
- How is the neuron uniquely adapted for its function?

ORGANS AND ORGAN SYSTEMS

Learning Objectives

6 Briefly describe the organ systems of a mammal, and summarize the homeostatic actions of each organ system.

7 Define *homeostasis,* and contrast negative and positive feedback systems.

Tissues associate to form **organs.** Although an animal organ may be composed mainly of one type of tissue, other types are needed to support, protect, provide a blood supply, and transmit information. For example, the heart is mainly cardiac muscle tissue, but its chambers are lined with endothelium and its walls contain blood vessels made of endothelium, smooth muscle, and connective tissue. The heart also has nerves that transmit information and help regulate the rate and strength of its contractions.

An organized group of tissues and organs that together perform a specialized set of functions make up an **organ system.** Working together in a very coordinated way, organ systems perform the functions required by the **organism.** We can identify 11 major organ systems that work together to carry out the physiological processes of a mammal: **integumentary, skeletal, muscular, digestive, cardiovascular, immune (lymphatic), respiratory, urinary, nervous, endocrine,** and **reproductive systems.** Table 38-4 and Figure 38-4 summarize their principal organs and functions.

The body maintains homeostasis

To survive and function, animals must regulate the composition of the fluids that bathe their cells. They must maintain the appropriate concentration of nutrients, oxygen, and other gases, ions, and compounds needed for metabolism at all times. Animals must also maintain pH and internal temperature within relatively narrow limits.

Cells, tissues, organs, and organ systems work together to maintain appropriate conditions in the body. The balanced internal environment is referred to as **homeostasis,** and the control processes that maintain these conditions are **homeostatic mechanisms.** Homeostasis is a basic concept in physiology. First coined by U.S. physiologist Walter Cannon, the word *homeostasis* is derived from the Greek *homoios,* meaning "same," and *stasis,* "standing." Actually, the internal environment never really stays the same. It is a dynamic equilibrium in which conditions are maintained within narrow limits, which we call a **steady state.**

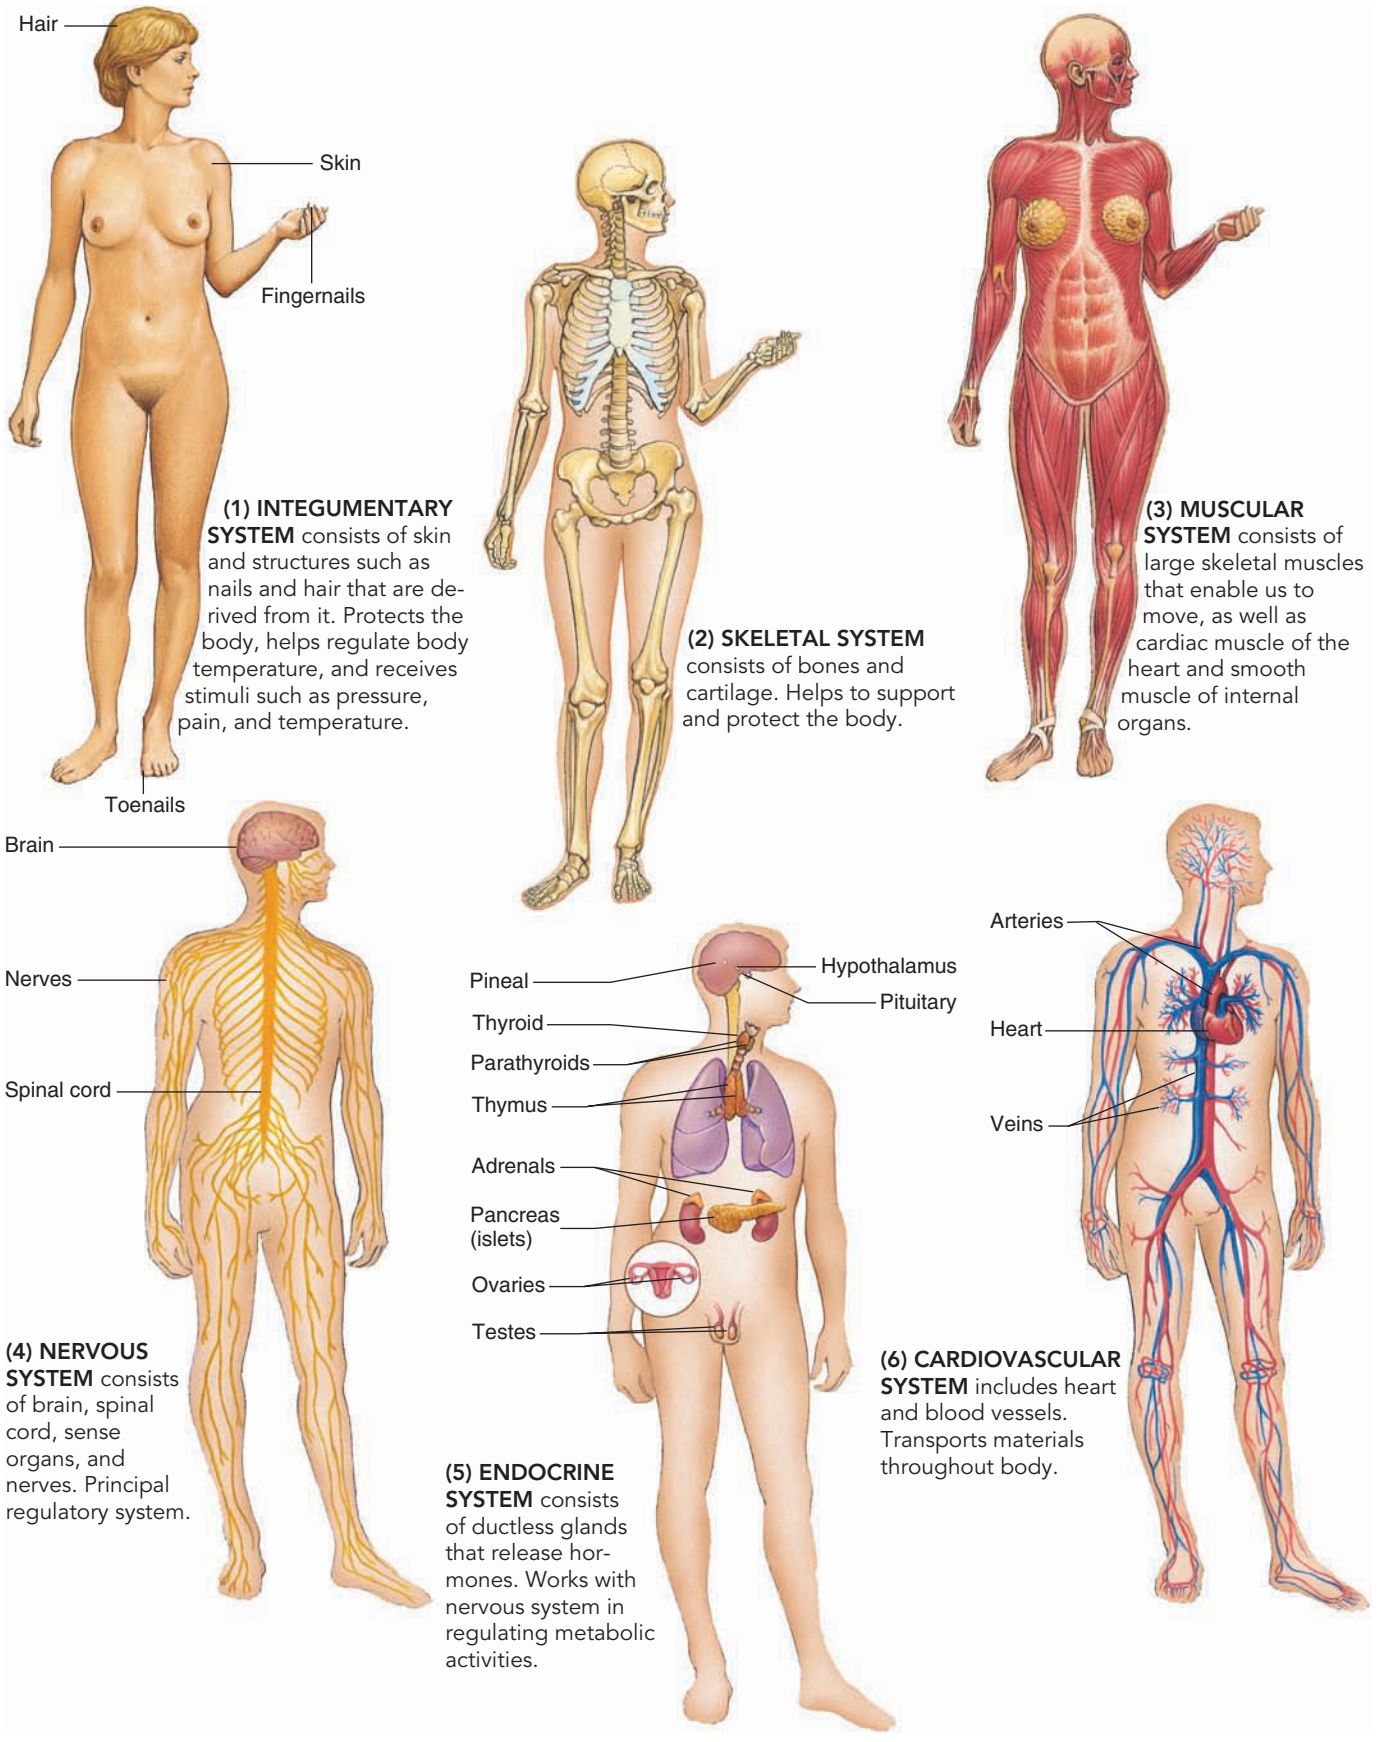

Figure 38-4 ***Animated*** The 11 principal organ systems of the human body

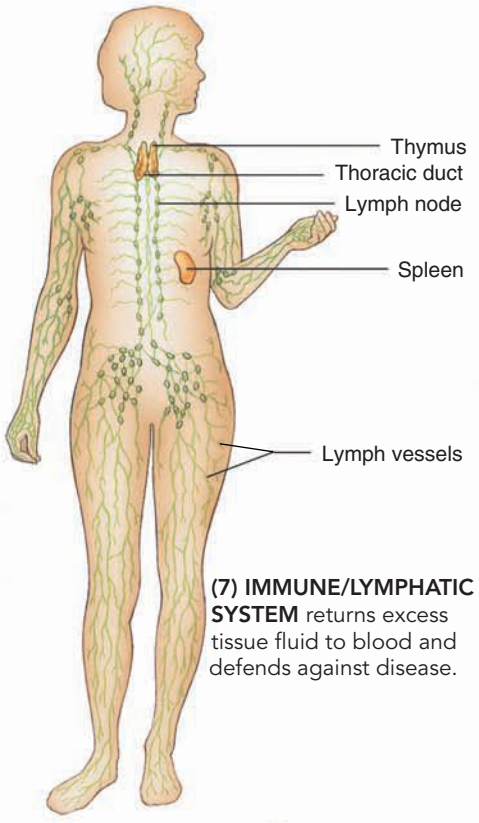
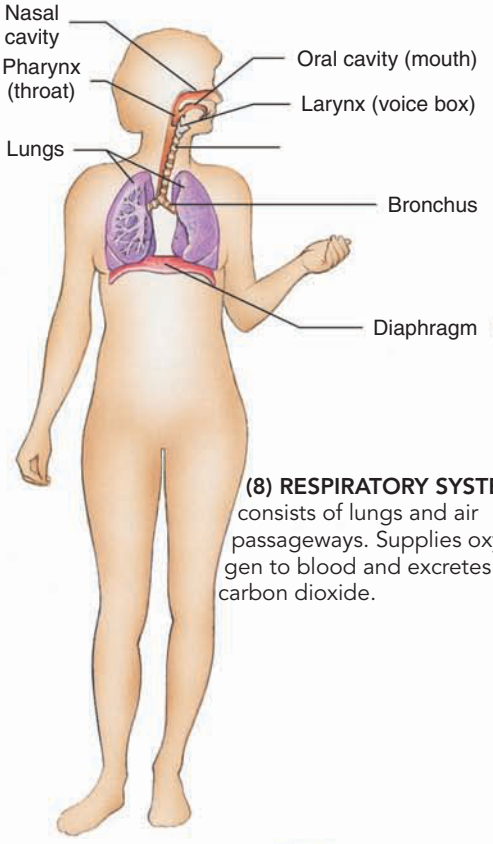
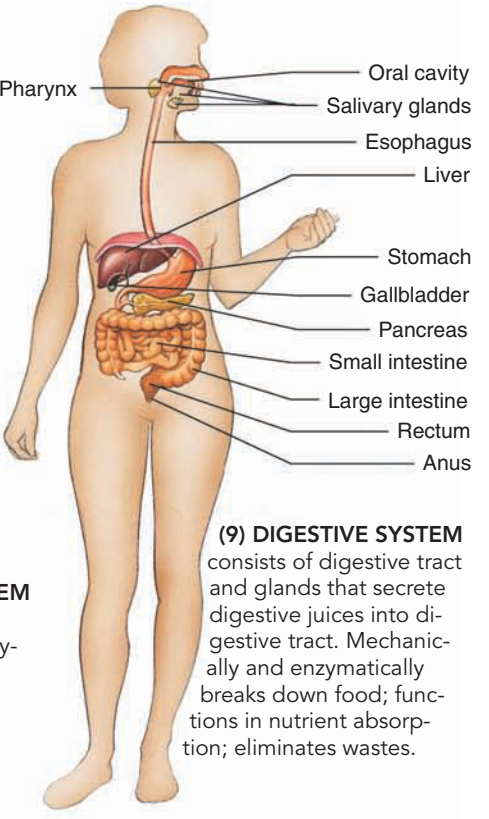


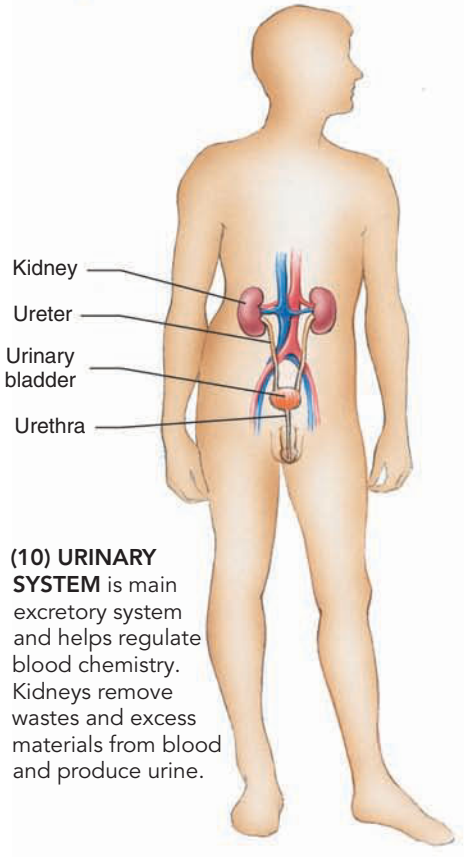
(7) IMMUNE/LYMPHATIC SYSTEM returns excess tissue fluid to blood and defends against disease.



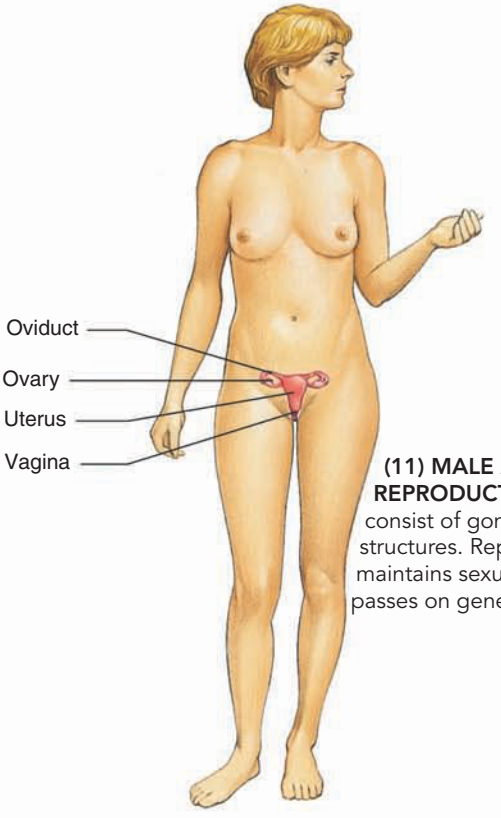
(8) RESPIRATORY SYSTEM consists of lungs and air passageways. Supplies oxygen to blood and excretes carbon dioxide.

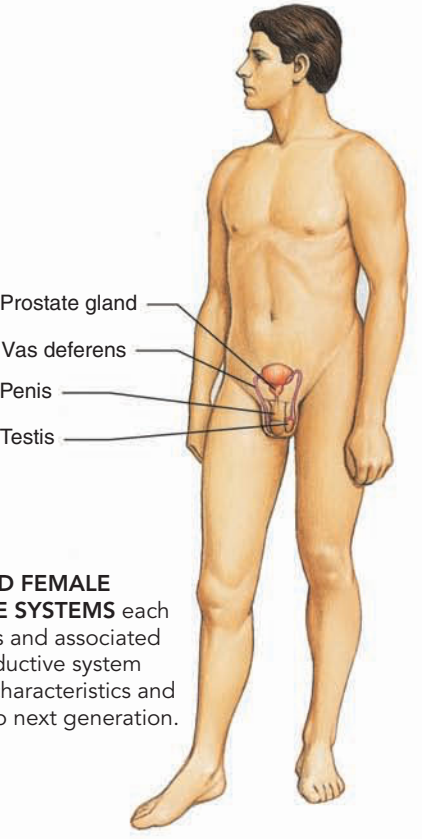


(9) DIGESTIVE SYSTEM consists of digestive tract and glands that secrete digestive juices into digestive tract. Mechanically and enzymatically breaks down food; functions in nutrient absorption; eliminates wastes.



(10) URINARY SYSTEM is main excretory system and helps regulate blood chemistry. Kidneys remove wastes and excess materials from blood and produce urine.





(11) MALE AND FEMALE REPRODUCTIVE SYSTEMS each consist of gonads and associated structures. Reproductive system maintains sexual characteristics and passes on genes to next generation.

TABLE 38-4

The Mammalian Organ Systems and Their Functions

System	Components	Functions	Homeostatic Ability
Integumentary	Skin, hair, nails, sweat glands	Covers and protects body	Sweat glands help control body temperature; as a barrier, the skin helps maintain a steady state
Skeletal	Bones, cartilage, ligaments	Supports and protects body; provides for movement and locomotion; stores calcium	Helps maintain constant calcium level in blood
Muscular	Skeletal muscle, cardiac muscle, smooth muscle	Moves parts of skeleton; provides locomotion; moves internal materials	Ensures vital functions requiring movement, e.g., cardiac muscle circulates the blood
Digestive	Mouth, esophagus, stomach, intestine, liver, pancreas, salivary glands	Ingests and digests food; absorbs nutrients into blood	Maintains adequate supplies of fuel molecules and building materials
Cardiovascular	Heart, blood vessels, blood	Transports materials from one part of body to another	Distributes nutrients, oxygen, hormones to cells; transports wastes from cells to excretory organs; helps maintain water and salt balance of tissues
Immune/lymphatic	Lymphatic vessels, lymph, lymph nodes, spleen, thymus, tonsils	Collects and transports tissue fluid to blood; absorbs lipids from digestive tract and transports them to circulatory system; defends body against organisms that cause disease	Helps maintain water and salt balance of tissues; helps prevent disease
Respiratory	Lungs, trachea, and other air passageways	Exchanges gases between blood and external environment	Maintains adequate blood oxygen content and helps regulate blood pH; removes carbon dioxide from the blood
Urinary	Kidney, bladder, and associated ducts	Excretes metabolic wastes; removes excessive substances from blood	Helps regulate volume and composition of blood and body fluids
Nervous	Nerves and sense organs; brain and spinal cord	Receives stimuli from external and internal environment; conducts impulses; integrates activities of other systems	Principal regulatory system
Endocrine	Ductless glands (e.g., pituitary, adrenal, thyroid) and tissues that secrete hormones	Regulates blood chemistry and many body functions	Regulates metabolic activities and blood levels of various substances
Reproductive	Testes, ovaries, and associated structures	Sexual reproduction	Maintains sexual characteristics

Stressors, changes in the internal or external environment that affect normal conditions within the body, continuously challenge homeostasis. An internal condition that moves out of its homeostatic range (either too high or too low) causes **stress.** An organism functions effectively because homeostatic mechanisms continuously operate to manage stress.

Mammals are superb **regulators.** They have complex homeostatic mechanisms that maintain relatively constant internal conditions despite changes in the outside environment. Many animals are **conformers** for certain environmental conditions. Certain internal states vary with changes in the environment. For example, most marine invertebrates conform to the salinity of the surrounding sea water.

How do homeostatic mechanisms work? Many are **feedback systems,** sometimes called *biofeedback systems.* In **negative feedback,** a change in some steady state (for example, normal body temperature) triggers a response that opposes the change. A **sensor** detects a change, a deviation from the desired condition, or **set point.** The sensor signals an **integrator,** or control center. Based on the input of the sensor, the integrator activates homeostatic mechanisms that restore the steady state (Fig. 38-5). The response counteracts the inappropriate change, thereby restoring the steady state

Note that in a negative feedback system, the response of the integrator is *opposite* (negative) to the output of the sensor. When some condition varies too far from the steady state (either too high or too low), a control system using negative feedback brings the condition back to the steady state. For example, when the glucose concentration in the blood *decreases* below its homeostatic level, negative feedback systems *increase* its concentration. Most homeostatic mechanisms in the body are negative feedback systems.

Let us discuss two specific examples: heat regulation in your home and in your body. In your home, you might set a particular room temperature on your thermostat. If the temperature in the room falls, the thermometer in the thermostat acts as a sensor that detects a change, or deviation, from the set point (Fig. 38-6a). The thermometer sends a signal to the thermostat, which then acts as an integrator, or control center. The thermostat compares the sensor's input with the set point. The thermo-

Key Point

In a negative feedback system, the response of the integrator is opposite to the input of the sensor.

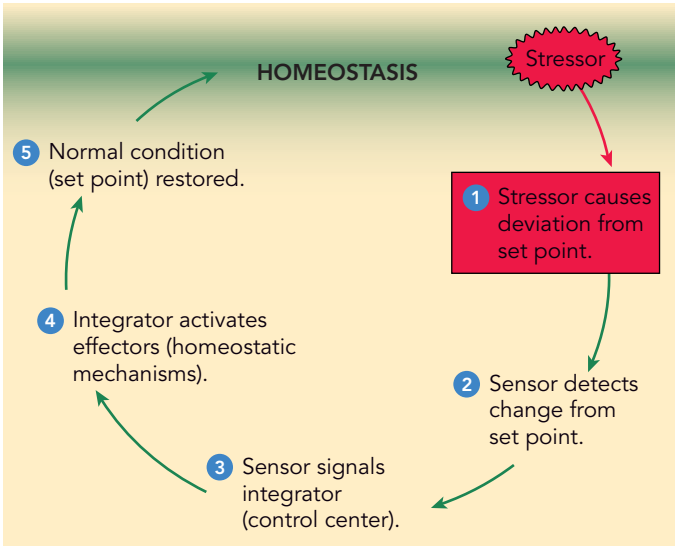


Figure 38-5 ***Animated*** Negative feedback

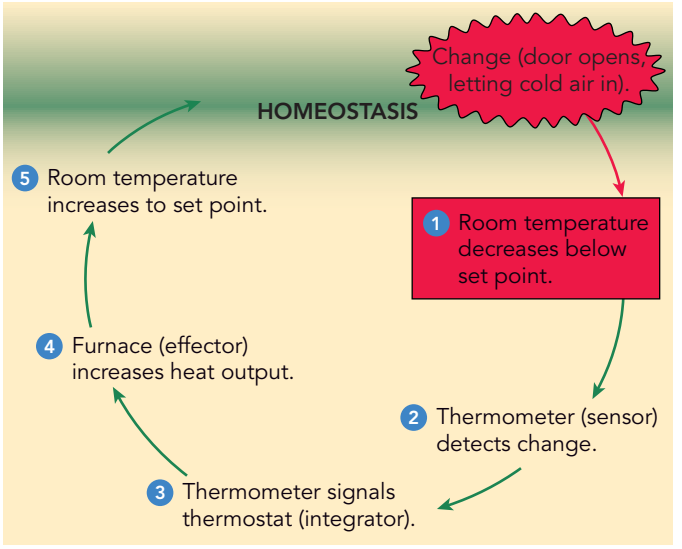
stat then signals the furnace, which is the **effector** in this system. An effector is the device, organ, or process that helps restore the desired condition. The furnace increases its heat output, a corrective response that brings the room temperature back to the set point. The thermometer no longer detects a change from the set point, so the thermostat and furnace are switched off.

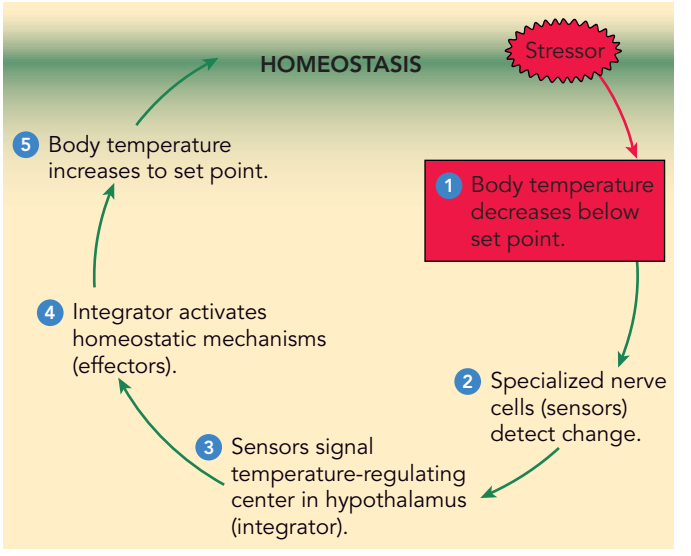
The temperature-regulating system in the human body is somewhat similar. A very simplified illustration of this negative feedback system is shown in Figure 38-6b. When body temperature decreases below normal limits, specialized nerve cells (sensors) signal the temperature-regulating center in the hypothalamus of the brain (the integrator). The integrator activates effectors that bring the temperature back to the set point. The return to normal temperature signals the sensors, and the temperature-regulating center switches off the effectors.

A few **positive feedback systems** also operate in the body. In these systems a deviation from the steady state sets off a series of changes that intensify (rather than reverse) the changes. Although many positive feedback mechanisms are beneficial, they do not maintain homeostasis. For example, a positive feedback cycle operates during the birth of a baby. As the baby's head pushes against the cervix (lower part of uterus), a reflex action causes the uterus to contract. The contraction forces the head against the cervix again, resulting in another contraction, and the positive feedback cycle repeats again and again until the baby is born. Some positive feedback sequences, such as those that deepen circulatory shock following severe hemorrhage, can disrupt steady states and lead to death. A simplified example is shown in Figure 38-7.

Homeostatic mechanisms maintain the internal environment within the physiological limits that support life. As you continue your study of animal processes, you will learn many ways in which organ systems interact to maintain the steady state of the organism. All organ systems participate in these regulatory processes, but the nervous and endocrine systems play major roles.



(a) Regulation of room temperature.



(b) Regulation of body temperature.

Figure 38-6 Negative feedback in temperature regulation

Note that the diagram in (b) is highly simplified. Figure 38-9 shows greater detail.

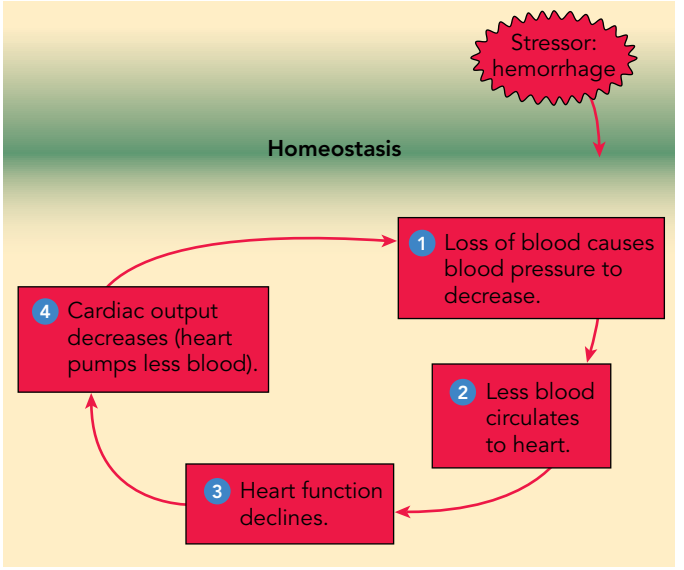


Figure 38-7 Positive feedback

In positive feedback, the changes that occur amplify the deviation from the set point. Loss of blood causes blood pressure to decrease. Less blood reaches the heart, so heart function decreases. The resulting decrease in cardiac output further decreases blood pressure, bringing about conditions farther from homeostasis.

In the next section, we discuss some homeostatic mechanisms that help regulate body temperature.

Review

- What are the main functions of each organ system?
- What is the basic difference between negative and positive feedback mechanisms?
- How do each of the following organ systems help maintain homeostasis: (1) respiratory, (2) urinary, and (3) endocrine? (Consult Table 38-4 for help.)

REGULATING BODY TEMPERATURE

Learning Objectives

8 Compare the costs and benefits of ectothermy.
9 Compare the costs and benefits of endothermy, and describe strategies animals use to adjust to challenging temperature changes.

Many animals have elaborate homeostatic mechanisms for regulating body temperature. Some are physiological, and others are structural or behavioral. **Thermoregulation** is the process of maintaining body temperature within certain limits despite changes in the surrounding temperature. Animals produce heat as a by-product of metabolic activities. Body temperature is determined by the rate at which heat is produced and the rate at which heat is lost to, or gained from, the outside environment.

The strategies for maintaining body temperature that are available to an animal may restrict the type of environment it can inhabit. Each species has an optimal environmental temperature range. Some animals, such as snowshoe hares, snowy owls, and weasels, can survive in cold arctic regions. Others, such as the

Breck P. Kent/Animals Animals/Earth Scenes

(a) Ectotherm. This marine iguana (*Amblyrhynchus cristatus*) increases its body temperature by sunning itself. Photographed in Galápagos Islands.

Frans Lanting/Minden Pictures

(b) Endotherm. The body temperature of this baby sooty tern (*Sterna fuscata*) is reduced as heat leaves the body through its open mouth. Photographed in Hawaii.

Figure 38-8 Behavioral adaptations for thermoregulation

Cape ground squirrel, which inhabits South Africa, are adapted to hot tropical climates. Although some animals can survive at temperature extremes, most survive only within moderate temperature ranges.

Ectotherms absorb heat from their surroundings

Ectotherms are animals that depend on the environment for their body heat. Their body temperature is determined mainly by the changing temperature of their surroundings. Most of the heat for their thermoregulation comes from the sun. You may be surprised to learn that most animals are ectotherms.

A benefit of ectothermy is that very little energy is used to maintain a high metabolic rate. In fact, an ectotherm's metabolic rate tends to change with the weather. As a result, ectotherms have a much lower daily energy expenditure than do endotherms. They survive on less food and convert more of the energy in their food to growth and reproduction. Ectothermy also has costs. One disadvantage is that daily and seasonal temperature conditions may limit activity.

Many ectotherms use behavioral strategies to adjust body temperature. For example, lizards may keep warm by burrowing in the soil at night. During the day, lizards take in heat by basking in the sun, orienting their bodies to expose the maximum surface area to the sun's rays (Fig. 38-8a). Many animals migrate to warmer climates during the winter. Another behavioral strategy for regulating temperature is *hibernation*.

Endotherms derive heat from metabolic processes

Birds and mammals, as well as some species of fish (such as tuna and some sharks) and some insects, are **endotherms,** which means they have homeostatic mechanisms that maintain body temperature despite changes in the external temperature. The most important benefit of endothermy is the high metabolic rate, which can be as much as 6 times higher than that of ectotherms. Their constant body temperature allows a higher rate of enzyme activity than is possible for ectotherms living in the same habitat. Endotherms respond more rapidly to internal and external stimuli and can be active even in low winter temperatures. However, these animals must pay the high energy cost of thermoregulation during times when they are inactive. You must maintain your body temperature even when you are asleep.

Endotherms have structural adaptations for maintaining body temperature. For example, the insulating feathers of birds, hair of mammals, and insulating layers of fat in birds and mammals reduce heat loss from the body. Birds and mammals also have behavioral adaptations for maintaining body temperature. The Cape ground squirrel positions its tail to shade its body from the direct rays of the sun. Elephants spray themselves with cool water.

Some insects use a combination of structural, behavioral, and physiological mechanisms to regulate body temperature. The "furry" body of the moth helps conserve body heat. When a moth prepares for flight, it contracts its flight muscles with little movement of its wings. The metabolic heat generated enables the moth to sustain the intense metabolic activity needed for flight.

Key Point

The hypothalamus maintains temperature homeostasis by activating mechanisms that cool (*upper arrows*) or warm the body.

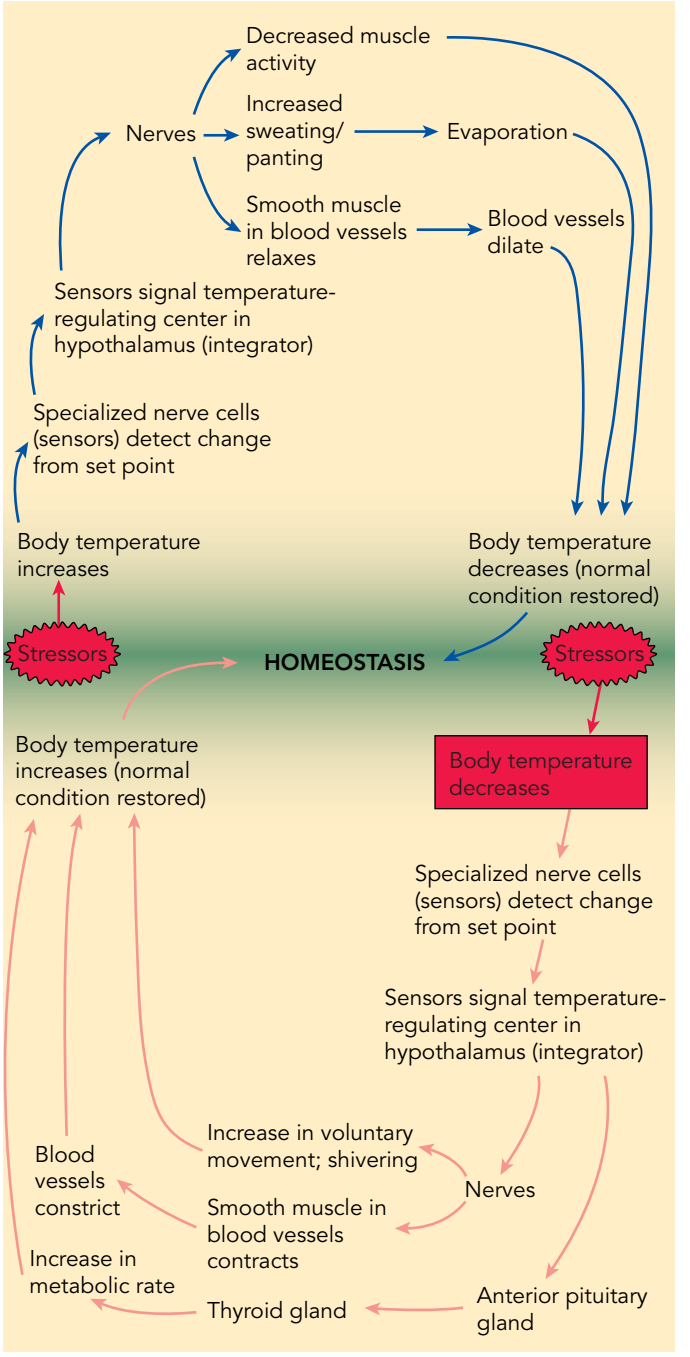

Figure 38-9 ***Animated*** Regulation of temperature in the human body

Endotherms have a variety of physiological mechanisms for maintaining temperature homeostasis. They regulate heat production and regulate heat exchange with the environment. Most of their body heat comes from their own metabolic processes (see *Focus On: Electron Transport and Heat,* in Chapter 8).

In mammals, receptors located in the hypothalamus of the brain and in the spinal cord regulate temperature. Heat from metabolic activities can be increased directly or can be increased indirectly by the action of hormones (such as thyroid hormones) that increase metabolic rate. Heat production is increased by contracting muscles, and in cold weather many animals shiver.

When body temperature rises, birds and many mammals pant and some mammals sweat (Fig. 38-8b on page 822). These processes provide fluid for **evaporation,** the conversion of a liquid, such as sweat, to water vapor. Recall from Chapter 2 that when molecules enter the vapor phase, they take their heat energy with them. Heat transfers from the body to the surroundings, resulting in evaporative cooling.

In the human body, about 2.5 million sweat glands secrete sweat. As sweat evaporates from the skin surface, body temperature decreases. Constriction and dilation of capillaries in the skin are also homeostatic mechanisms for regulating body temperature.

In humans, information about body temperature is sent to the temperature-regulating center in the hypothalamus (Fig. 38-9 on page 823). When your body temperature rises above normal, specialized nerve cells signal the temperature-regulating center in the hypothalamus. This center sends messages, by way of nerves to the sweat glands, that increase sweat secretion. At the same time, the hypothalamus sends messages to smooth muscle in the walls of blood vessels in the skin that cause them to dilate. More blood circulates through the skin, bringing heat to the body surface. The skin acts as a heat radiator that allows heat to radiate from the body surface into the environment. These homeostatic mechanisms help return body temperature to normal.

When body temperature decreases below normal, blood vessels in the skin constrict, so less heat is brought to the body surface. Hormonal messages increase heat production by body tissues. Nerves signal muscles to shiver or let you move muscles voluntarily to increase body temperature.

Many animals adjust to challenging temperature changes

Animals adjust to seasonal changes, a process called **acclimatization.** A familiar example is the thickening of a dog's coat in the winter. As water temperature decreases during fall and winter, a trout's enzyme systems decrease their level of activity, allowing the trout to remain active at the lowest metabolic cost.

When stressed by cold, many small endotherms sink into **torpor,** a state in which metabolic rate decreases, sometimes dramatically. Heart and respiratory rates decrease, and animals are less responsive to external stimulation. In endotherms, body temperature decreases below normal levels, an adaptive hypothermia. The decrease in body temperature is brought about by a decrease in the temperature set point in the hypothalamus. Daily torpor occurs in some small endotherms, for example, hummingbirds and shrews.

Hibernation is long-term torpor in response to winter cold and scarcity of food. Animals that hibernate store unsaturated fats as energy sources. **Estivation** is a state of torpor caused by lack of food or water during periods of high temperature. During estivation some mammals retreat to their burrows. The cactus mouse enters a state of hibernation during the winter in response to cold and scarcity of food. In summer, it estivates in response to lack of either food or water.

Review

- How do ectotherms adjust body temperature? What are some costs and benefits of ectothermy?
- What are some costs and benefits of endothermy?
- How is body temperature regulated in humans? Draw a diagram to illustrate your answer.
- What is acclimatization? Give an example.
- How do hibernation and estivation differ?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Compare the structure and function of the four main kinds of animal tissues: epithelial, connective, muscle, and nervous (page 808).

- A **tissue** consists of a group of similarly specialized cells that associate to perform one or more functions.
- **Epithelial tissue (epithelium)** forms a continuous layer, or sheet, of cells covering a body surface or lining a body cavity. Epithelial tissue functions in protection, absorption, secretion, or sensation.
- In contrast, **connective tissue** consists of relatively few cells separated by **intercellular substance,** composed of **fibers** scattered throughout a **matrix.** The intercellular substance contains **collagen fibers, elastic fibers,** and/or **reticular fibers.** Connective tissue contains specialized cells such as **fibroblasts** and **macrophages.** Connective tissue joins other tissues of the body, supports the body and its organs, and protects underlying organs.
- **Muscle tissue** consists of cells specialized to contract. Each cell is an elongated muscle fiber containing many contractile units called **myofibrils.**
- **Nervous tissue** consists of elongated cells called **neurons,** specialized for transmitting impulses, and **glial cells,** which support and nourish the neurons.

2 Compare the structure and function of the main types of epithelial tissue (page 808).

- Epithelial cells may be **squamous, cuboidal,** or **columnar** in shape. Epithelial tissue may be **simple, stratified,** or **pseudostratified** (summarized in Table 38-1).

- Simple squamous epithelium lines blood vessels and the air sacs in the lungs; it permits exchange of materials by diffusion. Simple cuboidal and columnar epithelia line passageways and are specialized for secretion and absorption. Stratified squamous epithelium forms the outer layer of the skin and lines passageways into the body; it provides protection. Pseudostratified epithelium also lines passageways and protects underlying tissues.
- Some epithelial tissue is specialized to form **glands. Goblet cells** are unicellular glands that secrete mucus. Goblet cells are **exocrine glands** that secrete their product through a duct onto an exposed epithelial surface. In contrast, **endocrine glands** release hormones into the **interstitial fluid** or blood.
- An **epithelial membrane** consists of a sheet of epithelial tissue and a layer of underlying connective tissue. A **mucous membrane** lines a cavity that opens to the outside of the body. A **serous membrane** lines a body cavity that does not open to the outside.

3 Compare the main types of connective tissue, and summarize their functions (page 808).

- The cells of **connective tissue** are embedded in an **intercellular substance** that consists of microscopic **collagen fibers, elastic fibers,** and **reticular fibers** (thin branched fibers) scattered through a **matrix,** a thin gel of polysaccharides. **Loose connective tissue** consists of fibers running in various directions through a semifluid matrix. This flexible tissue forms a covering for nerves, blood vessels, and muscles. **Dense connective tissue** is strong but less flexible than loose connective tissue. Its collagen fibers are arranged in a definite pattern. Dense connective tissue forms **tendons,** cords that connect muscles to bones, and **ligaments,** cables that connect bones to one another.
- **Elastic connective tissue,** which consists of bundles of parallel elastic fibers, is found in lung tissue and in walls of large arteries. **Reticular connective tissue,** which consists of interlacing reticular fibers, forms a supporting framework for many organs.
- **Adipose tissue,** which consists of fat cells, is found along with loose connective tissue in subcutaneous tissue.
- **Cartilage** consists of **chondrocytes** that lie in **lacunae,** small cavities in a hard matrix. **Osteocytes** secrete and maintain the matrix of **bone.** Unlike cartilage, bone is quite vascular. Cartilage and bone form the skeleton of vertebrates.
- **Blood** and **lymph** are circulating tissues that help various parts of an animal communicate with one another. The intercellular substances of blood and lymph are more fluid than those of other tissues.

4 Contrast the three types of muscle tissue and their functions (page 808).

- **Skeletal muscle** is **striated** and under voluntary control. Each elongated, cylindrical **muscle fiber** has several nuclei. When skeletal muscles contract, they move parts of the body.
- **Cardiac muscle** is also striated, but its contractions are involuntary. Its elongated, cylindrical fibers branch and fuse; each fiber has one or two central nuclei. When this muscle contracts, the heart pumps the blood.
- **Smooth muscle** contracts involuntarily. Its elongated, spindle-shaped fibers lack striations. Each fiber has a single central nucleus. Smooth muscle is responsible for movement of body organs; for example, it pushes food through the digestive tract.

5 Relate the structure of the neuron to its function (page 808).

- The elongated neuron is adapted for receiving and transmitting information. **Dendrites** receive signals and transmit them to the **cell body.** The **axon** transmits signals away from the cell body to other neurons or to a muscle or gland. A **synapse** is a junction between neurons.

6 Briefly describe the organ systems of a mammal, and summarize the homeostatic actions of each organ system (page 817).

- Tissues and **organs** work together, forming **organ systems.** In mammals, 11 organ systems work together to carry out the functions required by the **organism.** These include the **integumentary, skeletal, muscular, digestive, cardiovascular, immune (lymphatic), respiratory, urinary, nervous, endocrine,** and **reproductive systems.** Each organ system functions to maintain homeostasis (summarized in Table 38-4).

ThomsonNOW™ Watch body systems work together by clicking on the figure in ThomsonNOW.

7 Define *homeostasis,* and contrast negative and positive feedback systems (page 817).

- **Homeostasis** is the balanced internal environment, or steady state. The control processes that maintain these conditions are **homeostatic mechanisms.**
- Homeostasis is actually a dynamic equilibrium maintained by **negative feedback systems.** When a stressor causes a change in some steady state, a response is triggered that opposes the change. A **sensor** detects a change, a deviation from the desired condition, or **set point.** The sensor signals an **integrator,** or control center. Based on the output of the sensor, the integrator activates one or more **effectors,** organs or processes that restore the steady state.
- In a **positive feedback system,** a deviation from the steady state sets off a series of changes that intensify (rather than reverse) the changes.

8 Compare the costs and benefits of ectothermy (page 822).

- Animals have structural, behavioral, and physiological strategies for **thermoregulation,** the process of maintaining body temperature within certain limits despite changes in the surrounding temperature. In **ectotherms,** body temperature depends to a large extent on the temperature of the environment. Many ectotherms use behavioral strategies to adjust body temperatures.
- A benefit of ectothermy is that very little energy is used to maintain the metabolic rate. As a result, ectotherms can survive on less food. A disadvantage is that activity may be limited by daily and seasonal temperature conditions.

9 Compare the costs and benefits of endothermy, and describe strategies animals use to adjust to challenging temperature changes (page 822).

- **Endotherms** have homeostatic mechanisms for regulating body temperature within a narrow range.
- The most important benefit of endothermy is a high metabolic rate. Another advantage is that constant body temperature allows a higher rate of enzyme activity. Many endotherms are active even in low winter temperatures. A disadvantage of endothermy is its high energy cost.
- **Acclimatization** is the process of adjustment to seasonal changes.
- When challenged by a drop in surrounding temperature, many small endotherms enter a state of torpor. **Torpor** is an adaptive hypothermia; body temperature is maintained below normal levels. **Hibernation** is long-term torpor in response to winter cold. **Estivation** is torpor caused by lack of food or water during summer heat.

ThomsonNOW™ Explore negative feedback and temperature regulation in humans and other animals by clicking on the figures in ThomsonNOW.

TEST YOUR UNDERSTANDING

1. In animals, (a) organ systems are always present (b) cells specialize to perform specific functions (c) small size provides more opportunity for capturing food (d) organelles form organ systems (e) epithelial tissue contains glial cells
2. A group of closely associated cells that carry out specific functions is a(an) (a) colony (b) tissue (c) organ system (d) organelle (e) homeostatic mechanism
3. Which tissue consists of cells that fit tightly together to form a sheet of cells? (a) muscle tissue (b) nervous tissue (c) connective tissue (d) epithelial tissue (e) reticular tissue
4. Epithelial cells that produce and secrete a product into a duct form a(an) (a) endocrine gland (b) exocrine gland (c) pseudostratified membrane (d) endocrine or exocrine gland (e) serous membrane
5. A serous membrane (a) lines a body cavity that does not open to the outside of the body (b) consists of loose connective tissue (c) has a framework of reticular connective tissue (d) covers the body (e) lines the digestive and respiratory systems
6. The most numerous fibers in connective tissue are (a) reticular (b) myofibrils (c) collagen (d) elastic (e) glial
7. Dense connective tissue is likely to be found in (a) the outer layer of skin (b) tendons (c) bone (d) the air sacs of lungs (e) the framework of the lymph nodes
8. Osteocytes are most likely to be found in (a) the outer layer of skin (b) bone (c) cartilage (d) lungs (e) blood
9. Tissue that contains fibroblasts and a great deal of intercellular substance is (a) connective tissue (b) muscle tissue (c) nervous tissue (d) pseudostratified epithelium (e) simple squamous epithelium
10. Tissue that contracts and is striated and involuntary is (a) connective tissue (b) smooth muscle (c) skeletal muscle (d) pseudostratified (e) cardiac muscle
11. Glial cells are characteristic of (a) muscle that is striated and voluntary (b) cardiac muscle tissue (c) nervous tissue (d) stratified epithelium (e) loose connective tissue
12. Tissue that has a hard, rubbery matrix and lacks blood vessels is (a) integumentary tissue (b) bone (c) nervous tissue (d) stratified epithelium (e) cartilage
13. The contractile elements in muscle tissue are (a) myofibrils (b) elastic (c) collagen (d) lacunae (e) dendrites
14. Which system consists of glands that secrete hormones? (a) integumentary (b) skeletal (c) nervous (d) endocrine (e) exocrine
15. Which system has the homeostatic function of helping maintain a constant calcium level in the blood? (a) integumentary (b) skeletal (c) nervous (d) reproductive (e) exocrine
16. Which system has the homeostatic function of helping regulate volume and composition of blood and body fluids? (a) integumentary (b) muscular (c) reproductive (d) urinary (e) exocrine
17. Many homeostatic functions are maintained by (a) negative feedback systems (b) positive feedback systems (c) set points (d) stressors (e) exocrine glands
18. An ectotherm (a) may use behavioral strategies to help adjust body temperature (b) has a variety of homeostatic mechanisms to precisely regulate body temperature (c) depends on sensors in the hypothalamus to regulate temperature (d) has a higher rate of enzyme activity than a typical endotherm (e) must expend more energy on thermoregulation than an endotherm
19. The state of torpor caused in some animals by lack of food or water during periods of high temperature is known as (a) positive feedback (b) hibernation (c) endothermy (d) ectothermy (e) estivation

CRITICAL THINKING

1. Imagine that all the epithelium in an animal, such as a human, suddenly disappeared. What effects might this have on the body and its ability to function?
2. What would connective tissue be like if it had no intercellular substance? What effect would the absence of intercellular substance have on the body?
3. A high concentration of carbon dioxide in the blood and interstitial fluid results in more rapid breathing. Explain this observation in terms of homeostasis.
4. **Evolution Link.** What are some adaptive benefits of multicellularity?
5. **Evolution Link.** From an evolutionary perspective, why do you think most animals are ectotherms? (*Hint:* What are some benefits of ectothermy?)

Protection, Support, and Movement

Stephen Dalton

Grasshopper in midjump. The grasshopper (*Tropidacris dux*) uses powerful muscles in its hind legs to catapult itself into the air. Insect muscles attach to the exoskeleton.

KEY CONCEPTS

Many structures and processes have evolved in animals for protection, support, and movement.

Epithelial coverings protect underlying tissues and may be specialized for sensory, respiratory, or other functions.

Skeletal systems, whether they are hydrostatic skeletons, exoskeletons, or endoskeletons, support and protect the body and transmit mechanical forces important in movement.

Muscles contract; in most animals they move body parts by pulling on them.

During muscle contraction, energy from ATP is used to slide muscle filaments so that the muscle shortens.

In Chapter 38 we described animal tissues, organs, and systems, laying the foundation for the more detailed discussions in this and later chapters. Here we focus on epithelial coverings, skeletal systems, and muscle—structures that are closely interrelated in function. In our survey of the animal kingdom (Chapters 29 to 31), we described many adaptations involving these structures. For example, we discussed how the tough exoskeleton contributes to the great biological success of insects. In this chapter we compare these systems in several animal groups and then focus on their structures and functions in mammals.

In addition to protecting underlying tissues, the *epithelial coverings* of animals may be specialized to exchange gases, excrete wastes, regulate temperature, or secrete substances such as peptides that kill bacteria, mucus, or poison. Most animals are also protected by a *skeletal system*. Whether it is a fluid-filled compartment, a shell, or a system of bones, the skeletal system provides support for the body and typically protects internal organs. In vertebrates, bones store calcium and are important in maintaining homeostatic levels of calcium in the blood.

The skeletal system and *muscular system* work together to produce movement. Muscle tissue is specialized to contract. Although a few animals remain rooted to one spot, sweeping their surroundings with tentacles, **locomotion**—movement from place to place in the environment—is characteristic of most animals. In fact, for most animals dependable, rapid, and responsive movement is key to finding food and escaping from predators. Animals creep, walk, run, jump, swim, or fly (see photograph). Muscles responsible for

locomotion anchor to the skeleton, which gives them something firm on which to act. In most vertebrates, bones serve as levers that transmit the force necessary to move various parts of the body.

Muscle powers both locomotion and the physiological actions necessary to maintain homeostasis. Many animals have internal circulating fluids, pumped by hearts and contained by hollow vessels that maintain their pressure with gentle squeezing. Most have digestive systems that push food along with peristaltic contractions. In complex animals, effective movement depends on the cooperation and interactions of several body systems, including the muscular, skeletal, nervous, circulatory, respiratory, and endocrine systems. ■

EPITHELIAL COVERINGS

Learning Objectives

1 Compare the functions of the external epithelium of invertebrates and vertebrates.
2 Relate the structure of vertebrate skin to its functions.

Epithelial tissue covers all external and internal surfaces of the animal body. The structure and functions of the epithelial covering are adapted to the animal's environment and lifestyle. In both invertebrates and vertebrates, epithelial coverings protect the body. These coverings may also be specialized for secretion or gas exchange and typically contain receptors that receive sensory signals from the environment.

Invertebrate epithelium may function in secretion or gas exchange

In many invertebrates, the outer epithelium is specialized to secrete protective or supportive layers of nonliving material. In insects and many other animals, the secreted material forms an outer covering called a **cuticle.** Some animals, including corals and mollusks, secrete a shell made mainly of calcium carbonate. Epithelial cells may be modified as sensory cells that are selectively sensitive to light; chemical stimuli; or mechanical stimuli, such as contact with an object, or pressure. In many species, the epithelium contains cells that secrete lubricants or adhesives. Such cells may release odorous secretions used for communication or for marking trails. In other species, secretory cells produce toxins used for offense or defense. The earthworm epithelium secretes a lubricating mucus that promotes efficient diffusion of gases across the body wall and reduces friction during movement through the soil.

Vertebrate skin functions in protection and temperature regulation

The **integumentary system** of vertebrates includes the skin and structures that develop from it. In many fishes, in the African anteating pangolin (a mammal; see Fig. 18-12c), and in some reptiles, skin has developed into a set of scales formidable enough to be considered armor. Even human skin has considerable strength. In many amphibians, gas exchange takes place through the skin.

Derivatives of skin differ considerably among vertebrates. Fishes have bony or toothlike scales. Amphibians have naked skin covered with mucus, and some species are equipped with poison glands. Reptiles have epidermal scales, mammals have hair, and birds have feathers that provide even more effective insulation than fur. The feathers of birds and the fur of mammals are insulating structures that trap heat in the body, which helps maintain body temperature. Skin and its derivatives are often brilliantly colored in connection with courtship rituals, territorial displays, and other kinds of communication.

In mammals, structures derived from skin include claws (modified as fingernails and toenails in primates), hair, sweat glands, oil (sebaceous) glands, and several types of sensory receptors that give mammals the ability to feel pressure, temperature, and pain. The skin of mammals also contains mammary glands, specialized in females for secretion of milk.

In humans and other mammals, oil glands empty via short ducts into hair follicles. A **hair follicle** is the part of a hair below the skin surface, together with the surrounding epithelial tissue. Oil glands secrete **sebum,** a mixture of fats and waxes that inhibits the growth of harmful bacteria.

Although the skin of fishes, frogs, pelicans, and elephants appears very different, the basic structure of skin is the same in all vertebrates. The outer layer of skin, the **epidermis,** is a waterproof protective barrier. The epidermis consists of several strata, or sublayers. The deepest is **stratum basale,** and the most superficial is **stratum corneum** (Fig. 39-1). Pigment cells in stratum basale and in the dermis below produce **melanin,** a pigment that contributes to the color of the skin. In stratum basale, cells divide and are pushed outward as other cells are produced below them. Epidermal cells mature as they move toward the skin surface.

As they move toward the body surface, epidermal cells manufacture **keratin,** an elaborately coiled protein that gives the skin considerable mechanical strength and flexibility. Keratin is insoluble and serves as a diffusion barrier for the body surface. As epidermal cells move through stratum corneum, they die. When they reach the outer surface of the skin, they wear off and must be continuously replaced.

Beneath the epidermis lies the **dermis** (see Fig. 39-1), a dense, fibrous connective tissue made up mainly of collagen fibers. Collagen imparts strength and flexibility to the skin. The dermis also contains blood vessels that nourish the skin and sensory receptors for touch, pain, and temperature. Hair follicles and, in most mammals, sweat glands are embedded in the dermis. In birds and

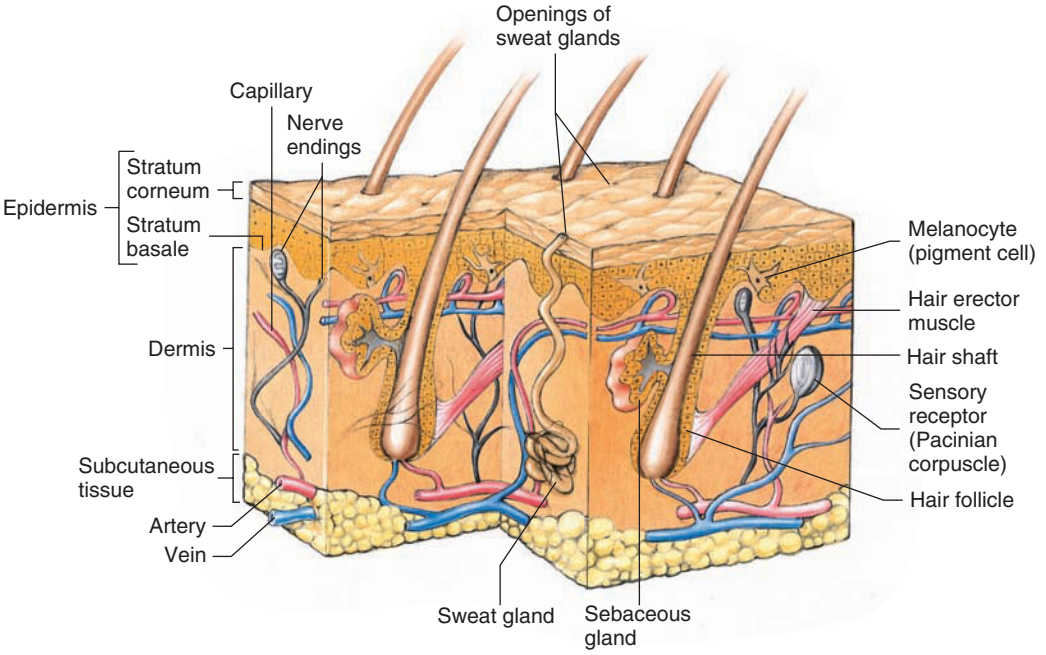

Figure 39-1 ***Animated*** Human skin

The integumentary system of humans and other mammals is a complex organ system consisting of skin and structures such as hair and nails that are derived from the skin. Stratum basale consists of a single layer of dividing epithelial cells.

mammals, the dermis rests on a layer of **subcutaneous tissue** composed mainly of adipose tissue that insulates the body from outside temperature extremes.

In humans, exposure to ultraviolet (UV) radiation, the short, invisible rays from the sun, causes the epidermis to thicken and stimulates pigment cells in the skin to produce melanin at an increased rate. Melanin is an important protective screen against the sun because it absorbs some of the harmful UV rays. An increase in melanin causes the skin to darken. The suntan so prized by sun worshipers is actually a sign that the skin has been exposed to too much UV radiation. When the melanin cannot absorb all the UV rays, the skin becomes inflamed, or sunburned. Dark-skinned people have more melanin and so suffer less sunburn, wrinkling, and skin cancer but still require protection from UV rays.

UV radiation damages DNA, causing mutations that lead to malignant transformation of cells (see Chapter 17). Most cases of skin cancer are caused by excessive, chronic exposure to UV radiation. The incidence of *malignant melanoma,* the most lethal type of skin cancer, is increasing faster than any other type of cancer.

Review

- How are the body coverings of invertebrates and vertebrates alike? How are they different?
- How is the structure of vertebrate skin related to its specific functions?
- What properties does keratin give human skin?
- What is the function of melanin?

SKELETAL SYSTEMS

Learning Objectives

3 Compare the structure and functions of different types of skeletal systems, including the hydrostatic skeleton, exoskeleton, and endoskeleton.

4 Describe the main divisions of the vertebrate skeleton and the bones that make up each division.

5 Describe the structure of a typical long bone, and differentiate between endochondral and intramembranous bone development.

6 Compare the main types of vertebrate joints.

In addition to having an epithelial covering, many animals are protected by a **skeletal system** that forms the framework of the body. The skeleton also functions in locomotion. Muscles typically act on hard structures such as chitin or bone. These skeletal structures transmit and transform mechanical forces generated by muscle contraction into the variety of motions that animals make. Three types of skeletons are hydrostatic skeletons, exoskeletons, and endoskeletons.

In hydrostatic skeletons, body fluids transmit force

Many soft-bodied invertebrates have **hydrostatic skeletons** made of fluid-filled body compartments. Imagine an elongated balloon

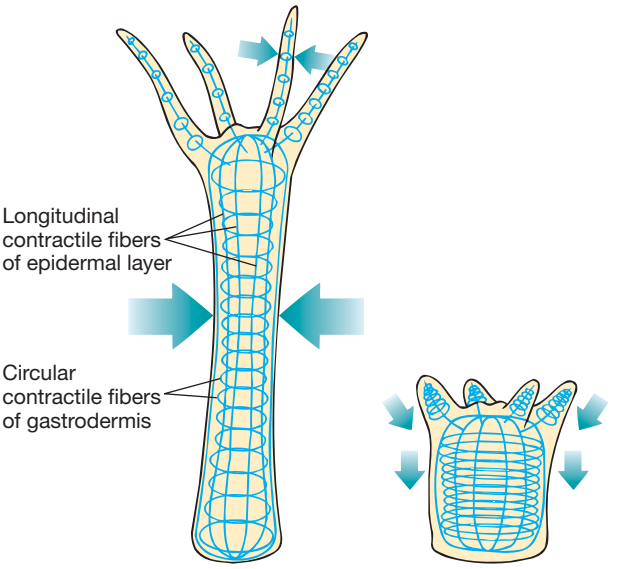
full of water. If you pull on the balloon, it lengthens and becomes thinner. It does the same if you squeeze it. Conversely, if you push the ends toward the center, the balloon shortens and thickens. Many animals, including most cnidarians, flatworms, annelids, and roundworms, have hydrostatic skeletons that work something like a balloon filled with water. Fluid in a closed compartment of the body is held under pressure. When muscles in the compartment wall contract, they push against the tube of fluid. Because fluids cannot be compressed, the force is transmitted through the fluid, changing the shape and movement of the body.

In *Hydra* and other cnidarians, cells of the two body layers can contract. The contractile cells in the outer epidermal layer lie longitudinally, whereas the contractile cells of the inner layer (the gastrodermis) are arranged circularly around the central body axis (Fig. 39-2). The two groups of cells work in **antagonistic** fashion: what one can do, the other can undo. When the epidermal (longitudinal) layer contracts, the hydra shortens. Due to the fluid in the gastrovascular cavity, force is transmitted so that the hydra thickens as well. In contrast, when the inner (circular) layer contracts, the hydra thins and its fluid contents force it to lengthen.

Mechanically, the hydra is a bag of fluid. The fluid acts as a hydrostatic skeleton because it transmits force when the contractile cells contract against it. (Although technically not a closed compartment, the gastrovascular cavity functions as a hydrostatic skeleton because its opening is small.) Hydrostatic skeletons permit only crude mass movements of the body or its appendages. Delicate movements are difficult, because force tends to be transmitted equally in all directions throughout the entire fluid-filled body of the animal. For example, it is not easy for the hydra to thicken one part of its body while thinning another.

The more sophisticated hydrostatic skeleton of the annelid worm lets it move with more flexibility. An earthworm's body consists of a series of segments divided by transverse partitions, or septa (see Fig. 30-12). The septa isolate portions of the body cavity and the coelomic fluid they contain. This structure allows the hydrostatic skeletons of each segment to be largely independent of one another. Thus, contraction of the circular muscle in the elongating anterior end does not interfere with the action of the longitudinal muscle in the segments at the posterior end.

You can find some examples of hydrostatic skeletons in invertebrates equipped with shells or endoskeletons, and even in vertebrates with endoskeletons of cartilage or bone. For example, sea stars and sea urchins move their tube feet by an ingenious adaptation of the hydrostatic skeleton (see Chapter 31). And the human penis becomes erect and stiff because of the turgidity of pressurized blood in its internal spaces.



(a) Contraction of circular contractile fibers elongates the body.

(b) Contraction of longitudinal fibers shortens the body.

Figure 39-2 Hydrostatic skeleton

In *Hydra*, fluid in the gastrovascular cavity transmits force when contractile cells in the body wall contract against it. The longitudinally arranged contractile cells of *Hydra* are antagonistic to the cells arranged in circles around the body axis.

Mollusks and arthropods have nonliving exoskeletons

In most animals, the skeleton is a lifeless shell, or **exoskeleton,** deposited atop the outer epithelial covering. In mollusks, the exoskeleton is a calcium carbonate shell secreted by the mantle, a thin sheet of epithelial tissue that extends from the body wall. The exoskeleton provides protection, a retreat used in emergencies, with the bulk of the naked, tasty body exposed at other times.

Exoskeletons of arthropods serve not only to protect but also to transmit forces. In this respect they are comparable to the skeletons of vertebrates. The arthropod exoskeleton is a nonliving *cuticle* that contains the polysaccharide **chitin.** Although it is a continuous, one-piece sheath covering the entire body, the arthropod exoskeleton varies greatly in thickness and flexibility. Large, thick, inflexible plates are separated from one another by thin, flexible joints arranged segmentally. Enough joints are provided to make the arthropod's body as flexible as those of many vertebrates. The arthropod exoskeleton is adapted to a vast variety of lifestyles, and parts of it are modified to function as specialized tools or weapons.

A disadvantage of the rigid arthropod exoskeleton is that to accommodate growth, an arthropod must **molt,** that is, shed its exoskeleton and replace it with a new, larger one (Fig. 39-3). (This process is also called *ecdysis.*) During molting the animal is weak and vulnerable to predators.

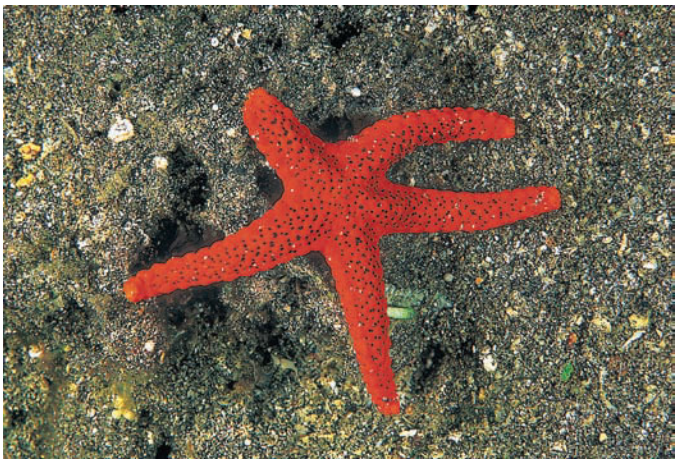
Internal skeletons are capable of growth

You are probably most familiar with the **endoskeleton** of echinoderms and chordates. This living internal skeleton consists of plates or shafts of calcium-impregnated tissue (such as cartilage or bone). Composed of living tissue, the endoskeleton grows along with the animal as a whole. The echinoderm endoskeleton consists of spines and plates of calcium salts embedded in the

Judy Davidson /Science Photo Library/Photo Researchers, Inc.

Figure 39-3 Ecdysis

A greengrocer cicada (*Magicicada*) requires 13 years to mature. It then emerges from the soil, climbs a tree, and molts, that is, sheds its exoskeleton (ecdysis), prior to reproducing.



Patricia Jordan/Peter Arnold, Inc.

Figure 39-4 The echinoderm endoskeleton

The endoskeleton provides support and protection. As in other echinoderms, the endoskeleton of the red sea star (*Formia milleporella*) is composed of spines and plates of nonliving calcium salts embedded in the body wall.

body wall, beneath an epidermis that covers the body. This endoskeleton forms what amounts to an internal shell that provides support and protection (Fig. 39-4). Many echinoderm endoskeletons bear spines that project to the outer surface.

The internal vertebrate skeleton provides support and protection and transmits muscle forces. Members of class Chondrichthyes (sharks and rays) have skeletons of cartilage, but in most vertebrates the skeleton consists mainly of bone. Many bones form systems of levers that transmit muscle forces.

The vertebrate skeleton has two main divisions

The two main divisions of the vertebrate skeleton are the axial and appendicular skeletons (Fig. 39-5). The **axial skeleton,** located along the central axis of the body, consists of the skull, vertebral column, ribs, and sternum (breastbone). The **appendicular skeleton** consists of the bones of the limbs (arms and legs) plus the bones making up the pectoral (shoulder) girdle and most of the pelvic (hip) girdle; these girdles connect the limbs to the axial skeleton.

The **skull,** the bony framework of the head, consists of the cranial and facial bones. In the human, 8 cranial bones enclose the brain, and 14 bones make up the facial portion of the skull. Several cranial bones that are single in the adult human result from the fusion of 2 or more bones that are separate in the embryo or newborn.

The vertebrate spine, or **vertebral column,** supports the body and bears its weight. In humans, it consists of 24 **vertebrae** and 2 bones composed of fused vertebrae, the **sacrum** and **coccyx.** The vertebral column consists of the **cervical** (neck) region, with 7 vertebrae; the **thoracic** (chest) region, with 12 vertebrae; the **lumbar** (back) region, with 5 vertebrae; the **sacral** (pelvic) region, with 5 fused vertebrae; and the **coccygeal** region, also composed of fused vertebrae.

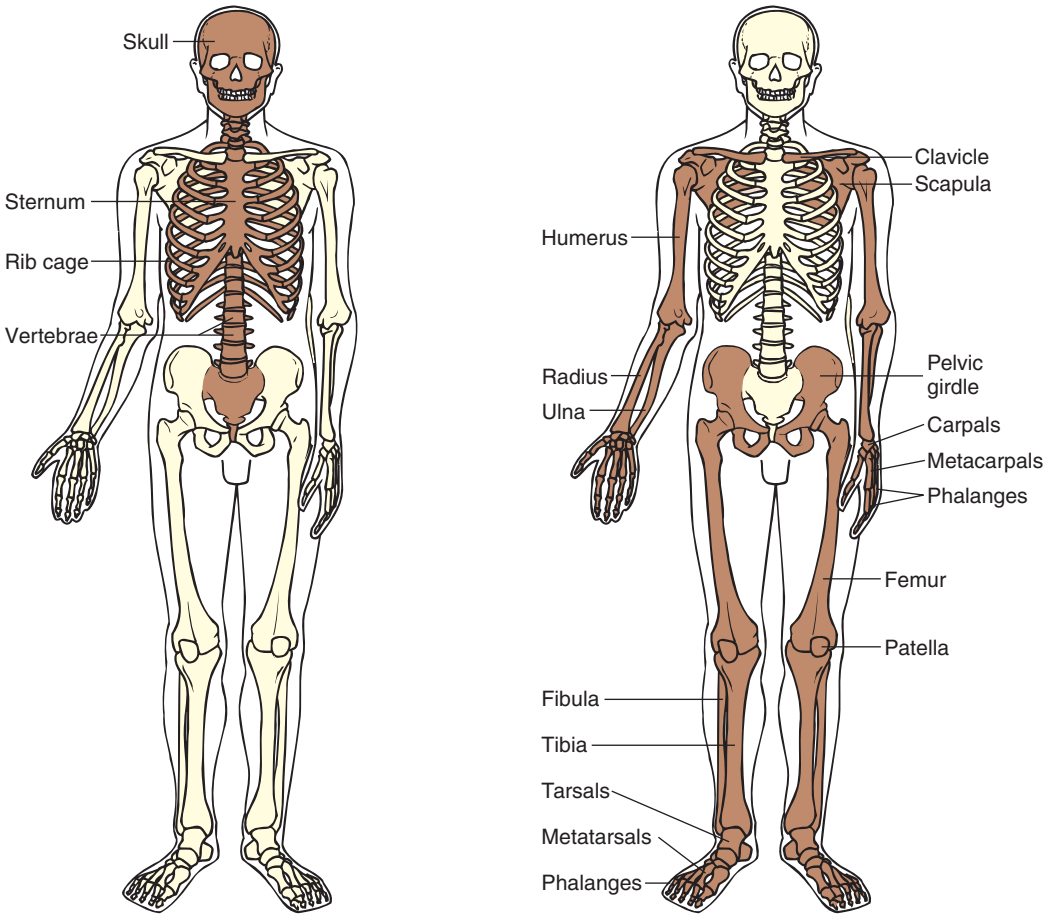
The **rib cage** is a bony "basket" formed by the **sternum** (breastbone), thoracic vertebrae, and, in mammals, 12 pairs of ribs. The rib cage protects the internal organs of the chest, including the heart and lungs. It also supports the chest wall, preventing it from collapsing as the diaphragm contracts with each breath. Each pair of ribs is attached dorsally to a separate vertebra. Of your 12 pairs of ribs, the first 7 are attached ventrally to the sternum; the next 3 are attached indirectly by cartilage; and the last 2, the "floating ribs," have no attachments to the sternum.

The **pectoral girdle** consists of two collarbones, or **clavicles,** and two shoulder blades, or **scapulas.** The **pelvic girdle** consists of a pair of large bones, each composed of 3 fused hipbones. Whereas the pelvic girdle is securely fused to the vertebral column, the pectoral girdle is loosely and flexibly attached to it by muscles.

Each human limb consists of 30 bones and terminates in five **digits,** the fingers and toes. The more specialized appendages of other tetrapods may be characterized by four digits (as in the pig), three (the rhinoceros), two (the camel), or one (the horse).

A typical long bone consists of compact and spongy bone

The radius, one of the two bones of the forearm, is a typical long bone (Fig. 39-6). Its numerous muscle attachments are arranged in such a way that the bone rotates about its long axis and oper-



(a) Axial skeleton (*brown*)

(b) Appendicular skeleton (*brown*)

Figure 39-5 ***Animated*** The human skeletal system

ates as a lever, amplifying the motion generated by the muscles. By themselves, muscles cannot shorten enough to produce large movements of the body parts to which they are attached.

Like other bones, the radius is covered by a connective tissue membrane, the **periosteum,** to which muscle tendons and ligaments attach. The periosteum can produce new layers of bone, thus increasing the bone's diameter. The main shaft of a long bone is its **diaphysis;** each expanded end is an **epiphysis.** In children, a disc of cartilage, the **metaphysis,** lies between the epiphyses and the diaphysis. Metaphyses are growth centers that disappear at maturity, becoming vague **epiphyseal lines.** Long bones have a central cavity that contains **bone marrow.** Yellow marrow consists mainly of a fatty connective tissue; the red marrow in certain bones produces blood cells.

The radius has a thin outer shell of **compact bone,** which is very dense and hard. Compact bone lies primarily near the surfaces of a bone, where it provides great strength. Recall from Chapter 38 that compact bone consists of interlocking spindle-shaped units called **osteons** (see Fig. 38-2). Within an osteon, **osteocytes** (bone cells) lie in small cavities called **lacunae** (sing., *lacuna*). The lacunae are arranged in concentric circles around central **Haversian canals.** Blood vessels that nourish the bone tissue pass through the Haversian canals. Osteocytes are connected by threadlike extensions of their cytoplasm that extend through narrow channels called *canaliculi.*

Interior to the thin shell of compact bone is a filling of **spongy bone,** which provides mechanical strength. Spongy bone consists of a network of thin strands of bone. Its spaces are filled with bone marrow.

Bones are remodeled throughout life

During fetal development, bones form in two ways. Long bones, such as the radius, develop from cartilage templates in a process called **endochondral bone development.** A bone begins to ossify (become bony) in its diaphysis, and secondary sites of bone production develop in the epiphyses. The part of the bone between the ossified regions can grow. Eventually the ossified regions fuse. In contrast, other bones, including the flat outer bones of the skull, develop from a noncartilage, connective tissue scaffold. This process is known as **intramembranous bone development.**

Osteoblasts are bone-building cells. They secrete the protein collagen, which forms the strong fibers of bone. The compound hydroxyapatite, composed mainly of calcium phosphate, is present in the interstitial fluid (tissue fluid). It automatically crystallizes around the collagen fibers to form the hard matrix of bone.

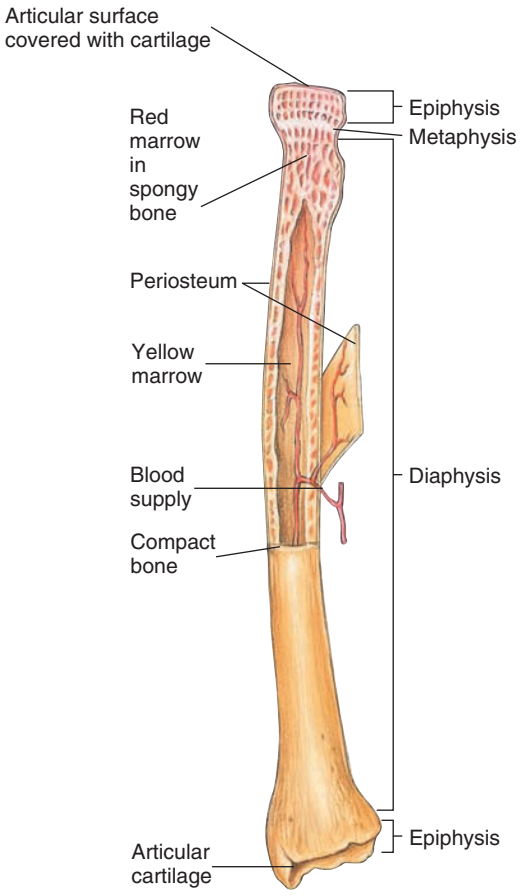


Figure 39-6 ***Animated*** A typical long bone

A long bone has a thin shell of compact bone and a filling of spongy bone that contains marrow.

As the matrix forms around the osteoblasts, they become isolated within the lacunae. The trapped osteoblasts are then called *osteocytes.*

Bones are modeled during growth and remodeled continuously throughout life in response to physical stresses and other changing demands. As muscles develop in response to physical activity, the bones to which they are attached thicken and become stronger. As a bone grows, tissue is removed from its interior, especially from the walls of the marrow cavity.

Osteoclasts are large, multinucleated cells that break down (resorb) bone. The osteoclasts move about, secreting hydrogen ions that dissolve the crystals and enzymes that digest the collagen. Osteoclasts and osteoblasts are synergistic; together they shape bones. The remodeling process is extensive—the adult human skeleton is completely replaced every 10 years!

In *osteoporosis,* the most common progressive, degenerative bone disease, bone resorption takes place more rapidly than bone formation. Patients lose so much bone mass that their bones become fragile, which greatly increases their risk for fracture. Certain drugs inhibit osteoclast-mediated bone resorption. Researchers are testing drugs that promote osteoblast activity, with the goal of promoting bone formation.

Joints are junctions between bones

Joints, or articulations, are junction sites of two or more bones. Joints facilitate flexibility and movement. At the joint, the outer surface of each bone consists of articular cartilage. One way to classify joints is according to the degree of movement they allow. The *sutures* between bones of the human skull are **immovable joints.** In a suture, bones are held together by a thin layer of dense fibrous connective tissue, which may be replaced by bone in the adult. **Slightly movable joints,** found between vertebrae, are made of cartilage and help absorb shock.

Most joints are **freely movable joints.** Each is enclosed by a joint capsule of connective tissue and lined with a membrane that secretes a lubricant called **synovial fluid.** This viscous fluid reduces friction during movement and absorbs shock. The joint capsule is typically reinforced by **ligaments,** bands of fibrous connective tissue that connect bones and limit movement at the joint.

With time and use, joints wear down. In *osteoarthritis,* a common joint disorder, cartilage repair does not keep up with degeneration, and the articular cartilage wears out. In *rheumatoid arthritis,* an autoimmune disease, the synovial membrane thickens and becomes inflamed. Synovial fluid accumulates, causing pressure, pain, stiffness, and progressive deformity, leading to loss of function.

Review

- What functions does a hydrostatic skeleton perform?
- How do the septa in the annelid worm contribute to the effectiveness of its hydrostatic skeleton?
- What are some disadvantages of an exoskeleton? Some advantages?
- What are the two main divisions of the human skeleton? Describe each division.
- How do osteoblasts and osteoclasts remodel bone?

MUSCLE CONTRACTION

Learning Objectives

7 Relate the structure and function of insect flight muscles.
8 Describe the structure of skeletal muscles and their antagonistic actions.
9 List, in sequence, the events that take place during muscle contraction.
10 Compare the roles of glycogen, creatine phosphate, and ATP in providing energy for muscle contraction.
11 Describe how muscles work, including factors that influence contraction.
12 Compare the structures and functions of the three types of skeletal muscle fibers.

Throughout most of the animal kingdom, a **muscular system** generates the mechanical forces and motion necessary for locomotion, manipulation of objects, circulation of blood, movement of food through the digestive tract, and various other life processes. Animals with very simple body plans do not have muscle tissue, but all eukaryotic cells do contain the contractile protein

actin. The major component of microfilaments (see Fig. 4-26), actin is important in many cell processes, including amoeboid movement and attachment of cells to surfaces. In most cells, actin is functionally associated with the contractile protein **myosin.** Actin and myosin are most highly organized in muscle cells.

Invertebrate muscle varies among groups

Earlier in the chapter we discussed the contractile cells of the hydrostatic skeleton of *Hydra* and other cnidarians. In flatworms and most other animal groups, muscle is a specialized tissue organized into definite layers, or straplike bands. Some invertebrate phyla have skeletal and smooth muscle. Bivalve mollusks, such as clams, have two sets of muscles for opening and closing the shell. Smooth muscle, which is capable of slow, sustained contraction, keeps the two shells tightly closed for long periods, even days or weeks at a time. Striated muscle, which contracts rapidly, is used to swim and to shut the shell quickly when the mollusk is threatened. Arthropod muscles are striated, even in the walls of the digestive tract.

Insect flight muscles are adapted for rapid contraction

Insects were the first animals in which flight evolved, an adaptation that has contributed to their impressive biological success (see Chapter 30). Just how insects fly has been an aerodynamic mystery, and scientists are working to understand their remarkable ability to maneuver. Insect flight muscles contract more rapidly than any other known muscle, up to 1000 contractions per second! Not surprisingly, insect flight muscles in action have the highest known metabolic rate of any muscle tissue.

As you might imagine, insect flight muscles are structurally well adapted to their function. They contain more mitochondria than any other known variety of muscle. Their mitochondria also have more cristae (folds of their inner membranes) and can consume oxygen twice as fast as mammalian mitochondria. Insect muscles are also elaborately infiltrated with *tracheae,* tiny air-filled tubes that carry oxygen directly to each fiber.

Many insects must warm up before they fly because an increase in body temperature increases the rate of ATP synthesis. Butterflies and some other insects bask in the sun before they fly. Honeybees "shiver" their muscles to increase body temperature.

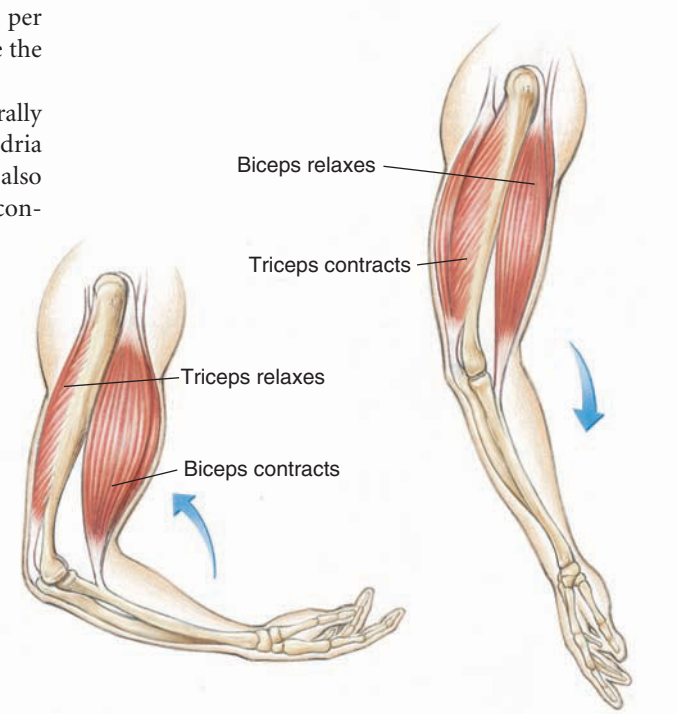
In the common blowfly, the wings may beat at 120 cycles *per second.* Yet in the same blowfly, the neurons that innervate those furiously contracting flight muscles are delivering impulses to them at the astonishingly low frequency of 3 per second. In fact, about 75% of flying insect species beat their wings too rapidly for each contraction to be controlled by a signal from a motor neuron. Instead, they have **asynchronous,** or indirect, muscle contractions in which muscle contraction is not synchronized with signals from motor neurons.

In insects with asynchronous muscle contractions, the striated flight muscles attach not directly to the wings but to the flexible portions of the exoskeleton that articulate with the wings. The mechanical properties of this musculoskeletal arrangement provide the stimuli for contraction by stretching the muscle fibers at a high frequency. Each contraction of the muscles "dimples" the exoskeleton in association with a downstroke and sometimes, depending on the exact arrangement of the muscles, on the upstroke as well. When the dimple springs back into resting position, the muscles attached to it stretch. The stretching immediately initiates another contraction, and the cycle repeats. Thus, the deformation of the exoskeleton is transmitted as a force to the wings, which beat so fast that we may perceive the sounds as a musical tone. However, nerve impulses are needed to maintain contraction.

Somehow insects create lift that is 20 times or more their body weight. A central question has been how their flapping wings generate enough force to keep them airborne. Insect flight involves much more than just flapping the wings up and down. The flapping motion of the insect wing changes direction and speed, and upstrokes alternate with downstrokes at very high rates. At each shift of stroke, the wing rotates about its long axis and tilts to just the right angle for the new direction of motion.

Vertebrate skeletal muscles act antagonistically to one another

Skeletal muscles produce movements by pulling on **tendons,** tough cords of connective tissue that anchor muscles to bone. Tendons then pull on bones. Skeletal muscles, or their tendons,



(a) Flexion. When the biceps muscle contracts, the arm flexes (bends).

(b) Extension. When the triceps muscle contracts, the arm extends.

Figure 39-7 ***Animated*** Muscle action
The biceps and triceps muscles function antagonistically.

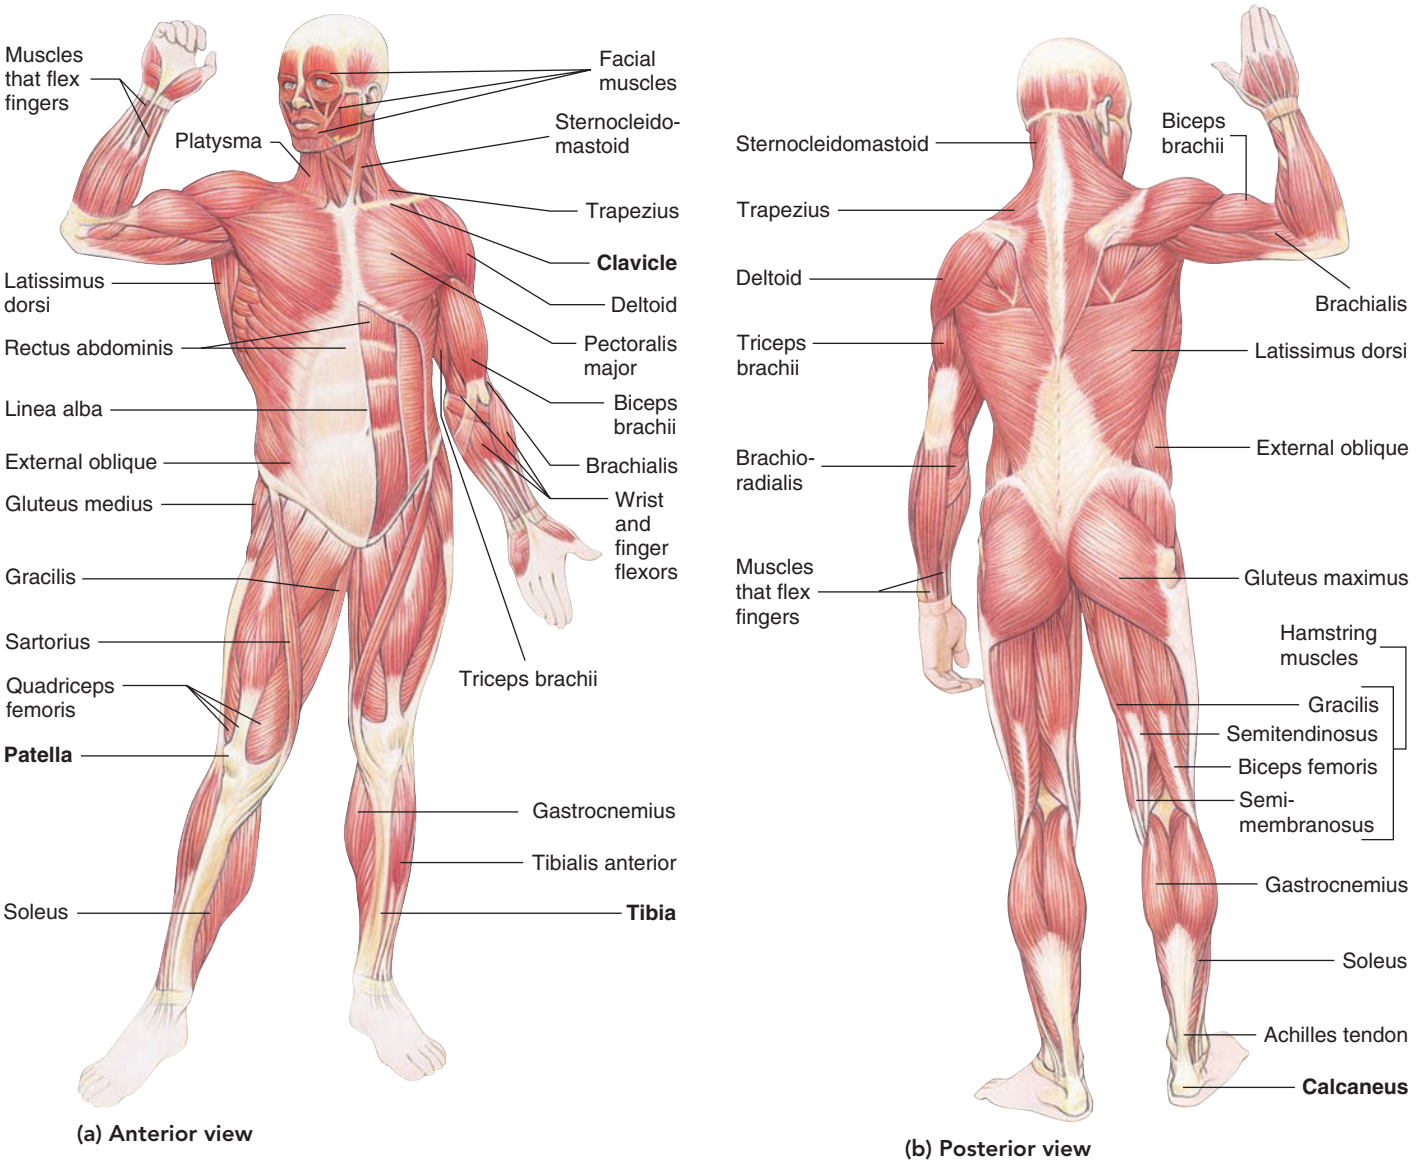


Figure 39-8 ***Animated*** Some superficial muscles of the human body

The labels in boldface are bones.

pass across a joint and are attached to the bones on each side of the joint. When the muscle contracts, it pulls one bone toward or away from the bone with which it articulates.

Because muscles can only contract, they can only pull; they cannot push. Muscles act **antagonistically** to one another, which means that the movement produced by one can be reversed by another. The biceps muscle, for example, flexes (bends) your arm, whereas contraction of the triceps muscle extends it (Fig. 39-7). Thus, the biceps and triceps work antagonistically.

The muscle that contracts to produce a particular action is known as the **agonist.** The muscle that produces the opposite movement is the **antagonist.** When the agonist is contracting, the antagonist is relaxed. Generally, movements are accomplished by groups of muscles working together, so several agonists and several antagonists may take part in any action. Note that muscles that are agonists in one movement may serve as antagonists in another. The superficial skeletal muscles of the human body are shown in Figure 39-8.

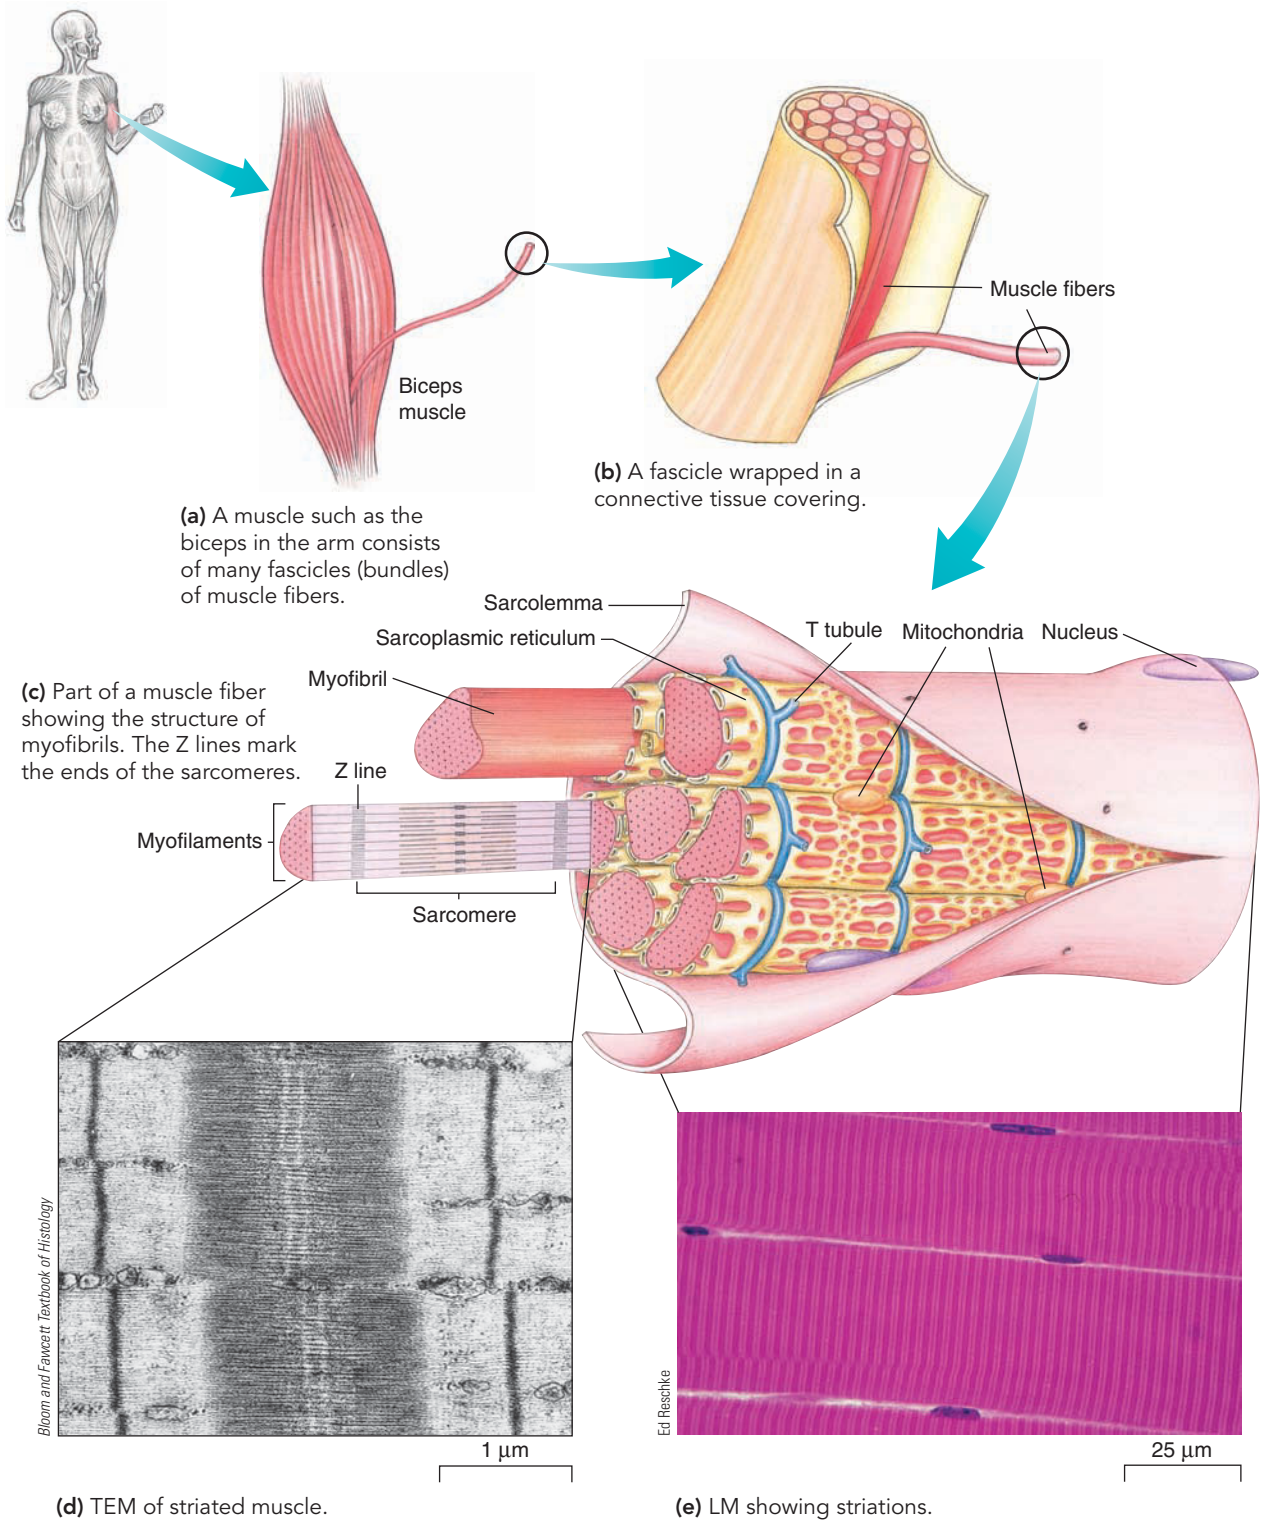
A vertebrate muscle may consist of thousands of muscle fibers

In vertebrates, **skeletal muscle** is the most abundant tissue in the body. Its elongated cells, called **muscle fibers,** are organized in bundles wrapped by connective tissue. The biceps in your arm, for example, consists of thousands of individual muscle fibers and their connective tissue coverings.

Each striated muscle fiber is a long, cylindrical cell with many nuclei (Fig. 39-9). The plasma membrane, known as the

Key Point

A skeletal muscle fiber is a cell containing myofibrils that consist of myofilaments; the myofilaments are organized into repeating units called sarcomeres.



(a) A muscle such as the biceps in the arm consists of many fascicles (bundles) of muscle fibers.

(b) A fascicle wrapped in a connective tissue covering.

(c) Part of a muscle fiber showing the structure of myofibrils. The Z lines mark the ends of the sarcomeres.

(d) TEM of striated muscle.

(e) LM showing striations.

Figure 39-9 ***Animated*** Muscle structure

The regular pattern of overlapping filaments gives skeletal and cardiac muscle their striated appearance. Myofibrils are threadlike structures composed of actin and myosin filaments.

sarcolemma in a muscle fiber, has multiple inward extensions that form a set of **T tubules** (transverse tubules). The cytoplasm of a muscle fiber is called **sarcoplasm,** and the endoplasmic reticulum is called the **sarcoplasmic reticulum.**

Myofibrils, which are threadlike structures, run lengthwise through the muscle fiber. They consist of even smaller structures, the **myofilaments,** or simply **filaments.** There are two types of myofilaments: myosin and actin filaments. **Myosin filaments** are thick, consisting mainly of the protein myosin. The thin **actin filaments** consist mostly of the protein actin; they also contain the proteins **tropomyosin** and the **troponin complex** that regulate the actin filament's interaction with myosin filaments.

Myosin and actin filaments are organized into repeating units called **sarcomeres,** the basic units of muscle contraction. Hundreds of sarcomeres connected end to end make up a myofibril. Sarcomeres are joined at their ends by an interweaving of filaments called the **Z line.** Each sarcomere consists of overlapping myosin and actin filaments. The filaments overlap lengthwise in the muscle fibers, producing the pattern of transverse bands or striations characteristic of striated muscle (Fig. 39-10; also see Fig. 39-9). The bands are designated by the letters *A, H,* and *I.*

The **I band** consists of parts of actin filaments of two adjacent sarcomeres. The **A band** is the wide, dark region that includes overlapping myosin and actin filaments. Within the A band is a narrow, light area, the **H zone,** made up exclusively of myosin filaments; the actin filaments do not extend into this region.

Contraction occurs when actin and myosin filaments slide past one another

Muscle contraction occurs when the sarcomeres, and thus the muscle fibers, shorten. This explanation of muscle contraction, known as the **sliding filament model,** was developed in the 1950s by two British biologists, Hugh Huxley and Andrew Huxley. (The Huxleys are not related. They worked separately and independently came to the same general conclusions at about the same time.) Thanks to the Huxleys, we now understand that the muscle shortens as the actin and myosin filaments slide past one another, so their overlap increases. You might think of an extension ladder. The overall ladder length changes as the ends get closer or farther apart, but the length of each ladder section stays the same. The I band and H zone decrease in length, but neither the actin nor myosin filaments themselves shorten.

Motor neurons transmit messages from the brain or spinal cord to muscle fibers. When a motor neuron transmits a message, it releases the neurotransmitter **acetylcholine** into the **synaptic cleft,** a small space between the motor neuron and each muscle fiber. Acetylcholine binds with receptors on each muscle fiber, causing **depolarization,** a change in the distribution of electric charge across its sarcolemma. Depolarization can cause an electrical signal, or **action potential,** to be generated in the muscle fiber.

In a muscle fiber, an action potential is a wave of depolarization that travels along the sarcolemma and into the system of T-tubule membranes. Depolarization of the T tubules opens calcium channels in the sarcoplasmic reticulum, and stored calcium ions are released into the myofibrils. Calcium ions bind to a protein in the troponin complex on the actin filaments, which changes the shape of the troponin. This change results in the troponin pushing the tropomyosin away from the active sites on the actin filament (Fig. 39-11). These active sites, also called *myosin-binding sites,* are now exposed.

One end of each myosin molecule is folded into two globular structures called *heads.* The rounded heads of the myosin molecules extend away from the body of the myosin filament. Each myosin molecule also has a long tail that joins other myosin tails to form the body of the thick filament. ATP is bound to the myosin when the muscle fiber is at rest (not contracting). Myosin is an adenosine triphosphatase (ATPase), an enzyme that splits ATP to form ADP and inorganic phosphate (P_i). Myosin converts the chemical energy of ATP into the mechanical energy of sliding filaments.

According to the current model of muscle contraction, the ADP and P_i initially remain attached to the myosin head. The myosin head (with ADP and P_i still bound to it) is in an energized state; it is "cocked." The myosin head binds to an exposed active site on the actin filament, forming a **cross bridge** linking the myosin and actin filaments. The inorganic phosphate is then released, which triggers a conformational change in the myosin head. The myosin head bends about 45 degrees, in a flexing motion. This movement, the *power stroke,* pulls the actin filament closer to the center of the sarcomere. During the power stroke, the ADP is released.

A new ATP must bind to the myosin head before the myosin can detach from the actin. If sufficient calcium ions are present, the cycle begins anew. Energized once again, myosin heads contact a second set of active sites on the actin filament; this next set is farther down the molecule, closer to the end of the sarcomere. The process repeats with a third set, and so on. This series of stepping motions pulls the actin filaments toward the center of the sarcomere.

Each time the myosin heads attach, move 45 degrees, detach, and then reattach farther along the actin filament, the muscle shortens. One way to visualize this process is to imagine the myosin heads engaging "hand over hand" with the actin filaments. When many sarcomeres contract simultaneously, they contract the muscle as a whole. The sequence of events in muscle contraction can be summarized as follows:

1. A motor neuron releases acetylcholine, which binds with receptors on the muscle fiber, causing depolarization and an action potential.
2. The action potential spreads through T tubules, triggering Ca^{2+} release from the sarcoplasmic reticulum.
3. Troponin that has bound Ca^{2+} undergoes a conformational change that causes binding sites on actin filaments to be exposed.
4. ATP (attached to myosin) is split, and the energized myosin head is cocked; it binds to the binding site on the actin filament, forming a cross bridge.
5. The release of P_i from the myosin head triggers the power stroke.

Images not available due to copyright restrictions

Key Point

The energy of ATP powers muscle contraction. During the power stroke, myosin heads move actin filaments toward the center of the sarcomere so that the muscle shortens.

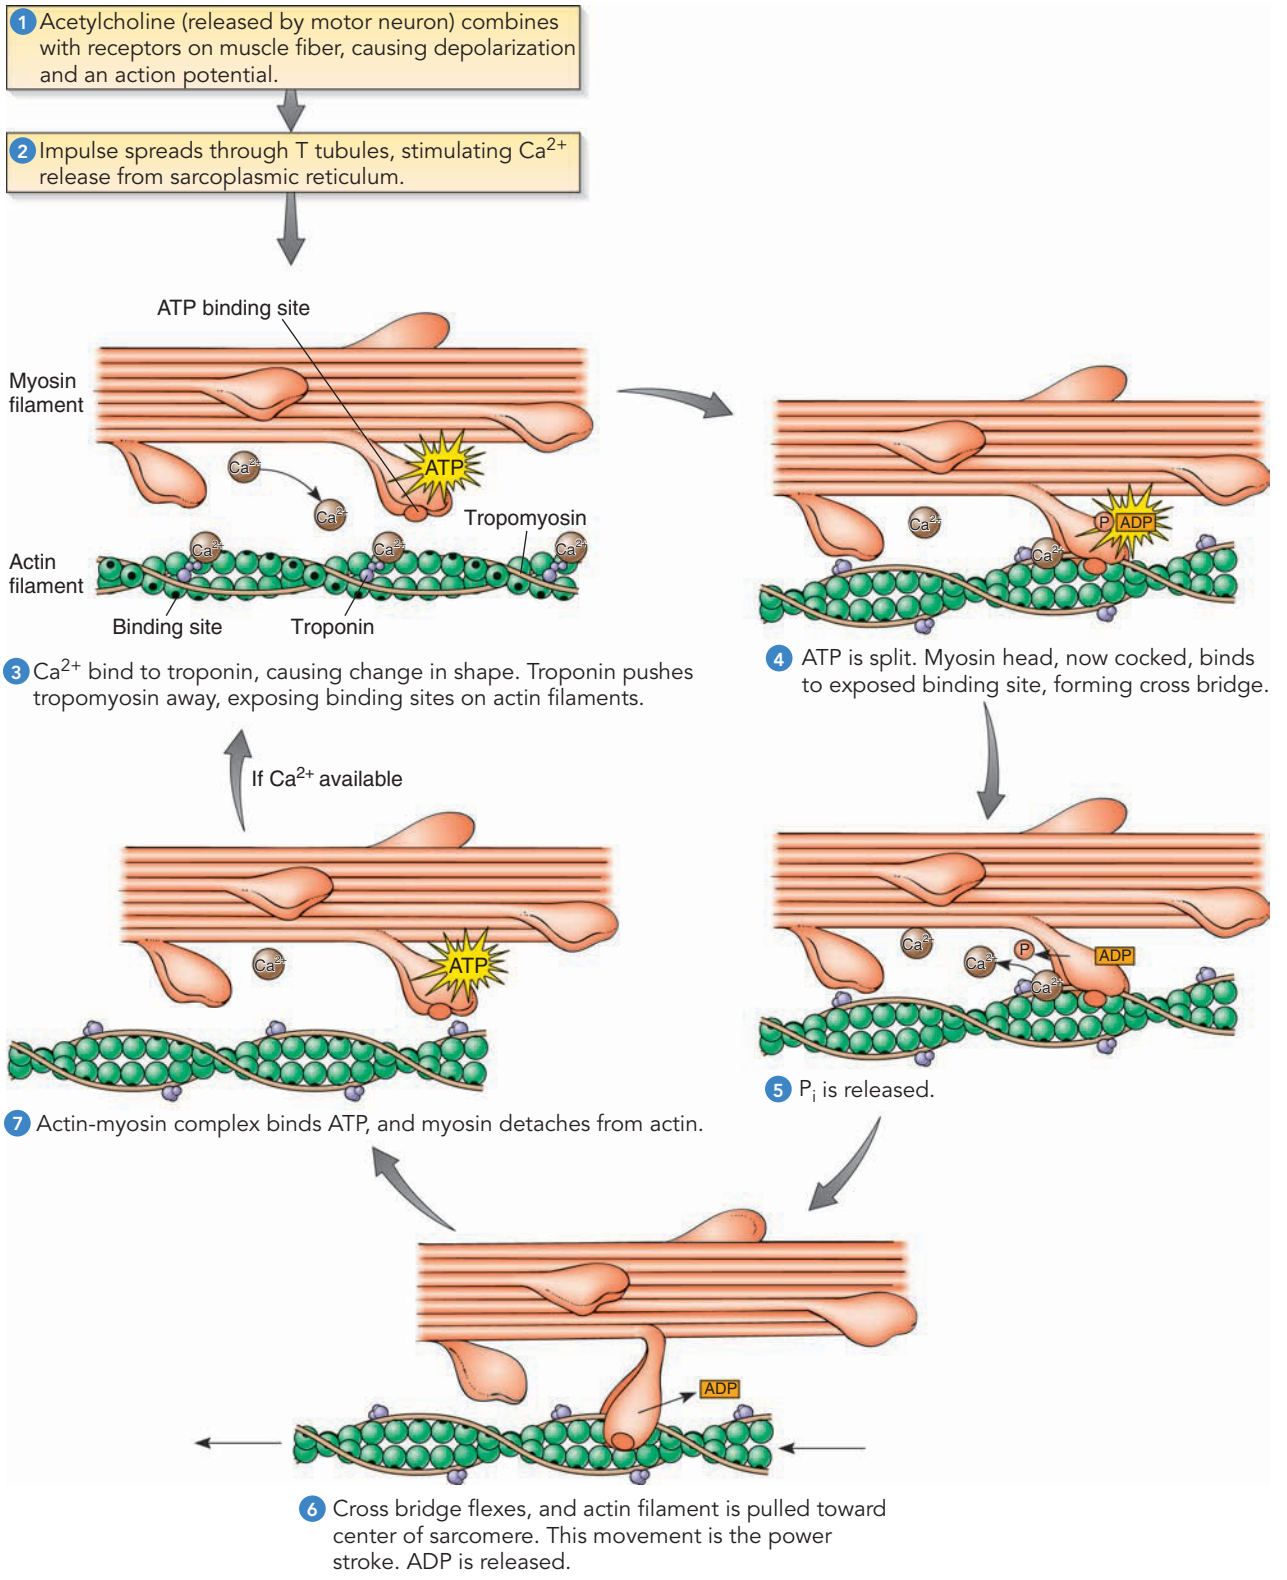


Figure 39-11 ***Animated*** Muscle contraction: Model of actin and myosin interactions

Contraction results when actin filaments slide toward the center of individual sarcomeres of a myofibril. After step 7, the cycle repeats from step 3 if calcium ions are available. In the absence of calcium ions, the muscle relaxes.

6. The power stroke occurs as the actin filament is pulled toward the center of the sarcomere, and ADP is released.
7. The myosin head binds ATP and detaches from actin. If the concentration of Ca^{2+} is high enough, the sequence repeats from step 3.

When impulses from the motor neuron cease, the enzyme acetylcholinesterase in the synaptic cleft inactivates acetylcholine. Muscle fibers return to their resting state. Calcium ions are pumped back into the sarcoplasmic reticulum by active transport, a process that requires ATP. Calcium removal is the key step in muscle relaxation. Without calcium ions, the tropomyosin–troponin complex once again covers active sites on the actin filaments. The actin filaments slide back to their original position, and the muscle relaxes. This entire series of events happens in milliseconds.

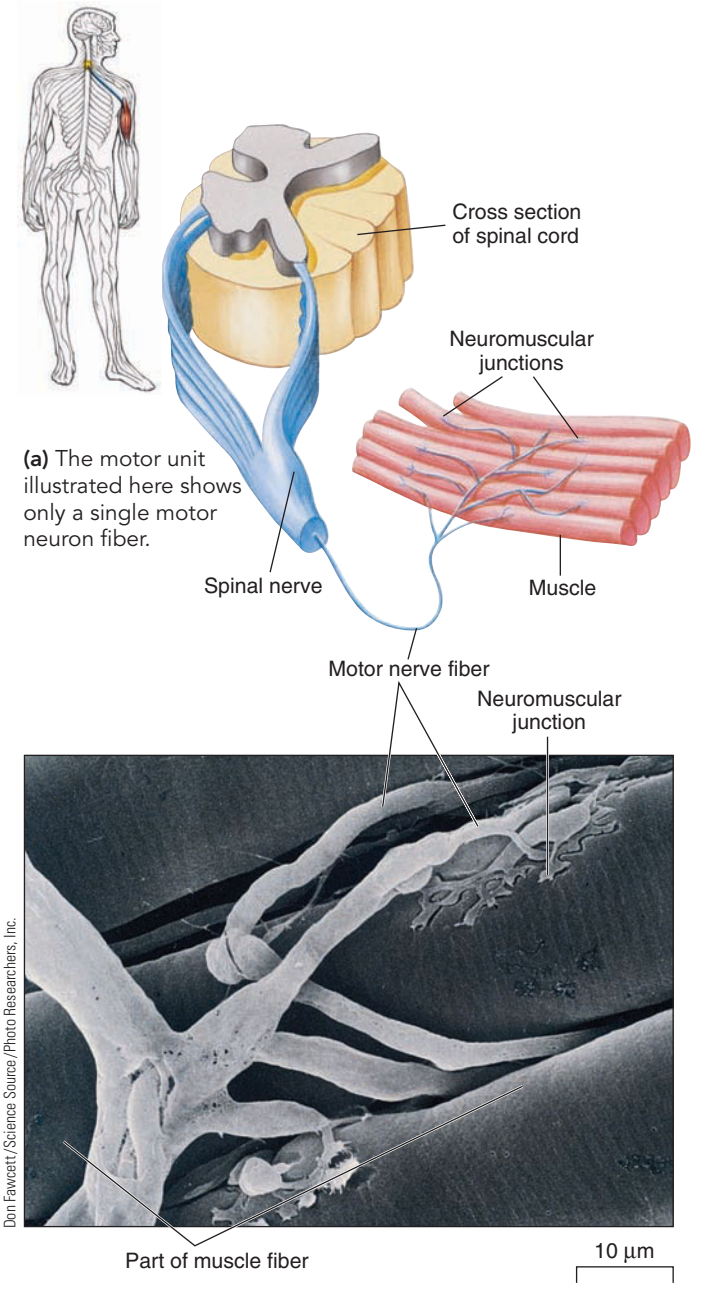
ATP powers muscle contraction

Muscle cells often perform strenuously and need large amounts of energy. As noted, the immediate source of energy for muscle contraction is ATP. Energy stored in ATP molecules powers the repeated cocking, attachment of the myosin heads to the actin filaments, flexion, and release of the myosin heads. Note that energy is needed not only for the pull exerted by the cross bridges but also for their release from each active site. *Rigor mortis,* the temporary but very marked muscular rigidity that appears after death, results from ATP depletion following the end of cellular respiration. Rigor mortis does not persist indefinitely, because the entire contractile apparatus of the muscles eventually decomposes, restoring pliability. The phenomenon is temperature dependent, so given the prevailing temperature, a medical examiner can estimate the time of death of a cadaver from its degree of rigor mortis.

ATP molecules can provide energy for only a few seconds of strenuous activity. Fortunately, muscle cells have a backup energy storage compound, **creatine phosphate,** that can be stockpiled. The energy stored in creatine phosphate is transferred to ATP as needed. But during vigorous exercise the supply of creatine phosphate is quickly depleted. Muscle cells must replenish their supplies of these energy-rich compounds.

Chemical energy is stored in muscle fibers in **glycogen,** a large polysaccharide formed from hundreds of glucose molecules. Glycogen can be degraded, yielding glucose, which is then degraded in cellular respiration. When sufficient oxygen is available, enough energy is captured from glucose to produce needed quantities of ATP and creatine phosphate.

During a burst of strenuous exercise, the circulatory system cannot deliver enough oxygen to keep up with the demand of the rapidly metabolizing muscle cells. This results in an **oxygen debt.** Under these conditions, muscle cells break down fuel molecules anaerobically (without oxygen) for short periods. Lactic acid fermentation is a method of generating ATP anaerobically, but not in great quantity (see Fig. 8-13). ATP depletion results in weaker contractions and muscle fatigue. Accumulation of the waste product **lactic acid** also contributes to muscle fatigue. Well-conditioned athletes develop the ability to tolerate the high levels of lactic acid generated during high-performance activity.



(b) SEM of some of the fibers in a motor unit. Note how neurons branch to innervate all muscle fibers in the motor unit.

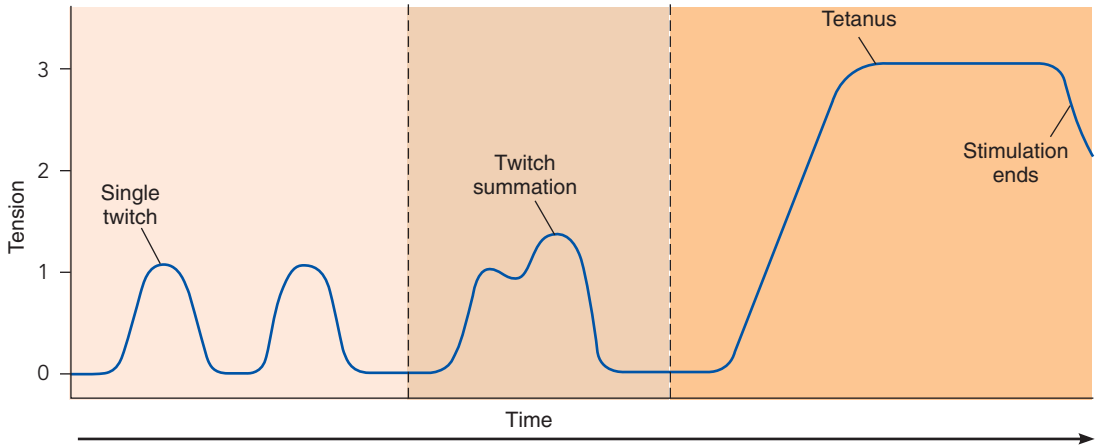
Figure 39-12 ***Animated*** A motor unit

A motor unit consists of a motor neuron fiber and the muscle fibers that it innervates.

The period of rapid breathing that generally follows strenuous exercise pays back the oxygen debt by consuming lactic acid.

The strength of muscle contraction varies

Contraction of a whole muscle depends on (1) the number of muscle fibers contracting and (2) the tension developed by each fiber. The more muscle fibers that contract, the greater is the tension in the muscle. In a **motor unit,** a motor neuron is func-



(a) When a muscle fiber is allowed to completely relax and is then stimulated a second time, the second twitch is the same magnitude as the first twitch.

(b) When a muscle fiber is stimulated a second time before it has completely relaxed, the second twitch is added on to the first twitch. The result is summation.

(c) A volley of rapid stimuli does not allow the muscle fiber to relax between stimuli. A sustained contraction, called tetanus, occurs.

Figure 39-13 ***Animated*** Summation and tetanus

tionally connected with an average of about 150 muscle fibers (Fig. 39-12). However, some motor units have less than a dozen motor neurons, and others have several hundred. Each junction of a motor neuron with a muscle fiber is called a **neuromuscular junction. Motor recruitment** depends on messages from the brain that activate motor neurons. The more motor units that are *recruited,* the stronger are the contractions.

One important factor affecting the tension of contracting muscle fibers is the frequency of stimulation. In response to a single, brief electrical stimulus, skeletal muscle contracts with a single, quick contraction called a **simple twitch.** When a second stimulus is received before the first contraction is complete, the two twitches may add together, a process called **summation** (Fig. 39-13). Typically, skeletal muscle receives a series of separate stimuli timed very close together. Summation results in a smooth, sustained contraction called **tetanus.** Depending on the identity and number of our muscle cells tetanically contracting, we might thread a needle, rock a baby, or run a mile.

Even when you are not moving, your muscles are in a state of partial contraction known as **muscle tone.** At any given moment some muscle fibers are contracted, stimulated by messages from motor neurons. Muscle tone is an unconscious process that keeps muscles prepared for action. When the motor nerve to a muscle is cut, the muscle becomes limp (completely relaxed, or flaccid) and eventually atrophies (decreases in size).

Muscle fibers may be specialized for slow or quick responses

Three major types of skeletal muscle fibers have been identified in vertebrates: slow-oxidative, fast-oxidative, and fast-glycolytic (Table 39-1). **Slow-oxidative fibers** are specialized for endurance activities such as swimming, running long distances, or maintaining posture. They contract slowly and fatigue slowly. These fibers require a steady supply of oxygen. They derive most of their energy from aerobic respiration and are rich in mitochondria and capillaries. Slow-oxidative fibers are rich in **myoglobin,** a red pigment similar to hemoglobin in red blood cells, which stores oxygen. Myoglobin enhances rapid diffusion of oxygen from blood into muscles during strenuous muscle exertion. Because of the myoglobin, slow-oxidative fibers are red.

Fast-oxidative fibers are specialized for rapid response. They contract rapidly and have an intermediate rate of fatigue. Like slow-oxidative fibers, they are rich in mitochondria and obtain most of their ATP from aerobic respiration. They have a high myoglobin content and a red color.

TABLE 39-1

Characteristics of Skeletal Muscle Fibers

Characteristics	Slow-Oxidative Fibers	Fast-Oxidative Fibers	Fast-Glycolytic Fibers
Contraction speed	Slow	Fast	Fast
Rate of fatigue	Slow	Intermediate	Fast
Major pathway for ATP synthesis	Aerobic respiration	Aerobic respiration	Glycolysis
Mitochondria	Many	Many	Few
Intensity of contraction	Low	Intermediate	High
Myoglobin content	High	High	Low
Color of fiber	Red	Red	White

Fast-glycolytic fibers generate a great deal of power and carry out rapid movements but can sustain that activity for only a short time. They are important in activities such as sprinting and weight lifting. Fast-glycolytic fibers contract rapidly, have few mitochondria, and obtain most of their energy from glycolysis. When their glycogen supply is depleted, they fatigue rapidly. These fibers have a low myoglobin content and are white. People who are sedentary have higher numbers of fast-glycolytic fibers than do physically fit individuals. With physical training, these fibers change to fast-oxidative fibers.

Entire muscles may be specialized for quick or slow responses. In chickens, for instance, the white breast muscles are efficient for quick responses, perhaps because a short flight is an escape mechanism for chickens. However, they walk about on the ground all day; the dark (red) meat of the leg and thigh is muscle specialized for more sustained activity. Birds that fly have red breast muscles specialized to support sustained activity. In humans, the proportions of slow-oxidative and fast-oxidative fibers vary among individuals and from muscle to muscle in the same person.

Smooth muscle and cardiac muscle are involuntary

The three types of vertebrate muscle—skeletal, smooth, and cardiac—are compared in Table 38-3. All three types of muscle have thin actin filaments that slide along thick myosin filaments in response to an increase in calcium ion concentration. All three muscle types use ATP to power contraction. However, each type of muscle is specialized for particular types of responses. Neither smooth muscle nor cardiac muscle is under voluntary control.

Smooth muscle is not attached to bones but instead forms tubes that squeeze like the muscle tissue in the body wall of the earthworm. Smooth muscle often contracts in response to simple stretching, and its contraction tends to be sustained. It is well adapted to performing such tasks as regulating blood pressure by sustained contraction of the walls of the arterioles. Although smooth muscle contracts slowly, it shortens much more than striated muscle does; it squeezes impressively.

Smooth muscle is not striated, because its actin and myosin filaments are not organized into myofibrils or into sarcomeres. The fibers of smooth muscle tissue function as a unit because they are connected by *gap junctions* (see Chapter 5). Gap junctions permit electrical signals to pass rapidly from fiber to fiber. Although smooth muscle contraction is basically similar to skeletal muscle contraction (occurring by a sliding filament mechanism), the cross bridges in smooth muscle remain in the attached state longer. For this reason, less ATP is required to maintain a high level of force.

Cardiac muscle contracts and relaxes in alternating rhythm, propelling blood with each contraction. Sustained contraction of cardiac muscle would be disastrous! Like smooth muscle fibers, cardiac muscle fibers are electrically coupled by gap junctions (the intercalated discs). Each heartbeat is initiated by a *pacemaker,* a mass of specialized cardiac muscle. A conduction system transmits the signal throughout the cardiac muscle, and the heart beats in a regular rhythm independent of a nerve supply. However, the heart rate is regulated, according to the needs of the body, by neurons in the cardiac centers in the medulla of the brain (discussed in Chapter 43).

Review

- Describe a skeletal muscle fiber. What are its two types of filaments?
- What events occur when a muscle fiber contracts (begin with release of acetylcholine and include cross-bridge action)?
- What is the role of ATP in muscle contraction? What are the functions of creatine phosphate and glycogen?
- What is summation?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Compare the functions of the external epithelium of invertebrates and vertebrates (page 828).
- **Epithelial tissue** in both invertebrates and vertebrates protects underlying tissues and may be specialized for sensory or respiratory functions. The outer epithelium may be specialized to secrete lubricants or adhesives, or odorous or poisonous substances.
- In many invertebrates, the outer epithelium is specialized to secrete a protective **cuticle,** or shell.
- The **integumentary system** of vertebrates includes the skin and structures that develop from it. Mammalian skin includes hair, claws or nails, sweat glands, oil glands, and sensory receptors.

2 Relate the structure of vertebrate skin to its functions (page 828).
- The feathers of birds and the hair of mammals form an insulating layer that helps maintain a constant body temperature.
- Mammalian skin is well adapted to protect the body from the wear and tear that occurs as it interacts with the outer environment. **Stratum corneum,** the most superficial layer of the **epidermis,** consists of dead cells. These cells are filled with the insoluble protein **keratin,** which gives mechanical strength to the skin and reduces water loss. Cells in **stratum basale** of the epidermis divide and are pushed upward toward the skin surface. These cells mature, flatten, produce keratin, and eventually die and slough off.
- The **dermis** consists of dense, fibrous connective tissue. In birds and mammals, the dermis rests on a layer of **subcutaneous tissue** composed largely of insulating fat.

3 Compare the structure and functions of different types of skeletal systems, including the hydrostatic skeleton, exoskeleton, and endoskeleton (page 829).
- The **skeletal system** supports and protects the body and transmits mechanical forces generated by muscles.

- Many soft-bodied invertebrates, including cnidarians, flatworms, and annelids, have a **hydrostatic skeleton** in which fluid in a closed body compartment is used to transmit forces generated by contractile cells or muscle.
- **Exoskeletons** are characteristic of mollusks and arthropods. The arthropod skeleton, composed partly of **chitin,** is jointed for flexibility and adapted for many lifestyles. This nonliving skeleton does not grow, making it necessary for arthropods to **molt** periodically.
- The **endoskeletons** of echinoderms and chordates consist of living tissue and therefore can grow.

4 Describe the main divisions of the vertebrate skeleton and the bones that make up each division (page 829).

- The vertebrate skeleton consists of an **axial skeleton** and an **appendicular skeleton.** The axial skeleton consists of **skull, vertebral column, rib cage,** and **sternum.** The appendicular skeleton consists of bones of the limbs, **pectoral girdle,** and **pelvic girdle.**

5 Describe the structure of a typical long bone, and differentiate between endochondral and intramembranous bone development (page 829).

- A typical long bone consists of a thin outer shell of **compact bone** surrounding the inner **spongy bone** and a central cavity that contains **bone marrow.**
- Long bones develop from cartilage templates during **endochondral bone development.** Other bones, such as the flat bones of the skull, develop from a noncartilage connective tissue model by **intramembranous bone development.**
- **Osteoblasts,** cells that produce bone, and **osteoclasts,** cells that break down bone, work together to shape and remodel bone.

ThomsonNOW™ Learn more about the human skeletal system and a typical long bone by clicking on the figures in ThomsonNOW.

6 Compare the main types of vertebrate joints (page 829).

- **Joints** are junctions of two or more bones. **Ligaments** are connective tissue bands that connect bones and limit movement at the joint.
- The sutures of the skull are **immovable joints.** Joints between vertebrae are **slightly movable joints.** A **freely movable joint** is enclosed by a joint capsule lined with a membrane that secretes **synovial fluid.**

7 Relate the structure and function of insect flight muscles (page 833).

- Large numbers of mitochondria and tracheae (air tubes) present in insect flight muscles support the high metabolic rate required for flight.

8 Describe the structure of skeletal muscles and their antagonistic actions (page 833).

- A **muscular system** is found in most invertebrate phyla and in vertebrates. As muscle tissue contracts (shortens), it moves body parts by pulling on them. Three types of muscle are **skeletal, smooth,** and **cardiac muscle.**
- Vertebrate skeletal muscles pull on **tendons,** connective tissue cords that attach muscles to bones. When a muscle contracts, it pulls a bone toward or away from the bone with which it articulates.
- Skeletal muscles act **antagonistically** to one another. The muscle that produces a particular action is the **agonist;** the **antagonist** produces the opposite movement.
- A skeletal muscle such as the biceps is an organ made up of hundreds of **muscle fibers.** Each fiber consists of threadlike **myofibrils** composed of smaller **myofilaments,** or simply **filaments.** The striations of skeletal muscle fibers reflect the overlapping of their **actin filaments** and **myosin filaments.** A **sarcomere** is a contractile unit of actin (thin) and myosin (thick) filaments.

9 List, in sequence, the events that take place during muscle contraction (page 833).

- **Acetylcholine** released by a motor neuron combines with receptors on the surface of a muscle fiber. This may cause **depolarization** of the sarcolemma and transmission of an **action potential.** The action potential spreads through the **T tubules,** releasing calcium ions from the **sarcoplasmic reticulum.**
- Calcium ions bind to **troponin** in the actin filaments, causing the troponin to change shape. Troponin pushes **tropomyosin** away from the binding sites on the actin filaments.
- ATP binds to myosin; ATP is split, putting the myosin head in a high-energy state (it is "cocked"). Energized myosin heads attach to the exposed binding sites on the actin filaments, forming **cross bridges** that link the myosin and actin filaments.
- After myosin attaches to the actin filament, the cross bridge flexes as phosphate is released. This is the power stroke, which pulls the actin filament toward the center of the sarcomere. ADP is released during the power stroke.
- The myosin head binds a new ATP, which lets the myosin head detach from the actin. As long as the calcium ion concentration remains elevated, the new ATP is split and the sequence repeats. The myosin reattaches to new active sites so that the filaments are pulled past one another, and the muscle continues to shorten.

10 Compare the roles of glycogen, creatine phosphate, and ATP in providing energy for muscle contraction (page 833).

- ATP is the immediate source of energy for muscle contraction. The energy from ATP hydrolysis provides the energy to "cock" the myosin. Muscle tissue has an intermediate energy storage compound, **creatine phosphate. Glycogen** is the fuel stored in muscle fibers.

11 Describe how muscles work, including factors that influence contraction (page 833).

- Contraction of a whole muscle depends (1) on the number of muscle fibers contracting and (2) on the tension developed by each fiber.
- A **motor unit** consists of all of the skeletal muscle fibers stimulated by a single motor neuron. **Motor recruitment** depends on messages from the brain that activate motor neurons. The more motor units that are *recruited,* the stronger are the contractions.
- When activated by a brief electrical stimulus, skeletal muscle responds with a **simple twitch.** When a second stimulus is received before the first contraction is complete, the two twitches can add together; this process is **summation.** Typically, skeletal muscle is stimulated with a series of separate stimuli timed close together and responds with a smooth, sustained contraction called **tetanus.**
- **Muscle tone** is the state of partial contraction characteristic of muscles.

ThomsonNOW™ Explore muscle action, structure, and contraction as well as summation and tetanus by clicking on the figures in ThomsonNOW.

12 Compare the structures and functions of the three types of skeletal muscle fibers (page 833).

- **Slow-oxidative fibers** are specialized for endurance activities. They contract slowly, fatigue slowly, are rich in mitochondria, and obtain most of their ATP from aerobic respiration. They have a red color because they have a high content of **myoglobin.** Myoglobin is a red pigment that stores oxygen.

- **Fast-oxidative fibers** are specialized for rapid response. They contract fast, have an intermediate rate of fatigue, are rich in mitochondria, and obtain most of their ATP from aerobic respiration. They have a high myoglobin content and a red color.
- **Fast-glycolytic fibers** generate a great deal of power for a brief period. They contract fast, fatigue quickly, have few mitochondria, and use glycolysis as a major pathway for ATP synthesis. These fibers are white.

TEST YOUR UNDERSTANDING

1. The vertebrate skin consists of an (a) outer epidermis and inner hypodermis (b) outer epidermis and inner endoskeleton (c) outer endodermis and inner epidermis (d) outer epidermis and inner dermis (e) outer subcutaneous layer and inner dermis
2. Cells actively divide in (a) stratum basale (b) stratum corneum (c) stratum dermis (d) the layer with cells that contain keratin (e) two of the preceding answers are correct
3. An endoskeleton (a) is typically composed of dead tissue (b) is characterized by fluid in a closed compartment (c) is typical of echinoderms (d) is typical of arthropods (e) requires the animal to molt
4. Which of the following is *not* part of the axial skeleton? (a) skull (b) vertebral column (c) pelvic girdle (d) rib cage (e) sternum
5. The thin outer shell of a long bone is made of (a) compact bone (b) spongy bone (c) epiphyses (d) cartilage (e) mainly chondrocytes
6. Which of the following connects bones to one another? (a) tendons (b) ligaments (c) osteoclasts (d) synovial membranes (e) smooth fibers
7. In endochondral bone development, (a) osteoclasts produce bone (b) joints connect fibers (c) the skeleton consists of cartilage (d) bones develop from cartilage templates (e) bones form in noncartilage connective tissue
8. All animals have (a) muscles (b) actin (c) bones (d) endoskeleton or exoskeleton (e) dermis
9. An energy storage compound that can be stockpiled in muscle cells for short-term use is (a) creatine phosphate (b) ADP (c) troponin (d) myosin (e) myoglobin
10. Myosin binds to actin, forming a cross bridge. What happens next? (a) acetylcholine is released (b) calcium ions stimulate exposure of active sites (c) filaments slide past one another, and the muscle fiber shortens (d) myosin is activated (e) P_i is released, and the cross bridge flexes
11. Calcium ions are released from the sarcoplasmic reticulum. What happens next? (a) acetylcholine is released (b) active sites on the actin filaments are exposed (c) filaments slide past one another, and the muscle fiber shortens (d) myosin is activated (e) P_i is released, and the cross bridge flexes
12. When skeletal muscle is stimulated by a series of closely timed separate stimuli, (a) it responds with a smooth, sustained contraction called tetanus (b) a simple twitch occurs (c) white fibers respond (d) red fibers respond (e) muscle tone occurs
13. Glycogen is (a) produced by actin (b) depleted within 1 second of strenuous activity (c) a form of long-term energy storage (d) synthesized when cross bridges form (e) depleted before creatine phosphate reserves are used
14. Slow-oxidative fibers (a) are white fibers (b) do not depend on ATP (c) have few mitochondria (d) obtain most of their energy from glycolysis (e) are rich in myoglobin
15. Insect flight muscles (a) work best at low temperature (b) have a very high metabolic rate (c) do not create much lift (d) evolved after bird wings (e) are always attached directly to the wing and make up the bulk of the wing
16. Which of the following pairs of systems function together most closely? (a) integumentary and skeletal (b) integumentary and cardiovascular (c) muscular and epithelial (d) skeletal and muscular (e) epithelial and muscular

CRITICAL THINKING

1. What are some examples of hydrostatic support in plants?
2. Why is it important that a muscle be able to shift functions, sometimes acting as an agonist and at other times acting as an antagonist?
3. Summarize the functional relationship between skeletal and muscle tissues.
4. **Evolution Link.** Very different skeletal systems have evolved in arthropods and vertebrates. What are some benefits and some disadvantages of each type of skeleton? In what ways is the insect skeleton an adaptation to the insect lifestyle?
5. **Analyzing Data.** Examine Figure 39-13. Based on the summation of two stimuli shown in this graph, draw a curve showing summation when the muscle fiber is stimulated three times.

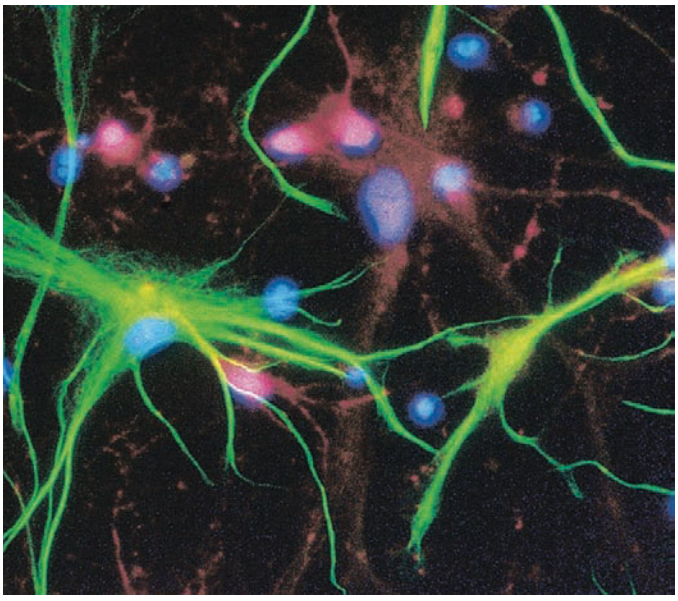
Neural Signaling



Nancy Kedersha/UCLA/Science Photo Library/Photo Researchers, Inc.

Immunofluorescence LM of several astrocytes (*green*) from mammalian spinal cord tissue. The smaller cells (*red*) are neurons. Their cell bodies appear pink. The blue dots are the nuclei of other glial cells.

KEY CONCEPTS

Neural signaling involves reception, transmission, integration, and action by effectors.

Neurons are specialized to receive stimuli and transmit signals; glial cells are supporting cells that protect and nourish neurons and that can modify neural signals.

The resting potential of a neuron is maintained by differences in concentrations of specific ions inside the cell relative to the extracellular fluid and by selective permeability of the plasma membrane to these ions.

Depolarization of the neuron plasma membrane to threshold level generates an action potential, an electrical signal that travels as a wave of depolarization along the axon.

Neurons signal other cells by releasing neurotransmitters at synapses.

During integration, incoming neural signals are summed; temporal and spatial summation can bring a neuron to threshold level.

An organism's ability to survive and to maintain homeostasis depends largely on how effectively it detects and responds to *stimuli*—changes in the environment. Most animals have a *nervous system* that, like a computer, takes in information, integrates it, and responds. The nervous system is composed mainly of two specialized types of cells—*neurons* and *glial cells* (see photograph). Just how animals respond to stimuli depends on how their neurons are organized and connected to one another. A single neuron in the vertebrate brain may be functionally connected to thousands of other neurons.

The nervous system is the principal regulatory system in animals. The endocrine system works with the nervous system to regulate many behaviors and physiological processes. In general, the endocrine system provides relatively slow and long-lasting regulation, whereas the nervous system responds rapidly, but briefly.

Neurobiology is one of the most exciting areas of biological research. Recent studies have challenged time-honored views about nervous system function. One of the most entrenched ideas was that the brain of mammals cannot generate new neurons after birth. Nobel Laureate Santiago Ramon y Cajal promoted this concept at the beginning of the 20th century, and the idea that we are born with all the brain cells we will ever have was widely held for almost a century. A second enduring idea was that glial cells, the most common cells in the brain, simply provide support services for neurons. As we will discuss in this chapter, both of these concepts have recently proved incorrect.

Another active area of research focuses on *neurotransmitters*, the chemical messengers used by neurons to signal other neurons.

More than 50 chemical compounds important in neuron and glial cell communication have been identified. Investigators are also studying the *receptors* that bind with the neurotransmitters.

In this chapter we focus on how information is communicated by neurons and glial cells. In Chapter 41 we discuss nervous systems, and in Chapter 42 we explore sensory reception. ■

INFORMATION FLOW THROUGH THE NERVOUS SYSTEM

Learning Objective

1 Describe the processes involved in neural signaling: reception, transmission, integration, and action by effectors.

Thousands of stimuli constantly bombard an animal, and its survival depends on identifying these stimuli and responding appropriately. Stimuli within the body include internal signals such as hunger or fluctuations in blood pressure. Stimuli from the outside world include changes in temperature, light, odors, or movement that may indicate the presence of a predator or of prey. In all animals except the sponges, responses to stimuli depend on **neural signaling,** cell signaling by networks of nerve cells, called **neurons.** In most animals, neural signaling involves four processes: reception, transmission, integration, and action by effectors (muscles or glands).

Reception, the process of detecting a stimulus, is the job of neurons and of specialized sensory receptors such as those in the skin, eyes, and ears (▮ Fig. 40-1). **Transmission** is the process of sending messages along a neuron, from one neuron to another or from a neuron to a muscle or gland. In vertebrates, a neural message is transmitted from a receptor to the **central nervous system (CNS),** which consists of the brain and spinal cord. Neurons that transmit information to the CNS are called **afferent** (meaning "to carry toward") **neurons,** or **sensory neurons.**

Afferent neurons generally transmit information to **interneurons,** or association neurons, in the CNS. Most neurons, perhaps 99%, are interneurons. Their function is to integrate input and output. **Integration** involves sorting and interpreting incoming sensory information and determining the appropriate response.

Neural messages are transmitted from the CNS by **efferent** (meaning "to carry away") **neurons** to **effectors**—muscles and glands. Efferent neurons that signal skeletal muscle are called **motor neurons.** The **action by effectors** is the actual response to the stimulus. Sensory receptors and afferent and efferent neurons are part of the **peripheral nervous system (PNS).** In summary, information flows through the nervous system in the following sequence:

Reception by sensory receptor ⟶ transmission by afferent neuron ⟶ integration by interneurons in CNS ⟶ transmission by efferent neuron ⟶ action by effectors

Review

- Imagine you are swimming and you suddenly spot a shark fin moving in your direction. What processes must take place within your nervous system before you can make your escape?
- What happens after neural signals are integrated in the CNS?

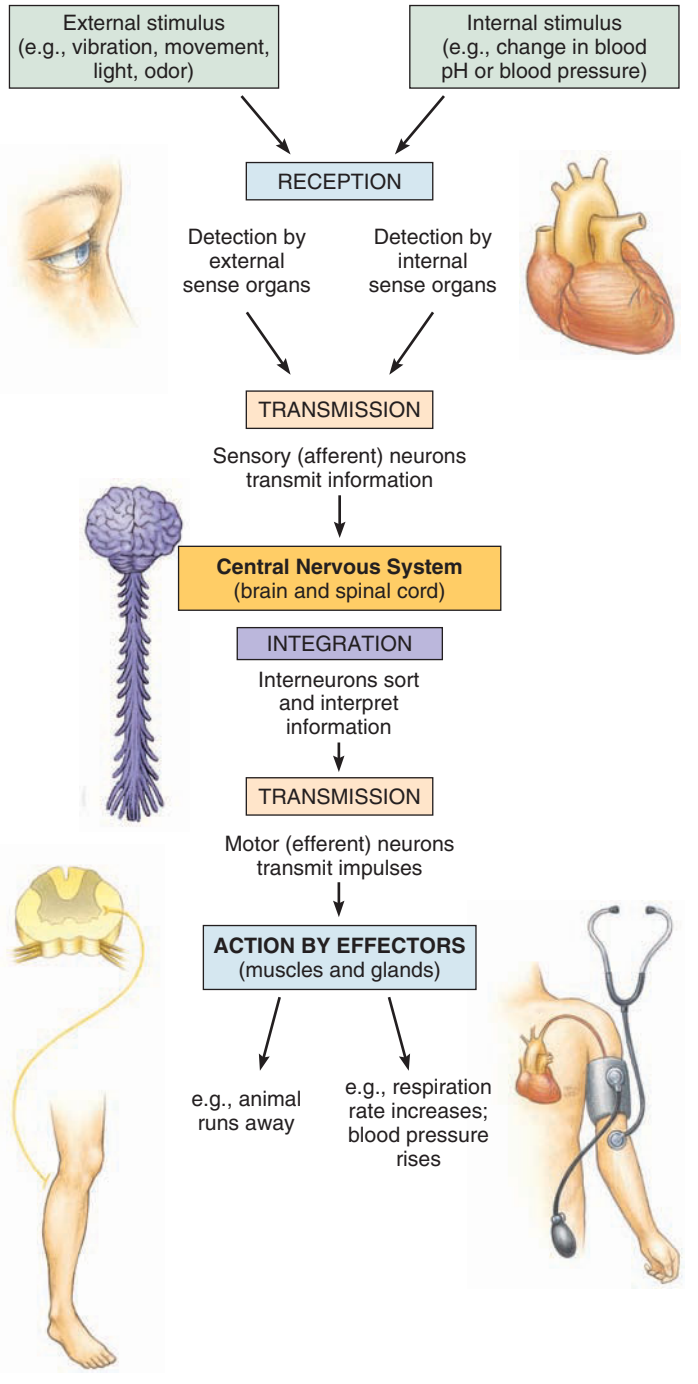


Figure 40-1 Response to a stimulus

Whether a stimulus originates in the outside world or inside the body, information must be received; transmitted to the central nervous system; integrated; and then transmitted to effectors, muscles or glands that carry out some action, the actual response.

NEURONS AND GLIAL CELLS

Learning Objectives

2 Describe the structure of a typical neuron, and give the function of each of its parts.

3 Name the main types of glial cells, and describe the functions of each.

Two types of cells unique to the nervous system are neurons and glial cells. Neurons are specialized to receive and send information. Glial cells support and protect the neurons and carry out many regulatory functions.

A typical neuron consists of a cell body, dendrites, and an axon

The neuron is highly specialized to receive stimuli and to transmit neural signals, which are electrical signals and chemical messages. Neurons produce and transmit electrical signals called **nerve impulses,** or *action potentials.* The neuron is distinguished from all other cells by its long **processes** (cytoplasmic extensions). Examine the structure of a common type of neuron, the multipolar neuron shown in Figure 40-2.

The largest portion of the neuron, the **cell body,** contains the nucleus, the bulk of the cytoplasm, and most of the organelles. Typically, two types of processes project from the cell body of a multipolar neuron. Numerous dendrites extend from one end, and a long, single axon projects from the opposite end. **Dendrites** are typically short, highly branched processes specialized to receive stimuli and send signals to the cell body. The cell body integrates incoming signals.

Although microscopic in diameter, an **axon** may be 1 m (more than 1 yd) or more in length and may divide, forming branches called **axon collaterals.** The axon conducts nerve impulses away from the cell body to another neuron or to a muscle or gland. At its end the axon divides, forming many **terminal branches** that end in **synaptic terminals.** The synaptic terminals release **neurotransmitters,** chemicals that transmit signals from one neuron to another or from a neuron to an effector. The junction between a synaptic terminal and another neuron (or effector) is called a **synapse.** Typically, a small space exists between the membranes of these two cells.

In vertebrates, the axons of many neurons outside the CNS are surrounded by a series of **Schwann cells,** glial cells that form an insulating covering called the **myelin sheath. Myelin** is a white, fatty material found in the plasma membranes of Schwann cells. Gaps in the myelin sheath, called **nodes of Ranvier,** occur between successive Schwann cells. At these points the axon is not insulated with myelin. Axons more than 2 μm in diameter have myelin sheaths and are described as *myelinated.* Those of smaller diameter are generally unmyelinated.

New neurons are produced in the CNS

At the beginning of the chapter, we described Cajal's idea that **neurogenesis,** the production of new neurons, does not occur in the CNS. The paradigm shift that has recently occurred with regard to this view demonstrates the power and importance of the process of science. Cajal's idea was so entrenched that for many years the researchers who attempted to study the issue were discouraged and discounted. Even images produced by an electron microscope showing neurons dividing were ridiculed and rejected. During the 1980s, studies on rhesus monkey brains appeared to support Cajal's idea. No new neurons were found in the monkeys' brains. The matter appeared settled.

However, matters are almost never settled in science. Researchers investigating a variety of seemingly unrelated problems made observations that shed new light on the neurogenesis issue. For more than 25 years, Fernando Nottebohm at Rockefeller University has studied birdsong, including its neural basis. Nottebohm found that birds produce new neurons daily in the brain center that regulates their songs. His work was at first dismissed as a phenomenon peculiar to birds and not relevant to mammals.

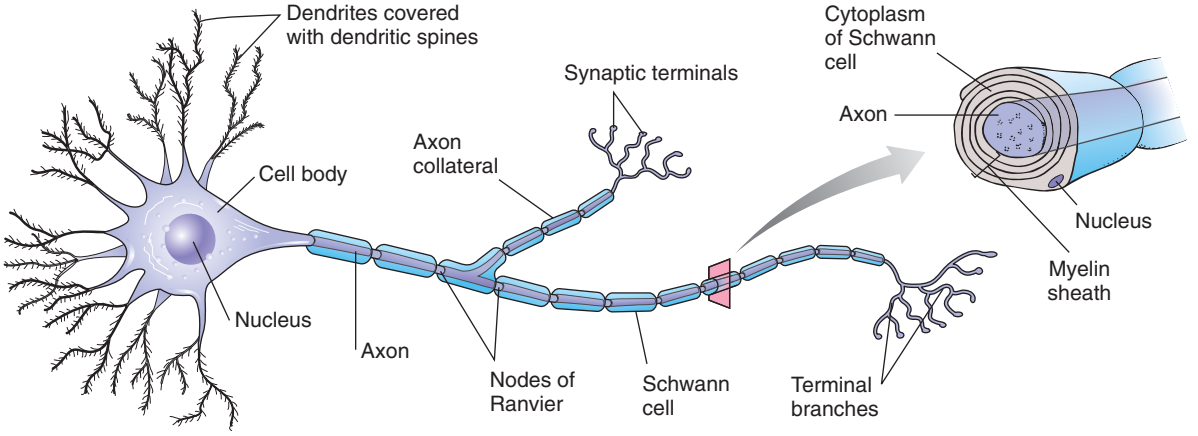

Figure 40-2 ***Animated*** Structure of a multipolar neuron

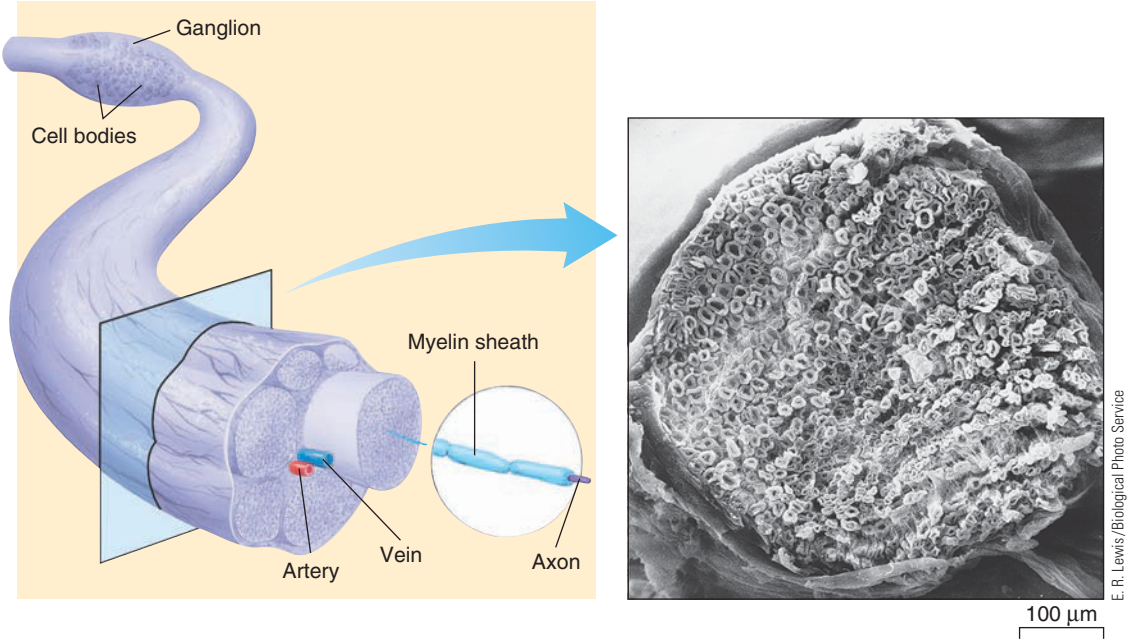
The cell body contains most of the organelles. Many dendrites and a single axon extend from the cell body. Schwann cells form a myelin sheath around the axon by wrapping their own plasma membranes around the neuron in jelly-roll fashion.



(a) A nerve consists of bundles of axons held together by connective tissue. The cell bodies belonging to the axons of a nerve are grouped in a ganglion.

(b) SEM showing a cross section through a myelinated afferent nerve of a bullfrog.

Figure 40-3 ***Animated*** Structure of a nerve

However, other investigators, most notably Elizabeth Gould at Princeton University, have provided additional data that together have falsified Cajal's concept. Gould demonstrated neuron proliferation in primates. She and her research team also discovered that stress damages the brain and inhibits mitosis of neurons. They stressed newborn rats by separating them from their mothers for up to 3 hours a day. These rats did not learn how to cope with stress, and as adults, they had fewer new neurons in certain areas of their brains than control rats. Earlier investigations may have failed to show new neurons in the brain because the animals being studied were in a state of stress and neurogenesis was inhibited. Neurobiologists now agree that neurogenesis does occur regularly in at least several regions of the adult mammalian brain. The paradigm has shifted.

Axons aggregate to form nerves and tracts

A **nerve** consists of hundreds or even thousands of axons wrapped together in connective tissue (Fig. 40-3).We can compare a nerve to a telephone cable. The individual axons correspond to the wires that run through the cable, and the sheaths and connective tissue coverings correspond to the insulation. Within the CNS, bundles of axons are called **tracts** or **pathways** rather than nerves.

Outside the CNS, the cell bodies of neurons are usually grouped in masses called **ganglia** (sing., *ganglion*). Inside the CNS, collections of cell bodies are generally called *nuclei* rather than *ganglia.*

Glial cells provide metabolic and structural support

Glial cells collectively make up the **neuroglia** (literally, "nerve glue"). Until recently, the glial cells were thought to be passive cells that simply support and protect the neurons. Armed with more sophisticated technology, researchers are beginning to discover that glial cells communicate and carry out major regulatory functions.

About 90% of the cells in the human CNS are glial cells. They account for about 50% of the brain volume, because they do not branch as extensively as neurons. Vertebrates have four main types of glial cells in the CNS: astrocytes, microglia, oligodendrocytes, and ependymal cells (Table 40-1).

Astrocytes are star-shaped glial cells that provide physical support for neurons and provide neurons with nutrients. Astrocytes help regulate the composition of the extracellular fluid in the CNS by removing excess potassium ions. This action helps maintain normal neuron excitability. Some astrocytes position the ends of their long processes on blood vessels in the brain. In response, endothelial cells lining the blood vessels form *tight junctions* (see Chapter 5) that prevent many substances in the blood from entering the brain tissue. This protective wall is the *blood–brain barrier.*

Neurobiologists have shown that astrocytes are functionally connected throughout the brain. These interesting glial cells may participate in information signaling in the brain by coordinating activity among neurons. They communicate through *gap junc-*

TABLE 40-1

Functions of Glial Cells

Type of Glial Cell	Functions
Astrocytes	Physically support neurons
	Provide neurons with nutrients
	Remove excess K^+, which helps regulate composition of extracellular fluid in CNS
	Induce blood vessels to form blood–brain barrier
	Communicate with one another and with neurons
	Induce synapse formation and strengthen activity of synapses
	May be important in memory and learning
	Guide neurons during embryonic development
Microglia	Secrete growth factors
	Phagocytosis of bacteria
Oligodendrocyte	Form myelin sheaths around neurons in CNS
Ependymal cells	Line cavities of CNS
	Help produce cerebrospinal fluid
	Function as neural stem cells

tions and with signaling molecules. Although astrocytes can generate only weak electrical signals, they communicate with one another and with neurons by means of chemical signals. Astrocytes can respond to neurotransmitters released by neurons, and they also help remove excess neurotransmitters from synapses. Neurobiologists have demonstrated that astrocytes induce synapse formation and can strengthen activity of synapses in the brain. These cells appear to be important in learning and memory.

Astrocytes play a role in development by guiding neurons to appropriate locations in the body. Neurobiologists have shown that certain astrocytes function as stem cells in the brain and spinal cord. These cells can give rise to new neurons, additional astrocytes, and certain other glial cells. Taken out of their normal environment in the adult mouse brain, astrocytes can give rise to cells of all germ layers (that is, the embryonic tissue layers: ectoderm, mesoderm, and endoderm). Human astrocytes may someday be used to produce specific types of cells needed for treating various medical conditions.

Microglia are glial cells that secrete growth factors, such as *nerve growth factor,* which is important for the survival of certain types of neurons. Recent findings suggest that microglia can respond to signals from neurons and are important in mediating responses in injury or disease. Microglia cells multiply when the brain is injured.

Microglia are found near blood vessels. During infection, these cells move to the affected area and remove bacteria and cell debris by phagocytosis. They also release chemical compounds that destroy bacteria. Oversecretion of these compounds may be a cause of neuron damage in stroke and certain diseases.

Oligodendrocytes are glial cells that envelop neurons in the CNS, forming insulating myelin sheaths around them. Because myelin is an excellent electrical insulator, its presence speeds transmission of neural impulses. In the neurological disease **multiple sclerosis,** which affects about 400,000 people in North America alone, patches of myelin deteriorate at irregular intervals along axons in the CNS and are replaced by scar tissue. This damage interferes with conduction of neural impulses, and the victim suffers loss of coordination, tremor, and partial or complete paralysis of parts of the body. Recent evidence suggests that the oligodendrocytes self-destruct, but the reason is not yet known. Do not confuse oligodendrocytes with Schwann cells. Although sometimes considered glial cells, Schwann cells are located outside the CNS. Schwann cells form myelin sheaths around axons of many neurons outside the CNS.

Ependymal cells are ciliated glial cells that line the internal cavities of the CNS. Ependymal cells help produce the *cerebrospinal fluid* that bathes the brain and spinal cord of vertebrates (discussed in Chapter 41). Investigators have recently shown that ependymal cells can function as neural stem cells. They are apparently able to produce new neurons, as well as new glial cells.

Review

- What are the functions of (1) dendrites, (2) synaptic terminals, and (3) the myelin sheath?
- How is a neuron different from a nerve?
- What are the functions of astrocytes? Of microglia?

TRANSMITTING INFORMATION ALONG THE NEURON

Learning Objectives

4 Explain how the neuron develops and maintains a resting potential.
5 Compare a graded potential with an action potential, describing the production and transmission of each.
6 Contrast continuous conduction with saltatory conduction.

Most animal cells have a difference in electric charge across the plasma membrane—a more negative electric charge inside the cell than the electric charge of the extracellular fluid. The plasma membrane is said to be electrically **polarized,** meaning that one side, or pole, has a different charge from the other side. When electric charges are separated in this way, a potential energy difference exists across the membrane.

The difference in electric charge across the plasma membrane gives rise to an *electrical gradient.* Voltage is the force that causes charged particles to flow between two points. The voltage measured across the plasma membrane is called the **membrane potential.** If the charges are permitted to come together, they have the ability to do work. Thus, the cell can be thought of as a biological battery. In excitable cells, such as neurons and muscle cells, the membrane potential can change rapidly. Such changes can transmit signals to other cells.

The neuron membrane has a resting potential

The membrane potential in a resting (not excited) neuron or muscle cell is its **resting potential.** The resting potential is generally expressed in units called *millivolts* (mV). (A millivolt equals

one thousandth of a volt.) Like other cells that can produce electrical signals, the neuron has a resting potential of about 70 mV. By convention this is expressed as −70 mV because the cytosol close to the plasma membrane is negatively charged relative to the extracellular fluid (Fig. 40-4).

Biologists can measure the potential across the membrane by placing one electrode inside the cell and a second electrode outside the cell and connecting them through a very sensitive voltmeter or oscilloscope. If you place both electrodes on the outside surface of the neuron, no potential difference between them is registered. (All points on the same side of the membrane have the same charge.) However, once one of the electrodes penetrates the cell, the voltage changes from zero to approximately −70 mV.

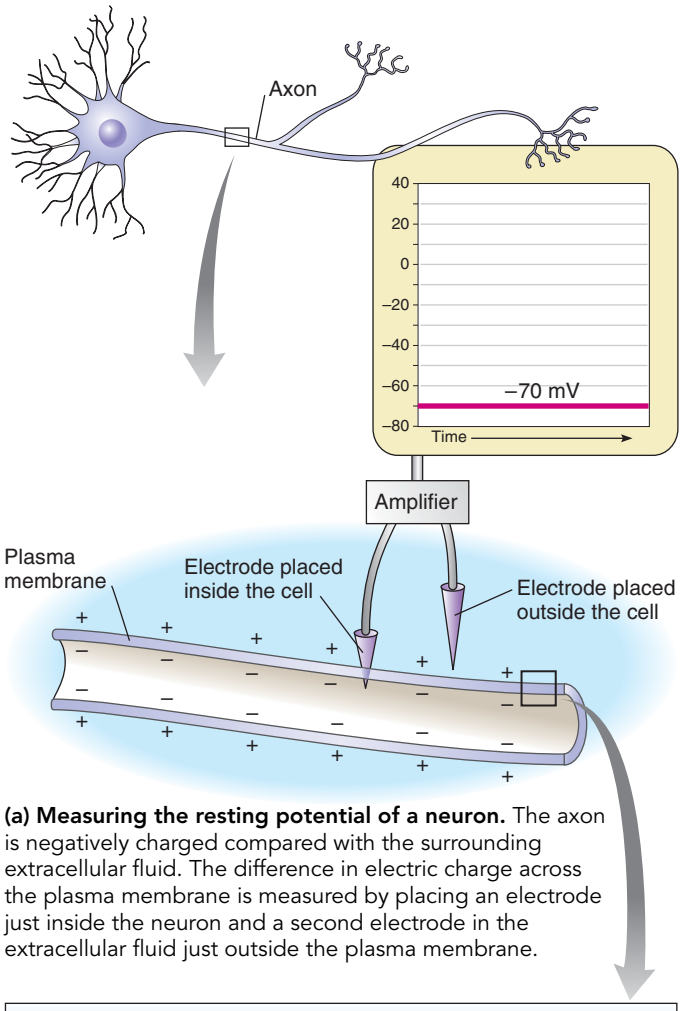
Two main factors determine the magnitude of the membrane potential: (1) differences in the concentrations between specific ions inside the cell and those in the extracellular fluid and (2) selective permeability of the plasma membrane to these ions. The distribution of ions inside neurons and in the extracellular fluid surrounding them is like that of most other cells in the body. The potassium ion (K^+) concentration is about 10 times as great inside as outside the cell. In contrast, the sodium ion (Na^+) concentration is about 10 times as great outside as inside. This asymmetric distribution of ions across the plasma membrane at rest is brought about by the action of selective ion channels and ion pumps. In vertebrate neurons (and skeletal muscle fibers), the resting membrane potential depends mainly on the diffusion of ions down their *concentration gradients.*

Ions cross the plasma membrane by diffusion through ion channels that are formed by membrane proteins. Net movement of ions occurs from an area of higher concentration of that ion to one of lower concentration (see discussion of diffusion in Chapter 5). Typically, these channels allow only specific types of ions to pass. Neurons have three types of ion channels: *passive ion channels, voltage-activated channels,* and *chemically activated ion channels.* **Passive ion channels** permit the passage of specific ions such as Na^+, K^+, Cl^-, and Ca^{2+} (see Fig. 40-4). Unlike voltage-activated and chemically activated ion channels, passive ion channels are not controlled by gates.

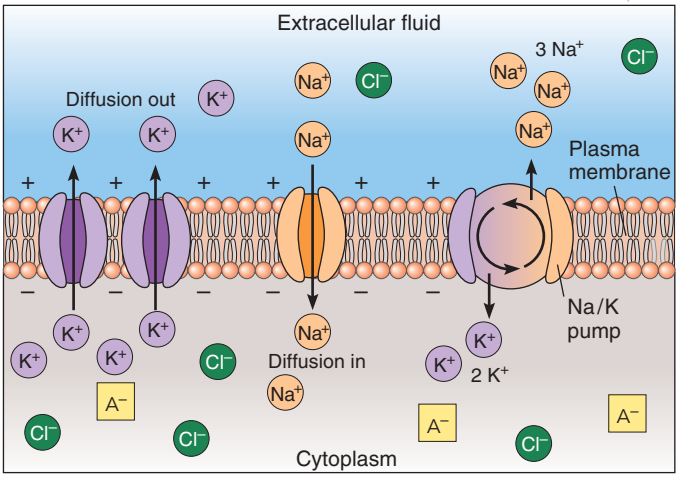
Potassium channels are the most common type of passive ion channel in the plasma membrane, and cells are more permeable to potassium than to other ions. In fact, in the resting neuron, the plasma membrane is up to 100 times as permeable to K^+ as to Na^+. Na^+ pumped out of the neuron cannot easily pass back into the cell, but K^+ pumped into the neuron easily diffuse out.

Potassium ions leak out through passive ion channels following their concentration gradient. As these positively charged ions diffuse out of the neuron, they increase the positive charge in the extracellular fluid outside the cell relative to the charge inside the cell. The resulting change in the electrical gradient across the membrane influences the flow of ions. This electrical gradient forces some of the positively charged potassium ions back into the cell.

The membrane potential at which the flux (flow) of K^+ inward (due to the electrical gradient) equals the flux of K^+ outward (because of the concentration gradient) is the **equilibrium potential** for K^+. The equilibrium potential for any particular



(a) Measuring the resting potential of a neuron. The axon is negatively charged compared with the surrounding extracellular fluid. The difference in electric charge across the plasma membrane is measured by placing an electrode just inside the neuron and a second electrode in the extracellular fluid just outside the plasma membrane.



(b) Permeability of the neuron membrane. The membrane is less permeable to Na^+ than to K^+. K^+ diffuse out along their concentration gradient and are largely responsible for the voltage across the membrane. Sodium–potassium pumps in the plasma membrane actively pump Na^+ out of the cell and pump K^+ in. The plasma membrane is permeable to negatively charged Cl^-, and they contribute slightly to the negative charge. Large anions (A^-) such as proteins also contribute to the negative charge.

Figure 40-4 Resting potential

ion is a steady state in which opposing chemical and electrical fluxes are equal and there is no net movement of the ion. The equilibrium potential for K^+ in the typical neuron is −80 mV. The equilibrium potential for Na^+ is −40 mV; it differs from the equilibrium potential of K^+ because of the difference in concentration of Na^+ across the membrane (concentration is high outside and low inside the cell). Because the membrane is much more permeable to K^+ than to Na^+, the resting potential of the neuron is closer to the potassium equilibrium potential than to the sodium equilibrium potential. (Remember that the resting potential of the neuron is about −70 mV.)

Although the resting potential is primarily established by K^+, and less so by Na^+, Cl^- also contribute slightly because the plasma membrane is permeable to negatively charged chloride ions. These ions accumulate in the cytosol close to the plasma membrane. Negative charges on large molecules such as proteins also contribute to the negative charge in the cytosol. These large anions cannot cross the plasma membrane.

Ion pumping maintains the gradients that determine the resting potential. The neuron plasma membrane has very efficient **sodium–potassium pumps** that actively transport Na^+ out of the cell and K^+ into the cell (see Fig. 5-17). Both sodium and potassium ions are pumped against their concentration and electrical gradients, and these pumps require ATP. For every three Na^+ pumped out of the cell, two K^+ are pumped in. Thus, more positive ions are pumped out than in. The sodium–potassium pumps maintain a higher concentration of K^+ inside the cell than outside, and a higher concentration of Na^+ outside than inside.

In summary, the development of the resting potential depends mainly on the diffusion of K^+ out of the cell. However, once the neuron reaches a steady state, Na^+ diffusion into the cell is greater than K^+ diffusion out of the cell. This situation is offset by the sodium–potassium pumps that pump three Na^+ out of the cell for every two K^+ pumped in.

Graded local signals vary in magnitude

Neurons are excitable cells. They can respond to stimuli and convert stimuli into nerve impulses. An electrical, chemical, or mechanical stimulus may alter the resting potential by increasing the membrane's permeability to sodium ions.

When a stimulus causes the membrane potential to become less negative (closer to zero) than the resting potential, that region of the membrane is **depolarized.** Because depolarization brings a neuron closer to transmitting a neural impulse, it is described as *excitatory.* In contrast, when the membrane potential becomes more negative than the resting potential, the membrane is **hyperpolarized.** Hyperpolarization is *inhibitory;* it decreases the ability of the neuron to generate a neural impulse.

A stimulus may change the potential in a relatively small region of the plasma membrane. Such a **graded potential** is a local response that functions as a signal only over a very short distance, because it fades out within a few millimeters of its point of origin. A graded potential varies in magnitude; that is, the potential charge varies depending on the strength of the stimulus applied. The larger the stimulus is, the larger the change in permeability and the greater the change in membrane potential.

An action potential is generated by an influx of Na^+ and an efflux of K^+

When a stimulus is strong enough, a rapid, large change in membrane potential occurs, depolarizing the membrane to a critical point known as the **threshold level.** At that point, the neuron fires a nerve impulse, or **action potential,** an electrical signal that travels rapidly down the axon into the synaptic terminals. All cells can generate graded potentials, but only neurons, muscle cells, and a few other cell types (certain cells of the endocrine and immune systems) can generate action potentials.

In a series of experiments in the 1940s, pioneering English researchers Alan Hodgkin and Andrew Huxley inserted electrodes into large axons found in squids. By measuring voltage changes as they varied ion concentrations, they showed that passage of Na^+ ions into the neuron and K^+ ions out of the neuron resulted in an action potential. In 1963, Hodgkin and Huxley received the Nobel Prize in Physiology or Medicine for this research.

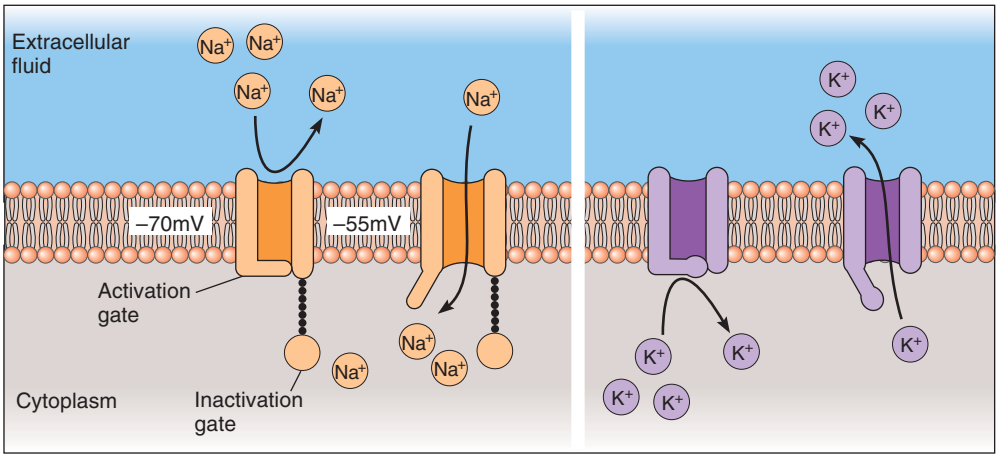
We now know that changes in voltage regulate specific **voltage-activated ion channels** (also called **voltage-gated ion channels**) in the plasma membrane of the axon and cell body. Biologists can study these channels by using the *patch clamp technique* to measure currents across a very small segment of the plasma membrane rather than across the entire membrane. The patch of membrane measured is so small that it may contain a single channel.

Biologists have used certain toxins that affect the nervous system to investigate how membrane channels function. For example, the poison tetrodotoxin (TTX) binds to voltage-activated Na^+ channels, blocking the passage of Na^+. Using TTX and other toxins, researchers were able to identify the channel protein. TTX was first isolated from the Japanese puffer fish, which is eaten as a delicacy (Fig. 40-5). In small amounts TTX tingles the taste buds, but in a larger dose it can prevent breathing. (The Japa-

Jeffrey L. Rotman /Peter Arnold, Inc.

Figure 40-5 Japanese puffer fish

A poison, tetrodotoxin, isolated from this fish (*Fugu rubripes*) binds to voltage-activated sodium ion channels, allowing neurobiologists to study them.



(a) Sodium channels. In the resting state, voltage-activated Na^+ channels are closed (left). When the voltage reaches threshold level, activation gates open quickly, allowing Na^+ to pass into the cell (right). After a certain time, inactivation gates close, blocking the channels. Inactivation gates are open when a neuron is in the resting state; they close slowly in response to depolarization. The ion channel is open only during the brief period when both activation and inactivation gates are open.

(b) Potassium channels. Voltage-activated K^+ channels have activation gates that open slowly in response to depolarization. These channels have no inactivation gates.

Figure 40-6 ***Animated*** Voltage-activated ion channels

nese government operates a certification program for puffer fish chefs!)

Investigators have established that voltage-activated ion channels have charged regions that act as gates. Voltage-activated Na^+ channels have two gates—an *activation gate* and an *inactivation gate* (Fig. 40-6a). Voltage-activated K^+ channels have a single gate (Fig. 40-6b).

Local anesthetics such as procaine (novocaine) and lidocaine (Xylocaine), as well as cocaine, bind to voltage-activated Na^+ channels and block them. The channels cannot open in response to depolarization, and the neuron cannot transmit an impulse through the anesthetized region. Signals do not reach the brain, so pain is not experienced.

An action potential is generated when the voltage reaches threshold level. The membrane of most neurons can depolarize by about 15 mV, that is, to a potential of about −55 mV, without initiating an action potential. However, when depolarization is greater than −55 mV, the threshold level is reached and an action potential is generated. The neuron membrane quickly reaches zero potential and even **overshoots** to +35 mV or more as a momentary reversal in polarity takes place. The sharp rise and fall of the action potential is called a *spike*. Figure 40-7a illustrates an action potential recorded by placing one electrode inside an axon and one just outside.

At resting potentials, Na^+ activation gates are closed and Na^+ cannot pass into the neuron (Fig. 40-7b 1). When the voltage reaches the threshold level, the channel protein changes shape, opening the activation gate (Fig. 40-7b 2). Sodium ions can then flow through the channel, and the inside of the neuron becomes positively charged relative to the fluid outside the plasma membrane; an action potential may be generated. Inactivation gates that are open in the resting neuron close slowly in response to depolarization. Sodium ions can pass through the channel only during the brief period when both activation and inactivation gates are open.

The generation of an action potential depends on a **positive feedback system.** (Recall from Chapter 38 that in a positive feedback system, a change in some condition triggers a response that *intensifies* the change.) As just discussed, when a neuron is depolarized, voltage-activated Na^+ channels open, increasing the membrane permeability to Na^+. Sodium ions diffuse into the cell and move from an area of higher concentration to an area of lower concentration. As Na^+ flow into the cell, the cytosol becomes positively charged relative to the extracellular fluid. This charge further depolarizes the neuron so that more voltage-activated Na^+ channels open, which increases membrane permeability to Na^+.

After a certain period, inactivation sodium gates close, and the membrane again becomes impermeable to sodium. This inactivation begins the process of **repolarization,** during which the membrane potential returns to its resting level. Voltage-gated K^+ channels slowly open in response to depolarization. When K^+ channels open, K^+ leak out of the neuron (Fig. 40-7b 3). This decrease in intracellular K^+ returns the interior of the membrane to its relatively negative state, repolarizing the membrane. Voltage-activated K^+ channels remain open until the resting potential has been restored (Fig. 40-7b 4). As a wave of depolarization moves down the membrane of the neuron, the normal polarized state is quickly re-established behind it. The entire process—depolarization and then repolarization—can take place in less than 1 millisecond.

During the millisecond or so in which it is depolarized, the axon membrane is in an **absolute refractory period:** it cannot transmit another action potential no matter how great a stimulus is applied, because the voltage-activated Na^+ channels are inactivated. Until their gates are reset, they cannot be reopened. When enough Na^+ channel gates have been reset, the neuron enters a **relative refractory period** that lasts for a few more milliseconds. During this period, the axon can transmit impulses, but the threshold is higher (less negative). Even with the limits imposed by their refractory periods, most neurons can transmit several hundred impulses per second.

In summary, neural action proceeds as follows:

Resting state ⟶ stimulus causes depolarization ⟶ threshold reached ⟶ action potential ⟶ repolarization and return to resting state

The action potential is an all-or-none response

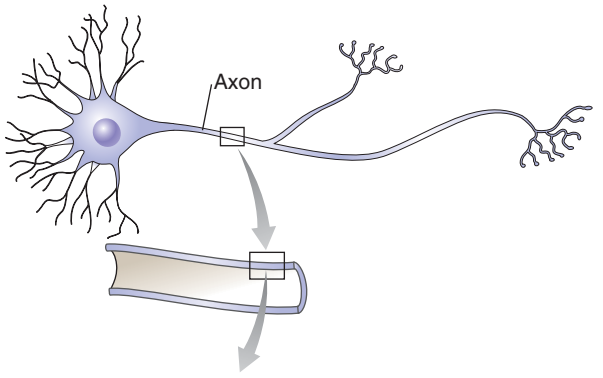
Any stimulus too weak to depolarize the plasma membrane to threshold level cannot fire the neuron. It merely sets up a local signal that fades and dies within a few millimeters from the point of stimulus. Only a stimulus strong enough to depolarize the membrane to its critical threshold level results in transmission of an impulse along the axon. An action potential is an **all-or-none response,** because either it occurs or it does not. No variation exists in the strength of a single impulse.

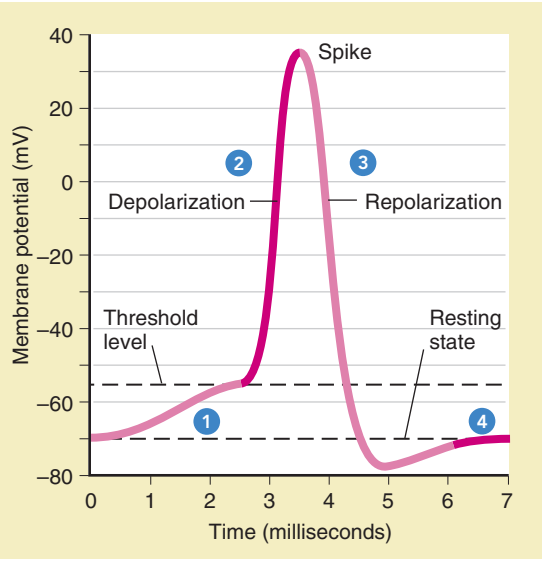
If the all-or-none law is valid, how can we explain differences in the levels of intensity of sensations? After all, we have no difficulty distinguishing between the pain of a severe toothache and that of a minor cut on the arm. We can explain this apparent inconsistency by the fact that intensity of sensation depends on the *number of neurons stimulated and on their frequency of discharge.* For example, suppose you burn your hand. If a large area is burned, more pain receptors are stimulated and more neurons become depolarized. Also, each neuron transmits more action potentials per unit of time.

An action potential is self-propagating

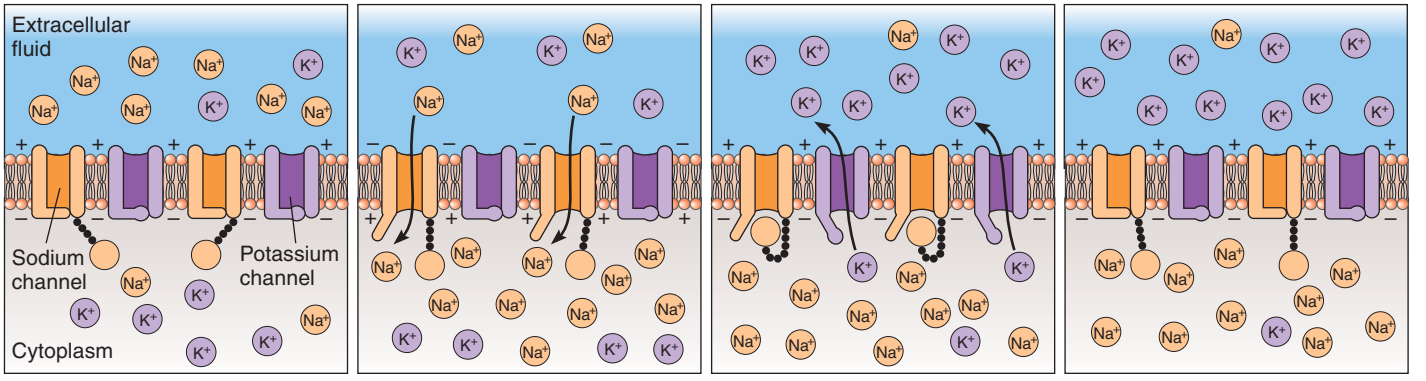
Once begun, an action potential is self-propagating. During depolarization, the affected area of the membrane is more positive relative to adjacent regions where the membrane is still at resting potential. The difference in potentials between active and resting membrane regions causes ions to flow between them (an electric current). The flow of Na^+ into the adjacent region induces the opening of voltage-activated Na^+ channels in one area of the

Figure 40-7 ***Animated*** State of voltage-activated ion channels during an action potential





(a) Action potential. When the axon depolarizes to about −55 mV, an action potential is generated. (The numerical values vary for different nerve cells.)



1 Resting state. Voltage-activated Na^+ and K^+ channels are closed.

2 Depolarization. At threshold, voltage-activated Na^+ channels open. Na^+ entering the neuron cause further depolarization. Action potential is generated.

3 Repolarization. Voltage-activated Na^+ channels close; voltage-activated K^+ channels are open; K^+ diffuse out of cell, restoring negative charge to inside of cell.

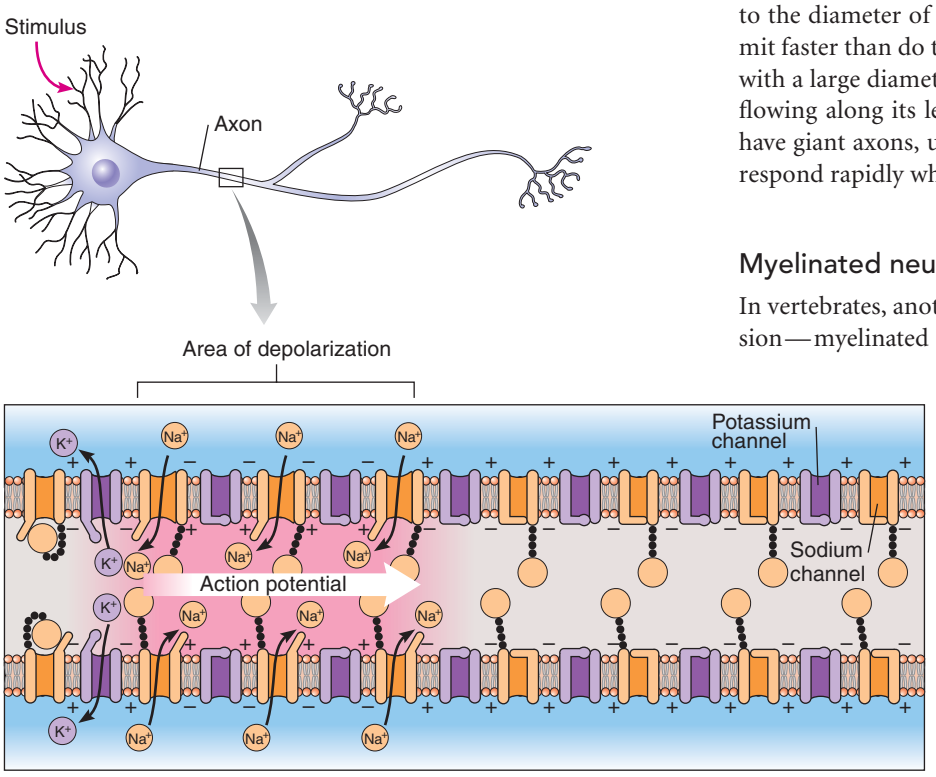
4 Return to resting state. Voltage-activated Na^+ and K^+ channels close.

(b) The action of ion channels in the plasma membrane determines the state of the neuron.

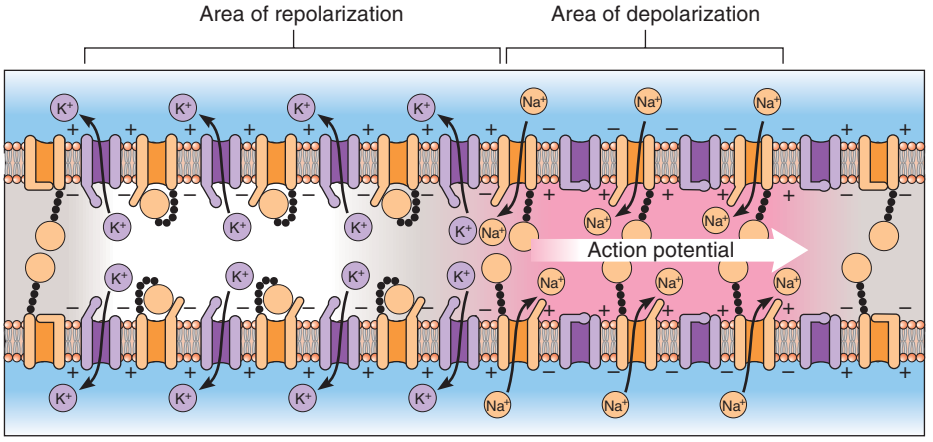
membrane (Fig. 40-8). This action causes the next adjacent voltage-activated ion channels to open, permitting Na^+ to enter in that area, and the process is repeated like a chain reaction until the end of the axon is reached. Thus, an action potential is a **wave of depolarization** that travels down the length of the axon.

An action potential is self-propagating and moves at a velocity that is constant for each type of neuron. Conduction of a neural impulse is sometimes compared with burning a trail of gunpowder. Once the gunpowder is ignited at one end of the trail, the flame moves steadily to the other end by igniting the powder particles ahead of it.

Compared with the flow of electrons in electrical wiring or the speed of light, a nerve impulse travels rather slowly. Most axons transmit impulses at about 1 to 10 m per second. The smooth, progressive impulse transmission just described, called **continuous conduction,** occurs in unmyelinated neurons. In unmyelinated axons, the speed of transmission is proportional to the diameter of the axon. Axons with larger diameters transmit faster than do those with smaller diameters, because an axon with a large diameter presents less internal resistance to the ions flowing along its length. Squids and certain other invertebrates have giant axons, up to 1 mm in diameter, which allow them to respond rapidly when escaping from predators.



1 Action potential is transmitted as wave of depolarization that travels down axon. At region of depolarization, Na^+ diffuse into cell.



2 As action potential progresses along axon, repolarization occurs quickly behind it.

Figure 40-8 Transmission of an action potential along the axon

When the dendrites (or cell body) of a neuron are stimulated sufficiently to depolarize the membrane to its threshold level, an action potential is generated.

Myelinated neurons transmit impulses rapidly

In vertebrates, another strategy has evolved that speeds transmission—myelinated neurons. Myelin acts as an effective electrical insulator around the axon except at the nodes of Ranvier, which are not myelinated. The axon plasma membrane makes direct contact with the surrounding extracellular fluid only at the nodes, and voltage-activated Na^+ and K^+ channels are concentrated there. Ion movement across the membrane occurs only at the nodes. The ion activity at the active node results in diffusion of ions along the axon that depolarize the next node; the action potential appears to jump from one node of Ranvier to the next (Fig. 40-9). This type of impulse transmission is known as **saltatory conduction** (from the Latin word *saltus,* which means "to leap").

In myelinated neurons, the distance between successive nodes of Ranvier affects speed of transmission. When nodes are farther apart, less of the axon must depolarize and the axon conducts the impulse faster. Using saltatory conduction, a myelinated axon can conduct an impulse up to 50 times as fast as the fastest unmyelinated axon. Saltatory conduction has another advantage over continuous conduction: it requires less energy. Ions move across the plasma membrane only at the nodes, so fewer Na^+ and K^+ are displaced. As a result, the sodium–potassium pumps do not expend as much ATP to re-establish resting conditions each time an impulse is conducted.

Review

- How do ion channels and sodium–potassium pumps contribute to the resting potential?

Key Point

In saltatory conduction, Na^+ rapidly diffuse from one node of Ranvier to the next in a myelinated neuron. Action potentials appear to leap from node to node.

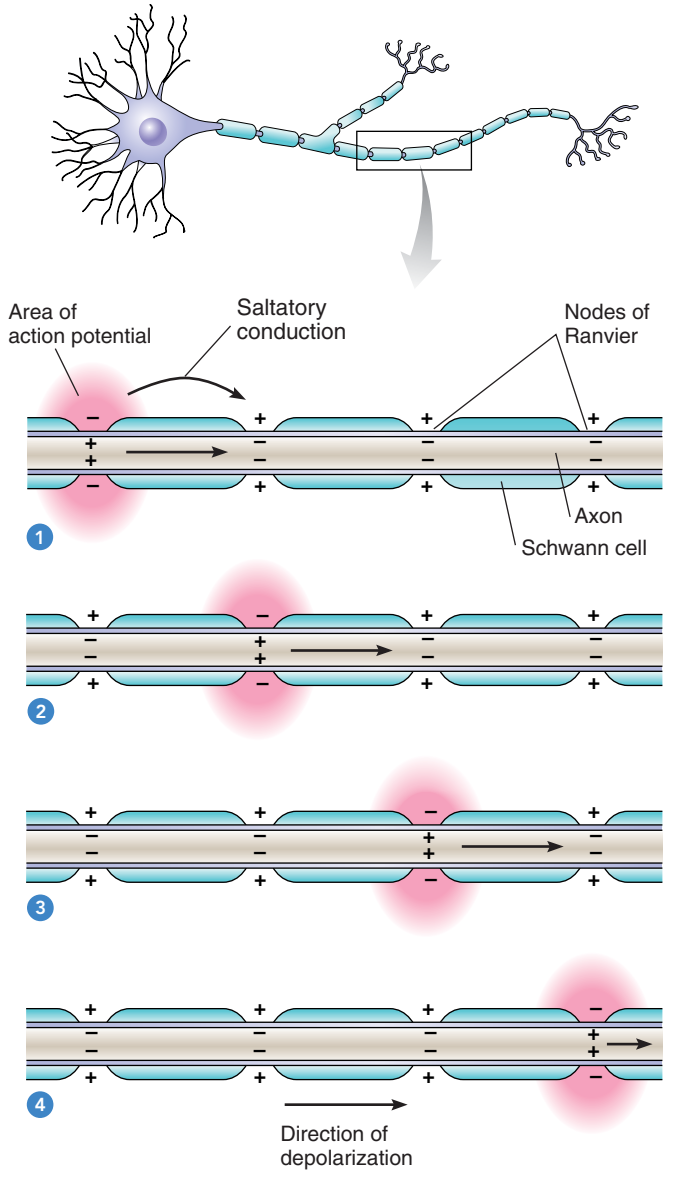


Figure 40-9 ***Animated*** Saltatory conduction

This sequence of diagrams (steps 1 through 4) illustrates transmission of an action potential in a myelinated neuron.

- What sequence of events occurs when threshold level is exceeded in a neuron?
- How do voltage-activated ion channels work?
- How does an action potential differ from a graded potential?
- What are the benefits of saltatory conduction compared with continuous conduction?

NEURAL SIGNALING ACROSS SYNAPSES

Learning Objectives

7 Describe the actions of the neurotransmitters identified in the chapter.

8 Trace the events that take place in synaptic transmission, and draw diagrams to support your description.

9 Compare excitatory and inhibitory signals and their effects.

A **synapse** is a junction between two neurons or between a neuron and an effector, such as between a neuron and a muscle cell. A neuron that *terminates* at a specific synapse is called a **presynaptic neuron,** whereas a neuron that *begins* at that synapse is a **postsynaptic neuron.** Note that these terms are relative to a specific synapse. A neuron that is postsynaptic with respect to one synapse may be presynaptic to the next synapse in the sequence.

Signals across synapses can be electrical or chemical

Based on how presynaptic and postsynaptic neurons communicate, two types of synapses have been identified: electrical synapses and chemical synapses. In **electrical synapses,** the presynaptic and postsynaptic neurons occur very close together (within 2 nm of one another) and form *gap junctions* (see Chapter 5). The interiors of the two cells are physically connected by a protein channel. Electrical synapses let ions pass from one cell to another, permitting an impulse to be directly and rapidly transmitted from a presynaptic to a postsynaptic neuron. The escape responses of many animals involve electrical synapses. For example, the "tail-flick" escape response of the crayfish involves giant neurons in the nerve cord that form electrical synapses with large motor neurons. The motor neurons signal muscles in the abdomen to contract. Electrical synapses are important in the mammalian nervous system as well. For example, many interneurons communicate by way of electrical synapses.

The majority of synapses are **chemical synapses.** Presynaptic and postsynaptic neurons are separated by a space, the **synaptic cleft,** about 20 nm wide (less than one millionth of an inch). Because depolarization is a property of the plasma membrane, when an action potential reaches the end of the axon, it cannot jump the gap. The electrical signal must be converted into a chemical one. Neurotransmitters are the chemical messengers that conduct the neural signal across the synapse and bind to chemically activated ion channels in the membrane of the postsynaptic neuron. This binding triggers specific gated ion channels to open (or close), resulting in changes in permeability of the postsynaptic membrane. When a postsynaptic neuron reaches threshold depolarization, it transmits an action potential.

Neurons use neurotransmitters to signal other cells

Many chemical compounds are now known or suspected to function as neurotransmitters, chemical messengers used by neurons

TABLE 40-2

Selected Neurotransmitters

Neurotransmitter	Structure	Site of Action	Action
Acetylcholine		CNS, neuromuscular junctions	Excitatory effect on skeletal muscle; inhibitory effect on cardiac muscle; excitatory or inhibitory at other sites
Biogenic Amines			
Norepinephrine		CNS, PNS	Excitatory or inhibitory; concentration in brain affects mood
Dopamine		CNS	Helps maintain balance between excitation and inhibition of neurons; important in motor functions; concentration in brain affects mood
Serotonin (5-hydroxytryptamine, 5-HT)		CNS	Excitatory effect on pathways that control muscle action; inhibitory effect on sensory pathways; helps regulate food intake; affects mood
Amino Acids			
Glutamate		CNS, invertebrate neuromuscular junctions	Major excitatory neurotransmitter in vertebrate brain; functions in learning and memory; excitatory effect at invertebrate neuromuscular junctions
Aspartate		CNS	Excitatory; functions in learning and memory
Glycine		CNS	Inhibitory
Gamma-aminobutyric acid (GABA)		CNS, invertebrate neuromuscular junctions	Inhibitory
Neuropeptides			
Endorphins and enkephalins	Tyr—Gly—Gly—Phe—Met (Methionine enkephalin)	CNS, PNS	Endogenous opiates; bind with opiate receptors on afferent fibers that transmit pain signals; inhibit release of substance P
Substance P	Arg—Pro—Lys—Pro—Gln—Gln—Phe—Phe—Gly—Leu—Met	CNS, PNS	Activates ascending pathways that transmit pain signals
Gaseous Neurotransmitters			
Nitric oxide	NO	Most neurons?	Retrograde messenger; transmits signals from postsynaptic to presynaptic neuron
Carbon monoxide	CO	Most neurons?	May be neuromodulator

to signal other neurons or to signal muscle or gland cells. We can categorize neurotransmitters into several chemical groups, including acetylcholine, biogenic amines, amino acids, neuropeptides, and gaseous neurotransmitters (▮ Table 40-2).

Acetylcholine is a low-molecular-weight neurotransmitter that is released from motor neurons and triggers muscle contraction. Acetylcholine is also released by some neurons in the brain and in the autonomic nervous system (see *Focus On: Alzheimer's Disease;* also see Chapter 41). Cells that release acetylcholine are called **cholinergic neurons.**

Neurons that release **norepinephrine** are called **adrenergic neurons.** Norepinephrine and the neurotransmitter **dopamine**

focus on

ALZHEIMER'S DISEASE

In **Alzheimer's disease (AD),** a progressive, degenerative brain disorder, neural signaling is disrupted and neurons are damaged and die prematurely. Alzheimer's disease is the leading cause of senile dementia, the loss of memory, judgment, and ability to reason that is sometimes associated with aging. This disease afflicts more than 4 million people in the United States alone.

The development of AD may be a lifelong process. One startling study demonstrated that a person's writing early in life can predict the disease. Young adults whose writings had a lower density of ideas were more likely to develop the disease. One approach to detecting development of AD is the use of positron emission tomography (PET) scans to study glucose uptake in the brain. Low glucose uptake in certain areas of the brain suggests that neurons in these areas may be damaged.

In AD, neurons are damaged in certain parts of the brain, including the cerebral cortex and hippocampus, areas that are important in thinking and remembering. Neurons that secrete the neurotransmitter acetylcholine are especially affected. Investigators have demonstrated that two of the abnormalities that develop in brain tissue as we age, *amyloid plaques* and *neurofibrillary tangles,* are especially characteristic of AD. Understanding the biochemistry and genetic basis of both plaques and tangles may provide clues to the causes and cures of AD.

Amyloid plaques were first identified in autopsied brains in 1906 by the German physician Alois Alzheimer. These plaques are extracellular deposits of a peptide called β-amyloid. Neurons near these plaques appear swollen and misshapen. Microglia are typically present, suggesting an attempt to remove the damaged cells or the plaques themselves.

Researchers have found that β-amyloid is cut from a protein called β-amyloid precursor protein, or β-APP, a large transmembrane protein coded by a gene on chromosome 21. Normal β-amyloid molecules have 40 amino acids. However, about 10% of the peptides produced have 2 additional amino acids. This longer peptide appears to form the plaques. Investigators have identified mutations in specific genes that result in the production of abnormal β-amyloid.

Just how the longer β-amyloid leads to AD is not known. The abnormal peptide appears to disrupt calcium regulation, killing neurons in the brain. The peptide may also damage mitochondria, releasing harmful free radicals. AD appears to begin with subtle changes in synaptic function in the hippocampus, a region of the brain important in memory. An early symptom is the loss of the ability to encode new memories. The loss of synaptic function may be caused by abnormal β-amyloid.

Neurofibrillary tangles, which form in the neuron cytoplasm, are another piece of the AD puzzle. The cytoskeletal protein tau normally associates with the protein tubulin, which forms microtubules. Mutations in the *tau* gene may interfere with the way the tau protein binds to microtubules, resulting in abnormal microtubules that cannot effectively transport materials through axons. Abnormal tau proteins accumulate in the cytoplasm, forming fibrous deposits that make up the neurofibrillary tangles. These tangles interfere with neural signaling.

Mechanisms that cause amyloid plaques and neurofibrillary tangles are connected. Using transgenic mice, researchers have demonstrated that β-amyloid deposits in the brain are responsible for the formation of neurofibrillary tangles in areas of the brain known to be affected in Alzheimer's disease.

Several drugs designed to slow the progress of Alzheimer's disease are in clinical trials. One of the challenges of developing a drug has been getting the medication through the blood–brain barrier. Two approaches to developing a treatment for AD are blocking formation of β-amyloid and dissolving the abnormal β-amyloid deposits that are already present.

A promising strategy is to stimulate the immune system to destroy β-amyloid deposits. When genetically engineered mice are immunized with a vaccine made of β-amyloid, the mice develop antibodies against the protein and destroy the β-amyloid plaques. This vaccine also reduces memory loss and enhances learning in aging mice. Vaccinated mice develop fewer plaques and perform significantly better on memory tests. Unfortunately, human clinical trials were abruptly halted when about 5% of the patients developed a dangerous brain inflammation. Studies are currently underway to develop a safer vaccine.

The neurotransmitter glutamate builds up to toxic levels in the brains of AD patients. The drug memantine, which blocks the action of glutamate, is being tested as a possible treatment for AD. Memantine slows cognitive decline but does not prevent the eventual damage that occurs in the brain. Another approach may be to increase the activity of the glutamate transporter in astrocytes. This pump clears glutamate from the synaptic cleft. Anti-inflammatory drugs and antioxidants (such as vitamin C or E) are also being tested as strategies that may prevent or slow the development of AD.

are **catecholamines.** The catecholamines and the neurotransmitter **serotonin** belong to a class of compounds called **biogenic amines.** Biogenic amines affect mood, and their imbalance has been linked to several disorders, including major depression, attention deficit disorder (ADD), and schizophrenia.

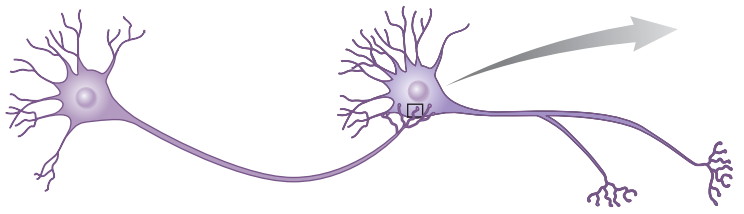
Several amino acids function as neurotransmitters. **Glutamate** is the major excitatory neurotransmitter in the brain. One type of glutamate receptor is the target of several mind-altering drugs, including phencyclidine ("angel dust").

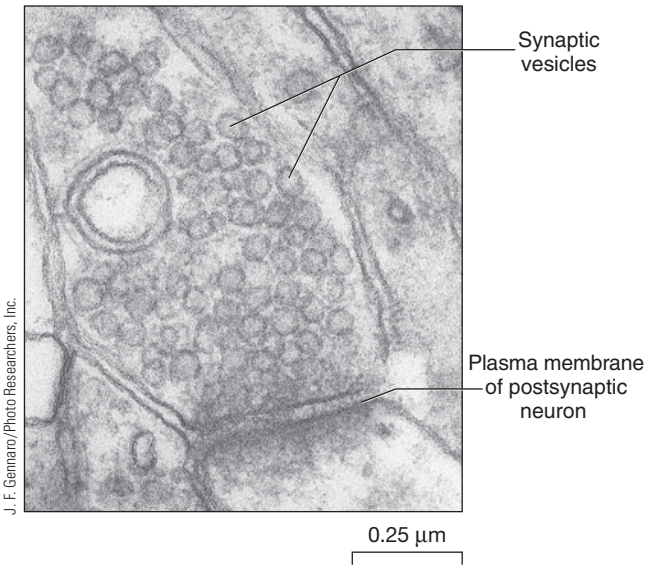
The amino acid **glycine** and a modified amino acid, **gamma-aminobutyric acid (GABA),** are neurotransmitters that inhibit neurons in the brain and spinal cord. Drugs that reduce anxiety enhance the actions of GABA by permitting lower concentrations of GABA to open Cl^- channels. These drugs include benzodiazepines, such as diazepam (Valium) and alprazolam (Xanax), and barbiturates, such as phenobarbital.

Neuropeptides, such as endorphins and enkephalins, appear to function mainly as **neuromodulators,** messenger molecules

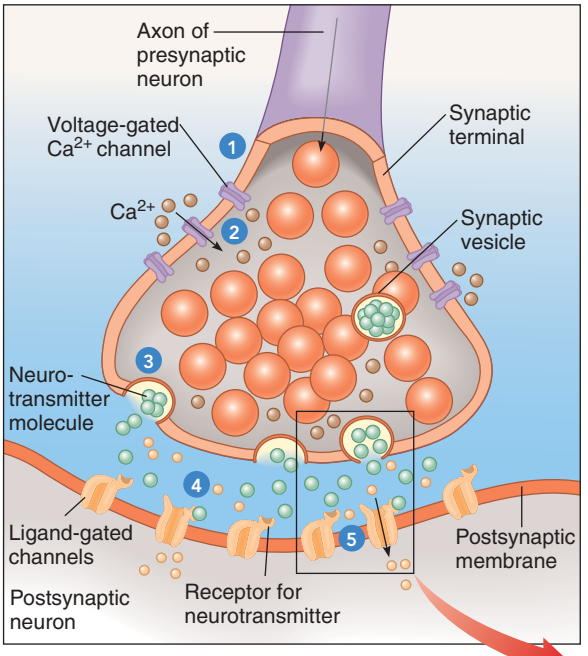
Key Point

At most synapses the action potential cannot jump across the synaptic cleft between the two neurons. The problem is solved by chemical signaling across synapses.



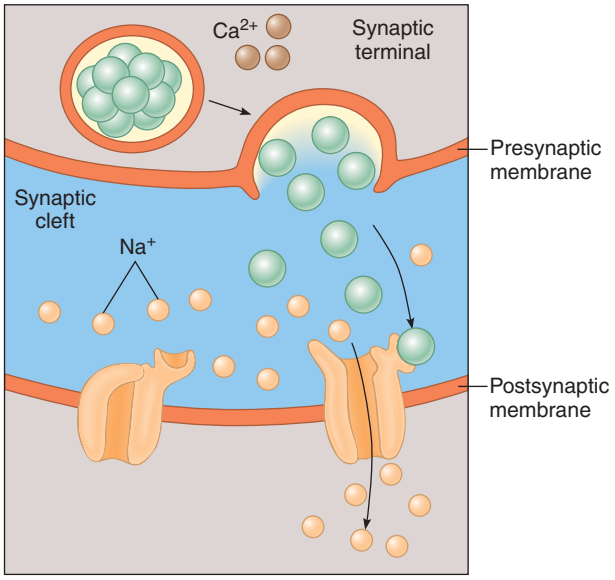


(a) The TEM shows synaptic terminals filled with synaptic vesicles.



(b) How a neural impulse is transmitted across a synapse.

1. Action potential reaches synaptic terminals at end of presynaptic neuron.
2. Calcium channels open in membrane, letting Ca^{2+} from extracellular fluid enter the synaptic terminal.
3. Ca^{2+} cause synaptic vesicles to fuse with plasma membrane and release neuro-transmitter into synaptic cleft.
4. Neurotransmitter binds with receptors on membrane of postsynaptic neuron.
5. In response, specific ion channels open or close, resulting in either depolarization or hyperpolarization. When depolarization reaches threshold level, action potential is generated in postsynaptic neuron.



(c) Neurotransmitter binds with receptor. Ligand-gated channel opens, resulting in depolarization.

Figure 40-10 ***Animated*** Synaptic transmission

that stimulate long-term changes that enhance or inhibit synaptic function. Some neurobiologists consider them a group of neurotransmitters, but others classify them as a separate group. **Endorphins,** such as **beta-endorphin,** and **enkephalins** are the body's own endogenous opioids. Opiate drugs, for example, morphine and codeine, are powerful analgesics, drugs that relieve pain without causing loss of consciousness. Endorphins and enkephalins bind to opioid receptors (the same receptors to which opiate drugs bind) and block pain signals. Opioids modulate the effect of other neurotransmitters, including **substance P,** which activates the pathways that transmit pain signals. (We discuss pain perception in Chapter 42.)

Much recent research has focused on the signaling molecule **nitric oxide (NO).** NO is a gas that acts as a *retrograde messenger* at some synapses. It transmits information from the postsynaptic neuron to the presynaptic neuron, the opposite direction of transmissions from other neurotransmitters. Carbon monoxide has also been identified as a gaseous neurotransmitter that may function as a neuromodulator.

Neurotransmitters bind with receptors on postsynaptic cells

Neurotransmitters are stored in the synaptic terminals within small membrane-enclosed sacs called **synaptic vesicles** (Fig. 40-10a). Each time an action potential reaches a synaptic terminal, voltage-gated Ca^{2+} channels open. Calcium ions from the extracellular fluid then flow into the synaptic terminal. The Ca^{2+} induce synaptic vesicles to fuse with the presynaptic membrane and release neurotransmitter molecules into the synaptic cleft by exocytosis (Fig. 40-10b).

Neurotransmitter molecules diffuse across the synaptic cleft and bind with specific receptors on the dendrites or cell bodies of postsynaptic neurons (or on the plasma membranes of effector cells). Many neurotransmitter receptors are chemically activated ion channels known as **ligand-gated ion channels.** When the neurotransmitter, the **ligand,** binds with the receptor, the ion channel opens. The acetylcholine receptor, for example, is a ligand-gated ion channel that permits the passage of Na^+ and K^+.

Some neurotransmitters, such as serotonin, operate by a different mechanism. They work indirectly through a **second messenger.** Binding of the neurotransmitter with a receptor activates a **G protein.** The G protein then activates an enzyme, such as adenylyl cyclase, in the postsynaptic membrane. Adenylyl cyclase converts ATP to **cyclic AMP (cAMP),** which acts as a second messenger (see Chapters 6 and 48). Cyclic AMP activates a kinase that phosphorylates a protein, which then closes K^+ channels.

For a postsynaptic neuron to repolarize quickly, any excess neurotransmitter in the synaptic cleft must be removed. Some neurotransmitters are inactivated by enzymes. For example, excess acetylcholine is degraded into its chemical components, choline and acetate, by the enzyme acetylcholinesterase. Other neurotransmitters, such as the biogenic amines, are actively transported back into the synaptic terminals, a process known as **reuptake.** These neurotransmitters are repackaged in vesicles and recycled.

Many drugs inhibit the reuptake of neurotransmitters. For example, some antidepressants are selective serotonin reuptake inhibitors (SSRIs). SSRIs such as fluoxetine (Prozac) selectively inhibit the reuptake of serotonin in the brain. This action concentrates serotonin in the synaptic cleft, elevating mood. Some antidepressants (and cocaine) also inhibit the reuptake of dopamine.

Activated receptors can send excitatory or inhibitory signals

A postsynaptic neuron may have receptors for several types of neurotransmitters. Some of its receptors may be excitatory, and others may be inhibitory. Depending on the type of postsynaptic receptor with which it combines, the same neurotransmitter can have different effects. For example, acetylcholine has an excitatory effect on skeletal muscle and an inhibitory effect on cardiac muscle.

When neurotransmitter molecules bind to receptors, the activated receptor can directly or indirectly open or close ion channels; this action changes the permeability of the postsynaptic membrane to certain ions. The resulting redistribution of ions changes the electrical potential of the membrane, and the membrane may depolarize. For example, when neurotransmitter molecules combine with receptors that open Na^+ channels, the resulting influx of Na^+ partially depolarizes the membrane. If sufficiently intense, a local depolarization can set off an action potential.

A change in membrane potential that brings the neuron closer to firing is called an **excitatory postsynaptic potential (EPSP).** Imagine that sufficient sodium ions enter to change the membrane potential from −70 mV to −60 mV. The membrane would be only −5 mV away from threshold. Under such conditions, an additional relatively weak stimulus, causing a small influx of Na^+, can cause the neuron to fire. Note that unlike action potentials, postsynaptic potentials are graded responses.

Some neurotransmitter–receptor combinations hyperpolarize the postsynaptic membrane. The membrane potential becomes more negative. Because such an action takes the neuron farther away from the firing level, a potential change in this direction is called an **inhibitory postsynaptic potential (IPSP).** For example, if the membrane potential changes from −70 mV to −80 mV, the membrane is farther away from threshold and a stronger stimulus is required to fire the neuron.

Like an EPSP, an IPSP can be produced in several ways. Two types of GABA receptors are known to produce IPSPs. When GABA binds to a $GABA_B$ receptor, K^+ channels open. As K^+ diffuses out, the neuron becomes more negative, hyperpolarizing the membrane. Activated $GABA_A$ receptors produce IPSPs by opening Cl^- channels. In this case, the influx of negative ions hyperpolarizes the membrane. Although the mechanisms are different, the inhibiting effect of GABA is the same in both cases.

In summary, when an action potential reaches the synaptic terminals at the end of a presynaptic neuron, the following sequence of events takes place:

Calcium ions enter synaptic terminal ⟶ synaptic vesicles release neurotransmitter into the synaptic cleft ⟶ neurotransmitter diffuses across synaptic cleft and combines with receptors in membrane of the postsynaptic neuron ⟶ ion channels open or close ⟶ depolarization or hyperpolarization of postsynaptic membrane

Review

- What are some functions of biogenic amines? Of glutamate?
- What events take place at a chemical synapse?
- How are EPSPs produced? IPSPs?

NEURAL INTEGRATION

Learning Objective

10 Define neural integration, and describe how a postsynaptic neuron integrates incoming stimuli and "decides" whether or not to fire.

Each neuron may synapse with hundreds of other neurons. Indeed, thousands of synaptic terminals of presynaptic neurons may cover as much as 40% of a postsynaptic neuron's dendritic surface and cell body. It is the job of the dendrites and the cell body of every neuron to integrate the messages that continually bombard them.

Neural integration is the process of summing, or integrating, incoming signals. EPSPs and IPSPs are produced continually in postsynaptic neurons, and IPSPs cancel the effects of some EPSPs. It is important to remember that each EPSP and IPSP is not an all-or-none response. Rather, each is a graded response that does not travel like an action potential but may be added to or subtracted from other EPSPs and IPSPs.

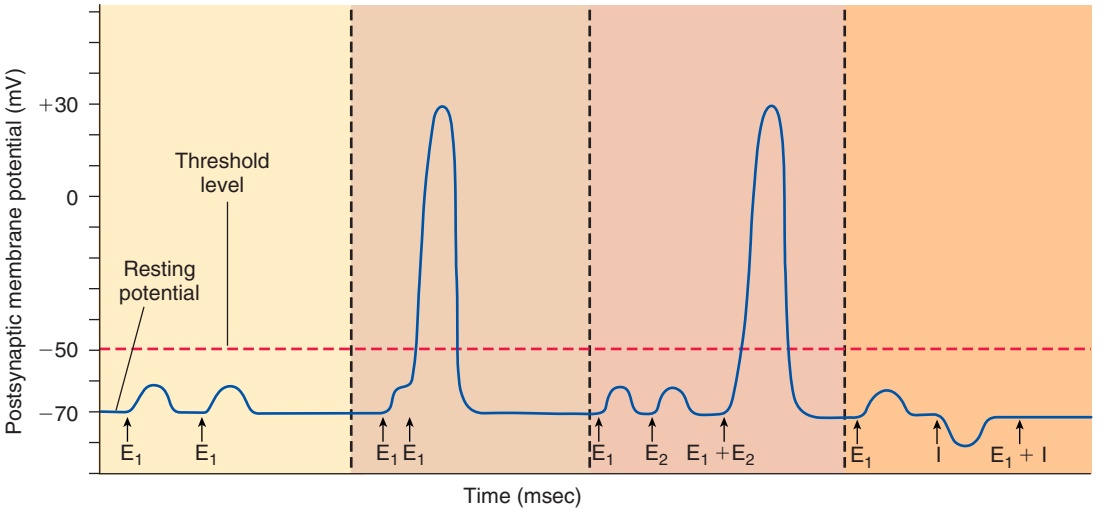
As the postsynaptic neuron membrane continuously updates its molecular tabulations, the neuron may be inhibited or brought to threshold level. This mechanism integrates hundreds of signals (EPSPs and IPSPs) before an action potential is actually transmitted along the axon of a postsynaptic neuron. Local responses permit the neuron and the entire nervous system a far greater range of response than would be possible if every EPSP generated an action potential.

Postsynaptic potentials are summed over time and space

Each EPSP or IPSP is a graded potential that varies in magnitude depending on the strength of the stimulus applied. One EPSP is usually too weak to trigger an action potential by itself. Its effect is below threshold level. However, even though subthreshold EPSPs do not produce an action potential, they do affect the membrane potential. EPSPs may add together in a process known as **summation** (Fig. 40-11).

Temporal summation occurs when repeated stimuli cause new EPSPs to develop before previous EPSPs have decayed. The summation of several EPSPs may bring the neuron to the critical firing level.

Spatial summation can also bring the postsynaptic neuron to the threshold level. **Spatial summation** occurs when several closely spaced synaptic terminals release neurotransmitter simultaneously. The postsynaptic neuron is stimulated at several places at once.



(a) Subthreshold (no summation). Each stimulus is at a subthreshold level, so no action potential is generated.

(b) Temporal summation. The second EPSP occurs before the first dies off, so the two EPSPs are summed. An action potential is generated.

(c) Spatial summation. EPSPs generated by input from two different presynaptic neurons are summed.

(d) Spatial summation of EPSPs and IPSPs. EPSPs and IPSPs are also summed and can cancel each other out.

Figure 40-11 Neural integration

E_1 and E_2 are excitatory stimuli. I represents an inhibitory stimulus.

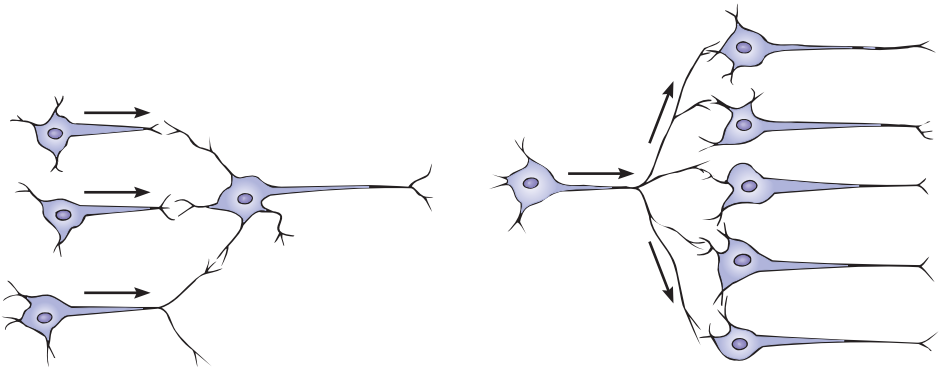
Neurons also sum IPSPs. As IPSPs are added together as a result of temporal and spatial summation, they move the membrane potential farther away from threshold.

Where does neural integration take place?

Every neuron sorts through (on a molecular level) the hundreds and thousands of bits of information simultaneously bombarding it. In vertebrates more than 90% of the neurons in the body are located in the CNS, so most neural integration takes place there, within the brain and spinal cord. These neurons are responsible for making most of the "decisions." In the next chapter, the brain and spinal cord are examined in some detail.

Review

- What is neural integration?
- How do temporal and spatial summation differ?
- Where does most neural integration take place in vertebrates?



(a) Convergence of neural input. Several presynaptic neurons synapse with one postsynaptic neuron.

(b) Divergence of neural output. A single presynaptic neuron synapses with many postsynaptic neurons.

Figure 40-12 Neural circuits

NEURAL CIRCUITS

Learning Objective

11 Distinguish among convergence, divergence, and reverberation, and explain why each is important.

The CNS contains millions of neurons, but it is not just a tangled mass of nerve cells. Its neurons are organized into separate **neural networks,** and within each network the neurons are arranged in specific pathways, or **neural circuits.** Although each network has some special characteristics, the neural circuits in all the networks share many organizational features. For example, convergence and divergence are probably characteristic of them all.

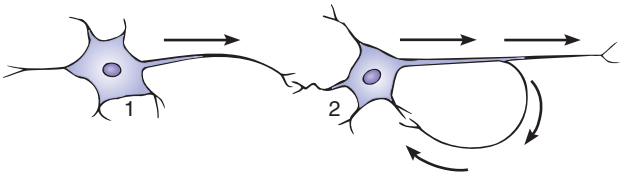
In **convergence,** a single neuron is controlled by converging signals from two or more presynaptic neurons (Fig. 40-12a). An interneuron in the spinal cord, for instance, may receive converging information from sensory neurons entering the cord, from neurons bringing information from various parts of the brain, and from neurons coming from different levels of the spinal cord. Information from all these sources must be integrated before an action potential is transmitted and an appropriate motor neuron stimulated. Convergence is an important mechanism by which the CNS integrates the information that impinges on it from various sources.

In **divergence,** a single presynaptic neuron stimulates many postsynaptic neurons (Fig. 40-12b). Each presynaptic neuron may branch and synapse with thousands of different postsynaptic neurons. For example, a single neuron transmitting an impulse from the motor area of the brain may synapse with hundreds of interneurons in the spinal cord, and each of these may diverge, in turn, so that hundreds of muscle fibers are stimulated.

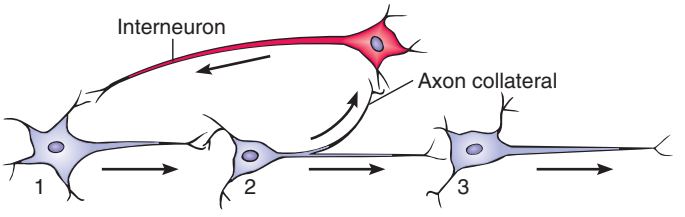
Another important type of neural circuit is the **reverberating circuit,** a neural pathway arranged so that an axon collateral synapses with an interneuron (Fig. 40-13). The interneuron synapses with a neuron in a sequence that can send new impulses through the circuit. This is an example of positive feedback. New impulses can be generated again and again until the synapses fatigue (from depletion of neurotransmitter) or until stopped by some sort of inhibition. Researchers think that reverberating circuits are important in rhythmic breathing, mental alertness, and short-term memory.

Review

- How does convergence differ from divergence?
- What is the role of positive feedback in a reverberating circuit?



(a) Simple reverberating circuit. An axon collateral of the second neuron turns back on its own dendrites, so the neuron continues to stimulate itself.



(b) Reverberating circuit with interneuron. An axon collateral of the second neuron synapses with an interneuron. The interneuron synapses with the first neuron in the sequence. New impulses are triggered again and again in the first neuron, causing reverberation.

Figure 40-13 Reverberating circuits

SUMMARY WITH KEY TERMS

Learning Objectives

1 Describe the processes involved in neural signaling: reception, transmission, integration, and action by effectors (page 846).

- Neural signaling involves (1) **reception** of information by a sensory receptor, (2) **transmission** by an **afferent neuron** to the **central nervous system (CNS),** (3) **integration** by **interneurons** in the central nervous system (CNS), (4) transmission by an **efferent neuron** to other neurons or to an effector, and (5) **action by effectors,** the muscles and glands. Sensory receptors and neurons outside the CNS make up the **peripheral nervous system (PNS).**

2 Describe the structure of a typical neuron, and give the function of each of its parts (page 847).

- **Neurons** are specialized to receive stimuli and transmit electrical and chemical signals. In a typical neuron a **cell body** contains the nucleus and most of the organelles. Many branched **dendrites** extend from the cell body; they are specialized to receive stimuli and send signals to the cell body.
- The single long **axon** extends from the cell body and forms branches called **axon collaterals.** The axon transmits signals into its **terminal branches,** which end in **synaptic terminals.** Many axons are surrounded by an insulating **myelin sheath.** In the PNS the myelin sheath is formed by **Schwann cells.** In the CNS the sheath is formed by other glial cells. **Nodes of Ranvier** are gaps in the sheath between successive Schwann cells. A **nerve** consists of several hundred axons wrapped in connective tissue; a **ganglion** is a mass of neuron cell bodies in the PNS.

ThomsonNOW™ **Learn more about the structure of neurons and nerves by clicking on the figures in ThomsonNOW.**

3 Name the main types of glial cells, and describe the functions of each (page 847).

- **Glial cells** support and nourish neurons and are important in neural communication. **Astrocytes** physically support neurons. They help regulate the composition of the extracellular fluid in the CNS by taking up excess potassium ions. They communicate with one another and with neurons. Astrocytes also induce and stabilize synapses.
- **Oligodendrocytes** are glial cells that form myelin sheaths around axons in the CNS; Schwann cells form sheaths around axons in the PNS.
- **Microglia** are phagocytic cells.
- **Ependymal cells** line cavities in the CNS and contribute to formation of cerebrospinal fluid. They also serve as neural stem cells.

4 Explain how the neuron develops and maintains a resting potential (page 849).

- Neurons use electrical signals to transmit information along axons. The plasma membrane of a resting neuron, one that is not transmitting an impulse, is **polarized.** The inner surface of the plasma membrane is negatively charged relative to the extracellular fluid just outside the membrane.
- The **resting potential** is the potential difference of about −70 mV that exists across the membrane. The magnitude of the resting potential is determined by (1) differences in concentrations of specific ions (mainly Na^+ and K^+) inside the cell relative to the extracellular fluid and (2) selective permeability of the plasma membrane to these ions.
- Ions pass through specific **passive ion channels.** K^+ leak out more readily than Na^+ can leak in. Cl^- accumulate along the inner surface of the plasma membrane. Large anions, such as proteins, that cannot cross the plasma membrane contribute negative charges.
- The gradients that determine the resting potential are maintained by ATP-requiring **sodium–potassium pumps** that continuously transport three Na^+ out of the neuron for every two K^+ transported in.

5 Compare a graded potential with an action potential, describing the production and transmission of each (page 849).

- If a stimulus causes the membrane potential to become less negative, the membrane becomes **depolarized.** If the membrane potential becomes more negative than the resting potential, the membrane is **hyperpolarized.**
- A **graded potential** is a local response that varies in magnitude depending on the strength of the applied stimulus. A graded potential fades out within a few millimeters of its point of origin.
- If voltage across the membrane declines to a critical point, called the **threshold level,** the **voltage-activated ion channels** open, allowing Na^+ to flow into the neuron, and an **action potential** is generated. The action potential is a **wave of depolarization** that moves down the axon.
- The action potential conforms to an **all-or-none response;** no variation exists in the strength of a single impulse. Either the membrane potential exceeds threshold level, leading to transmission of an action potential, or it does not. Once begun, an action potential is self-propagating.
- As the action potential moves down the axon, **repolarization** occurs behind it. During depolarization, the axon enters an **absolute refractory period,** a time when it cannot transmit another action potential. When enough gates controlling Na^+ channels have been reset, the neuron enters a **relative refractory period,** a time when the threshold is higher.

ThomsonNOW™ **Learn more about ion channels and action potentials by clicking on the figures in ThomsonNOW.**

6 Contrast continuous conduction with saltatory conduction (page 849).

- **Continuous conduction,** which involves the entire axon plasma membrane, takes place in unmyelinated neurons.
- **Saltatory conduction,** which is more rapid than continuous conduction, takes place in myelinated neurons. Depolarization appears to skip along the axon from one node of Ranvier to the next—sites where the axon is not covered by myelin and where Na^+ channels are concentrated.

7 Describe the actions of the neurotransmitters identified in the chapter (page 855).

- The junction between two neurons or between a neuron and effector is a **synapse.** Although there are electrical synapses, most synapses are chemical. In synaptic transmission, a **presynaptic neuron** releases **neurotransmitter,** a chemical messenger, from its **synaptic vesicles.**
- **Acetylcholine** triggers contraction of skeletal muscle.
- The **biogenic amines** include **norepinephrine, serotonin,** and **dopamine.** These neurotransmitters play important roles in regulating mood. Dopamine is also important in motor function.

- Several amino acids function as neurotransmitters, including **glutamate,** the main excitatory neurotransmitter in the brain, and **GABA,** a widespread inhibitory neurotransmitter.
- The neuropeptides, which are opioids, include the **endorphins** (for example, **beta-endorphin**) and the **enkephalins.**
- **Nitric oxide (NO)** is a gaseous neurotransmitter that transmits signals from the postsynaptic neuron to the presynaptic neuron, the opposite direction from other neurotransmitters.

8 Trace the events that take place in synaptic transmission, and draw diagrams to support your description (page 855).

- Calcium ions cause synaptic vesicles to fuse with the presynaptic membrane and release neurotransmitter into the **synaptic cleft.** A neurotransmitter diffuses across the synaptic cleft and combines with specific receptors on a postsynaptic neuron.
- Many neurotransmitter receptors are proteins that form **ligand-gated ion channels.** Others work through a **second messenger** such as **cAMP.**

ThomsonNOW™ **Learn more about synaptic transmission by clicking on the figure in ThomsonNOW.**

9 Compare excitatory and inhibitory signals and their effects (page 855).

- Binding of a neurotransmitter to a receptor can cause either an **excitatory postsynaptic potential (EPSP)** or an **inhibitory postsynaptic potential (IPSP),** depending on the type of receptor. EPSPs bring the neuron closer to firing. IPSPs move the neuron farther away from its firing level.

10 Define neural integration, and describe how a postsynaptic neuron integrates incoming stimuli and "decides" whether or not to fire (page 860).

- **Neural integration** is the process of summing, or integrating, incoming signals.
- Each EPSP or IPSP is a graded potential that varies in magnitude depending on the strength of the stimulus applied. The mechanism of neural integration is **summation,** the process of adding and subtracting incoming signals. By summation of several EPSPs, the neuron may be brought to critical firing level.
- **Temporal summation** occurs when repeated stimuli cause new EPSPs to develop before previous EPSPs have decayed. **Spatial summation** occurs when several closely spaced synaptic terminals release neurotransmitter simultaneously, stimulating the postsynaptic neuron at several different places.

11 Distinguish among convergence, divergence, and reverberation, and explain why each is important (page 861).

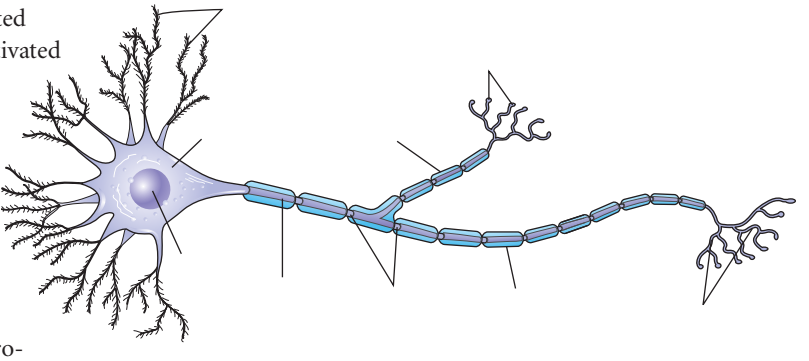
- Complex **neural circuits** are possible because of associations such as convergence and divergence. In **convergence,** a single neuron is affected by converging signals from two or more presynaptic neurons. Convergence allows the CNS to integrate incoming information from various sources. In **divergence,** a single presynaptic neuron stimulates many postsynaptic neurons, allowing widespread effect.
- **Reverberating circuits** depend on positive feedback. New impulses can be generated again and again until the synapses fatigue. Reverberating circuits are important in rhythmic breathing, mental alertness, and short-term memory.

TEST YOUR UNDERSTANDING

1. Summing incoming neural signals is part of (a) reception (b) transmission (c) integration (d) action by effectors (e) afferent neuron transmission
2. Which of the following are phagocytic cells that remove bacteria and debris from the CNS? (a) Schwann cells (b) axons (c) oligodendrocytes (d) effectors (e) microglia
3. Most of the neuron cytoplasm is located in the (a) cell body (b) axon (c) dendrites (d) synaptic terminals (e) nodes
4. Action potentials are transmitted to synaptic terminals by the (a) ganglia (b) axon (c) dendrites (d) cell body (e) nodes
5. In responding to a stimulus, a motor neuron signals a(an) (a) efferent neuron (b) receptor (c) afferent neuron (d) interneuron (e) effector
6. The myelin sheath is produced around axons in the PNS by (a) axons (b) neuron cell bodies (c) dendrites (d) Schwann cells (e) oligodendrocytes
7. Neurotransmitters are released by (a) effectors (b) neuron cell bodies (c) dendrites (d) ganglia (e) synaptic terminals
8. Which of the following does *not* contribute to the resting potential of a neuron? (a) sodium–potassium pumps (b) ion channels (c) differences in concentration of ions across the membrane (d) differences in permeability to certain ions (e) graded potentials
9. Which of the following occurs first when voltage reaches the threshold level? (a) gates of certain voltage-activated ion channels open (b) K^+ channels close (c) the membrane hyperpolarizes (d) neurotransmitter is released (e) neurotransmitter reuptake takes place at the synapse
10. Saltatory conduction (a) requires more energy than continuous conduction (b) occurs in unmyelinated neurons (c) occurs when the action potential jumps from one node of Ranvier to the next (d) slows transmission of an impulse (e) depends on the presence of GABA
11. Acetylcholine (a) is a biogenic amine (b) is recycled (c) is released by motor neurons and by some neurons in the brain (d) is deactivated by G proteins (e) binds to opioid receptors
12. Some neurotransmitter receptors (for example, serotonin receptors) (a) are voltage-activated ion channels (b) permit influx of chloride ions, leading to depolarization of the membrane (c) work through a second messenger (d) inhibit reuptake of the neurotransmitter (e) are passive ion channels
13. IPSPs (a) excite presynaptic neurons (b) excite postsynaptic neurons (c) can cancel the effects of some EPSPs (d) release large amounts of neurotransmitters (e) are released by postsynaptic cell bodies
14. A presynaptic neuron in the cerebrum synapses with hundreds of other neurons. This is an example of (a) convergence

(b) divergence (c) summation (d) a reverberating circuit (e) a graded potential

15. During a relative refractory period, (a) IPSPs are generated (b) opioid neurotransmitters are released (c) voltage-activated sodium channels are inactivated (d) an axon can transmit impulses but the threshold is higher (less negative) (e) an axon cannot transmit an action potential
16. In spatial summation, (a) repeated stimuli cause new EPSPs to develop before previous ones decay (b) divergence occurs at two or more synapses (c) EPSPs and IPSPs cancel each other in the space of the axon (d) two or more EPSPs transmit a summed chemical signal (e) several closely spaced synaptic terminals release neurotransmitter simultaneously
17. Label the diagram. Use Figure 40-2 to check your answers.



CRITICAL THINKING

1. Discuss several specific ways in which the nervous system helps maintain homeostasis.
2. Stimulant drugs such as amphetamines increase the activity of the nervous system. Describe two mechanisms involving synaptic transmission that could explain the action of such drugs.
3. Develop a hypothesis to explain the fact that acetylcholine has an excitatory effect on skeletal muscle but an inhibitory effect on cardiac muscle.
4. Investigators have genetically engineered cells to produce acetylcholine, dopamine, GABA, and other neurotransmitters. In what ways might these cells be useful in neurobiological research? How might they be useful in clinical medicine?
5. **Evolution Link.** From the perspective of adaptation, hypothesize the advantages of neural circuits characterized by a great deal of convergence and divergence.
6. **Analyzing Data.** State whether each of the following would result in an EPSP or IPSP (explain your answer): (a) Na^+ enter postsynaptic neuron; (b) K^+ diffuse out of postsynaptic neuron; (c) Cl^- enter postsynaptic neuron.

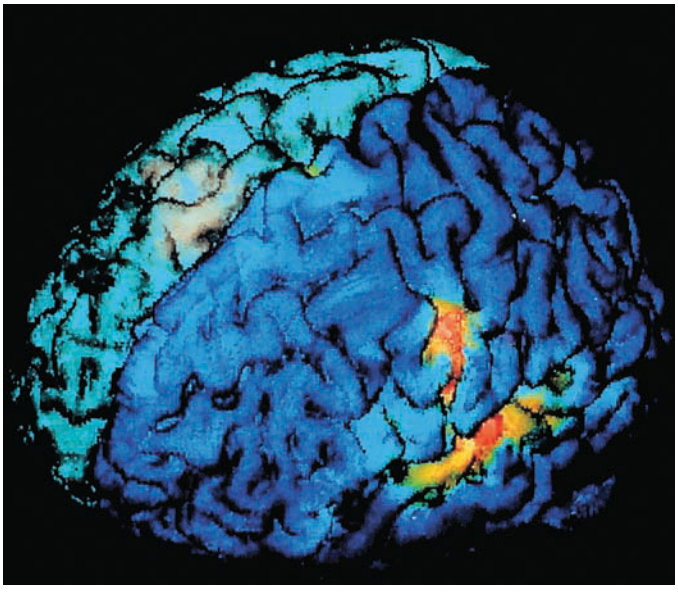
Neural Regulation



Volker Steger/Peter Arnold, Inc.

Functional magnetic resonance imaging (fMRI) of the brain during speech. In this image, red indicates areas of greatest activation during speech; yellow indicates medium activation.

KEY CONCEPTS

Trends in nervous system evolution include increased number and concentration of neurons and interneurons, more complex synaptic contacts, specialization of function, and cephalization.

The vertebrate nervous system consists of a central nervous system (brain and spinal cord) and a peripheral nervous system (sensory receptors and nerves).

Although different regions of the brain are specialized in various vertebrate classes, the brain develops in the same way and has the same basic structure; during the evolution of the vertebrate brain, the cerebrum and cerebellum have become larger and more complex.

Sensory areas of the cerebrum receive incoming sensory information; motor areas control voluntary movement; association areas link sensory and motor areas and are responsible for learning, memory, language, thought, and judgment.

A frog flicks out its tongue with lightning speed to capture a fly, a rabbit escapes from a predator, and you learn biology—perhaps not that quickly. In a complex nervous system, millions of neurons work together to produce effective responses to stimuli in the external environment. The nervous system also regulates heart rate, breathing, and hundreds of other internal activities. Researchers have focused extensively on just how neurons interact, and we are only beginning to understand the mechanisms that permit the many functions of the nervous system.

Neurobiologists use a variety of methods to study the mechanisms of neural function. For example, improved imaging methods have revolutionized the study of the brain. Functional magnetic resonance imaging (fMRI) has provided investigators with a window through which to observe brain function. Functional MRI allows neurobiologists to study the responses of neural networks in the brain while an individual is actually performing a task, such as speaking (see photograph). During the performance of the task, an area of the brain becomes active and flow of oxygenated blood to that area increases. Functional MRI detects changes that take place in response to a very brief stimulus. For example, a visual stimulus lasting only 30 milliseconds stimulates brain activation that can be detected by fMRI.

In this chapter we compare various animal nervous systems. We then examine the structure and function of the vertebrate nervous system, with emphasis on the function of the human brain. We explore some of the frontiers of neurobiology, such as the mechanisms involved in information processing. ■

INVERTEBRATE NERVOUS SYSTEMS

Learning Objectives

1 Contrast nerve nets and radial nervous systems with bilateral nervous systems.
2 Identify trends in the evolution of the invertebrate nervous system.

An animal's lifestyle is closely related to the organization and complexity of its nervous system. *Hydra* and other cnidarians have a **nerve net** consisting of interconnected neurons with no central control organ. Sensory cells are located in the epidermis, and the cnidarian can respond to stimuli from any direction. When a neuron is stimulated, electrical signals are sent from neuron to neuron in all directions (Fig. 41-1). Responses may involve large parts of the body.

An advantage of the nerve net is that the cnidarian responds effectively to predator or prey approaching from any direction. *Hydra* responds by discharging nematocysts (stinging structures) and coordinating the movements of its tentacles to capture food. Some cnidarians have two or more nerve nets. In some jellyfish, a slow-transmission nerve net coordinates movement of the tentacles, and a second nerve net, which is faster, coordinates swimming.

The **radial nervous system** of the sea star and other echinoderms (see Chapter 31) is a modified nerve net. This system shows some degree of selective organization of neurons into more than a diffuse network. It consists of a nerve ring around the mouth, from which a large radial nerve extends into each arm. Branches of these nerves, which form a network somewhat similar to the nerve net of *Hydra,* coordinate the animal's movement.

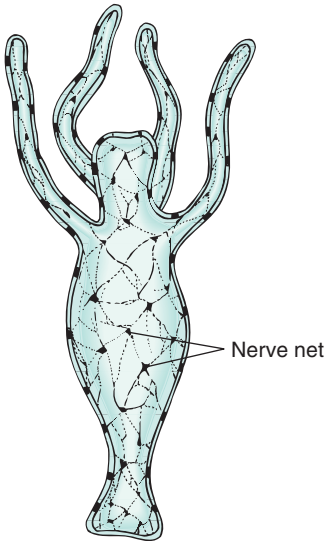


Figure 41-1 ***Animated*** *Hydra*'s nerve net

Hydra and other cnidarians have a network of neurons with no central control organ.

We can identify the following trends in the evolution of nervous systems:

1. *Increased number of nerve cells.*
2. *Concentration of nerve cells.* The nerve cells form masses of tissue that become **ganglia** (concentrations of cell bodies) and **brain** and form thick cords of tissue that become **nerve cords** and **nerves.**
3. *Specialization of function.* For example, transmission of nerve impulses in one direction requires both **afferent nerves,** which conduct impulses toward a central nervous system (CNS), and **efferent nerves,** which transmit impulses away from the CNS to the **effectors** (muscles and glands). Certain parts of the CNS are typically specialized to perform specific functions, and distinct structural and functional regions can be identified.
4. *Increased number of interneurons and more complex synaptic contacts.* These contacts permit greater integration of incoming messages, provide a greater range of responses, and allow more precision in responses.
5. ***Cephalization,*** *or formation of a head.* A bilaterally symmetrical animal generally moves in a forward direction. Concentration of sense organs at the front end of the body lets the animal detect an enemy quickly enough to escape or to see or smell food in time to capture it. Response can be rapid if short pathways link sense organs to decision-making nerve cells nearby. Therefore, nerve cells are typically concentrated in the head region and organized to form ganglia or a brain.

Bilaterally symmetrical animals have a **bilateral nervous system.** In planarian flatworms, the head region contains concentrations of nerve cells called **cerebral ganglia** (Fig. 41-2). These serve as a primitive brain and have some control over the rest of the nervous system. Typically, two solid, ventral, longitudinal nerve cords extend from the ganglia to the posterior end of the body. Transverse nerves connect the two nerve cords and connect the brain with the eyespots. This arrangement is called a "ladder-type" nervous system.

Annelids and arthropods typically have a solid ventral nerve cord (Fig. 41-3). The cell bodies of many of the neurons are massed into ganglia. Afferent and efferent neurons lie in lateral nerves that link the ganglia with muscles and other body structures. If an earthworm's brain is removed, the animal can move almost as well as before. However, when it bumps into an obstacle, it persists in a futile effort to move forward rather than turns aside. To respond adaptively to environmental change, the earthworm needs its brain.

The cerebral ganglia of some arthropods differ from those of annelids in that they have specific functional regions. These areas are specialized for integrating information transmitted to the ganglia from sense organs.

Mollusks with inactive lifestyles have relatively simple nervous systems with little cephalization and very simple sense organs. Typically, there are two nerve cords; one extends down each side of the body. Several pairs of ganglia are located along the cords.

The cephalopod mollusks (squids and octopods) have well-developed nervous systems that include well-developed sense

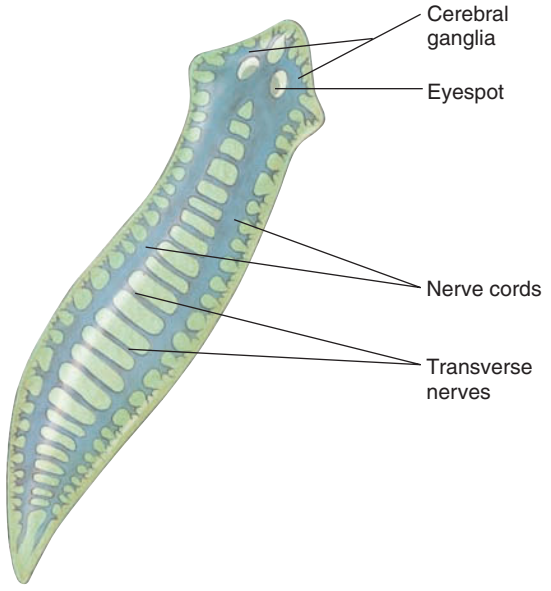

Figure 41-2 ***Animated*** Ladder-type nervous system of flatworms

Cerebral ganglia in the head region serve as a simple brain. The longitudinal nerve cords are connected by transverse nerves.

organs. The cephalopod nervous system is adapted to the active, predatory lifestyle of these animals. Neurons concentrated in ganglia are massed in a ring surrounding the esophagus; they make up a brain that contains about 168 million nerve cells. Like the vertebrate brain, the cephalopod brain has lobes and intricate folds, and particular areas are specialized as centers for specific functions. The octopus is capable of considerable learning and can be taught difficult tasks. In fact, cephalopods are considered the most intelligent invertebrates.

Review

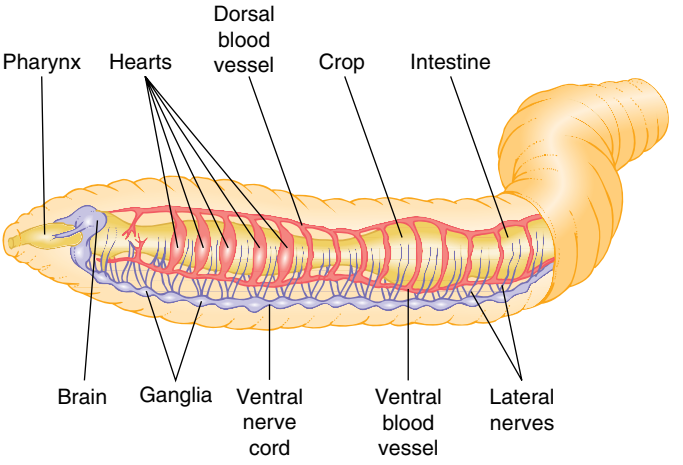
- What are some trends in the evolution of nervous systems?
- What are some advantages of cephalization?

ORGANIZATION OF THE VERTEBRATE NERVOUS SYSTEM

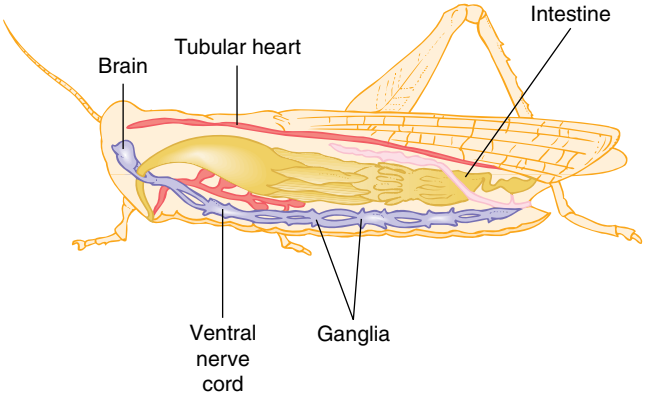
Learning Objective

3 Describe the two main divisions of the vertebrate nervous system.

An animal's range of possible responses depends in large part on how many neurons it has and how they are organized in the nervous system. Some invertebrate nervous systems have only a few hundred neurons. As animal groups evolved, nervous systems became increasingly complex. The human brain has about 9×10^{10} neurons. Elephants and other large mammals have considerably more neurons. How neurons are organized is critical in determining learning ability and flexibility of behavior.



(a) Earthworm nervous system. Annelids have a dorsal anterior brain and one or more ventral nerve cords. Cell bodies of the neurons are located in ganglia that are connected by the ventral nerve cord.



(b) Insect nervous system. The arthropod brain is connected to a ventral nerve cord. The brain is more specialized than in annelids.

Figure 41-3 ***Animated*** The annelid and arthropod nervous systems

The vertebrate nervous system has two main divisions: the **central nervous system (CNS)** and the **peripheral nervous system (PNS)** (Fig. 41-4). The CNS consists of a highly developed brain that is continuous with the dorsal, tubular **spinal cord.** Serving as central control, these organs integrate incoming information and determine appropriate responses.

The PNS is made up of the sensory receptors (for example, tactile, auditory, and visual receptors) and the nerves, which are the communication lines. Various parts of the body are linked to the brain by cranial nerves and to the spinal cord by spinal nerves. Afferent neurons in these nerves continuously inform the CNS of changing conditions. Then efferent neurons transmit the "decisions" of the CNS to appropriate muscles and glands, which make the adjustments needed to maintain homeostasis.

For convenience the PNS is subdivided into somatic and autonomic divisions. Most of the receptors and nerves concerned with changes in the external environment are somatic. Those that regulate the internal environment are autonomic. Both divisions

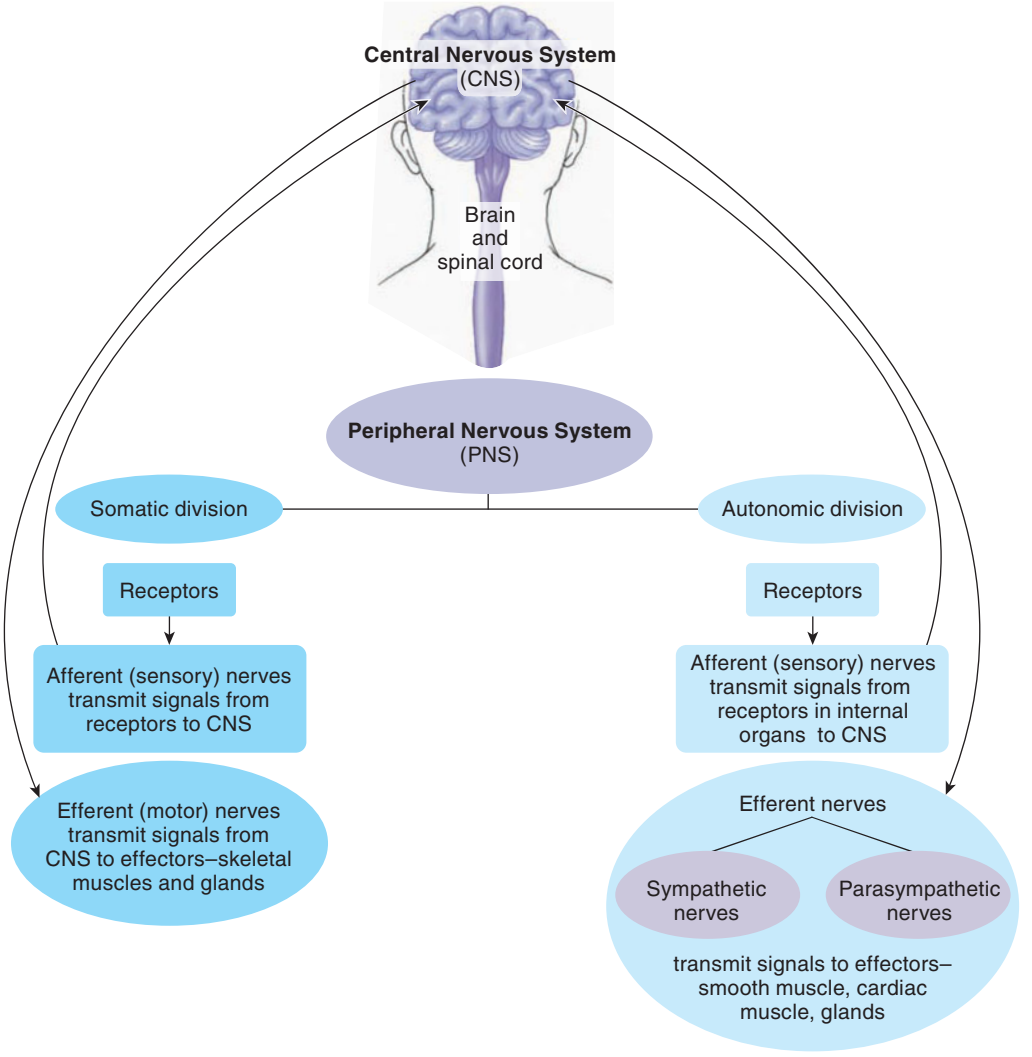


Figure 41-4 ***Animated*** Organization of the vertebrate nervous system

have afferent nerves, which transmit messages from receptors to the CNS, and efferent nerves, which transmit information back from the CNS to the structures that respond. The autonomic division has two kinds of efferent pathways: sympathetic and parasympathetic nerves (discussed later in the chapter).

Review

- What are the main components of the CNS?
- What are the main components of the PNS?

EVOLUTION OF THE VERTEBRATE BRAIN

Learning Objective

4 Trace the development of the principal vertebrate brain regions from the hindbrain, midbrain, and forebrain; and compare the brains of fishes, amphibians, reptiles, birds, and mammals.

All vertebrates, from fishes to mammals, have the same basic brain structure, although different parts of the brain are specialized in the various vertebrate classes. The evolutionary trend is toward increasing complexity, especially of the cerebrum and cerebellum.

In the early vertebrate embryo, the brain and spinal cord differentiate from a single tube of tissue, the **neural tube.** Anteriorly, the tube expands and develops into the brain. Posteriorly, the tube becomes the spinal cord. Brain and spinal cord remain continuous, and their cavities communicate. As the brain begins to differentiate, three bulges become visible: the hindbrain, midbrain, and forebrain (Fig. 41-5).

The hindbrain develops into the medulla, pons, and cerebellum

The **hindbrain** subdivides to form the **metencephalon,** which gives rise to the **cerebellum** and **pons,** and the **myelencephalon,** which gives rise to the **medulla.** The medulla, pons, and midbrain make up the **brain stem,** the elongated portion of the brain that looks like a stalk holding up the cerebrum.

The medulla, the most posterior part of the brain, is continuous with the spinal cord. Its cavity, the **fourth ventricle,** is continuous with the central canal of the spinal cord and with a channel that runs through the midbrain. The walls of the medulla are thick and made up largely of *nerve tracts* (bundles of axons) that connect the spinal cord with various parts of the brain. The medulla contains centers that regulate life-sustaining functions such as respiration, heartbeat, and blood pressure. Other reflex centers in the medulla regulate activities such as swallowing, coughing, and vomiting.

The cerebellum coordinates muscle activity and is responsible for muscle tone, posture, and equilibrium. Its size and shape vary among the vertebrate classes (Fig. 41-6). Development of the cerebellum is roughly correlated with the extent and complexity of muscular activity, reflecting the principle that the relative size of a brain part correlates with its importance to the behavior of the species. In some fishes, birds, and mammals, the cerebellum

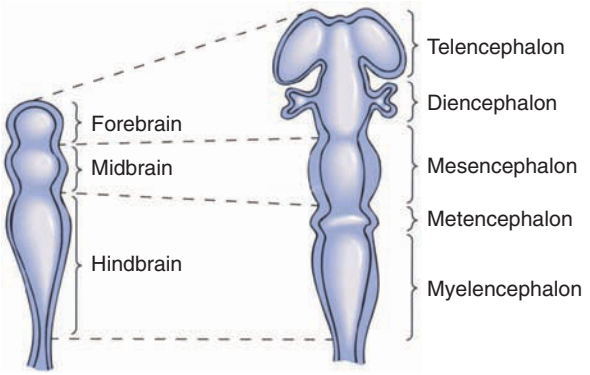

Figure 41-5 ***Animated*** Early development of the vertebrate nervous system

Early in the development of the vertebrate embryo, the anterior end of the neural tube differentiates into the hindbrain, midbrain, and forebrain. These primary divisions subdivide and eventually give rise to specific structures of the adult brain.

is highly developed, whereas it tends to be small in jawless fishes, amphibians, and reptiles.

Injury or removal of the cerebellum results in impaired muscle coordination. A bird without a cerebellum cannot fly, and its wings thrash about jerkily. When the human cerebellum is injured by a blow or by disease, muscular movements are uncoordinated. Any activity requiring delicate coordination, such as threading a needle, becomes very difficult, if not impossible.

In mammals, a large mass of fibers forms the pons, a bridge connecting the spinal cord and medulla with upper parts of the brain. The pons contains centers that help regulate respiration and nuclei that relay impulses from the cerebrum to the cerebellum. A **nucleus** is a group of cell bodies within the CNS.

The midbrain is prominent in fishes and amphibians

In fishes and amphibians, the **midbrain,** or **mesencephalon,** is the most prominent part of the brain and serves as the main association area. It receives incoming sensory information, integrates it, and sends decisions to appropriate motor nerves. The dorsal portion of the midbrain is differentiated to some extent. For example, the optic lobes are specialized for visual interpretations.

In reptiles, birds, and mammals, many functions of the optic lobes are assumed by the cerebrum, which develops from the forebrain. In mammals, the midbrain consists of the **superior colliculi,** centers for visual reflexes such as pupil constriction, and the **inferior colliculi,** centers for certain auditory reflexes. The mammalian midbrain also contains a center (the *red nucleus*) that helps maintain muscle tone and posture.

The forebrain gives rise to the thalamus, hypothalamus, and cerebrum

As indicated in Table 41-1, the **forebrain** subdivides to form the *telencephalon* and *diencephalon.* The **diencephalon** gives rise to the thalamus and hypothalamus.

In all vertebrate classes, the **thalamus** is a relay center for motor and sensory messages. In mammals, all sensory messages except those from the olfactory receptors are delivered to the thalamus before they are relayed to the sensory areas of the cerebrum.

The **hypothalamus,** which lies below the thalamus, forms the floor of the third ventricle. The hypothalamus is a major coordinating center for regulating autonomic and somatic responses. It integrates incoming information and provides input to centers in the medulla and spinal cord that regulate activities such as heart rate, respiration, and digestive system function. In reptiles, birds, and mammals, the hypothalamus controls body temperature. It also contains olfactory centers, regulates appetite and water balance, and is important in emotional and sexual responses. As discussed in Chapter 48, the hypothalamus links the nervous and endocrine systems and produces certain hormones.

The **telencephalon** gives rise to the **cerebrum.** The *lateral ventricles* (also called the first and second ventricles) lie within the cerebrum. Each lateral ventricle connects with the third ventricle (within the diencephalon) by way of a channel. In most vertebrate groups, the telencephalon also gives rise to the **olfactory bulbs.** These structures are important in the chemical sense of

TABLE 41-1

Differentiation of CNS Structures

Early Embryonic Divisions	Subdivisions	Derivatives in Adult	Cavity
Brain			
Forebrain	Telencephalon	Cerebrum	Lateral ventricles (first and second ventricles)
	Diencephalon	Thalamus, hypothalamus, epiphysis (pineal body)	Third ventricle
Midbrain	Mesencephalon	Optic lobes in fish and amphibians; superior and inferior colliculi in mammals	Cerebral aqueduct
Hindbrain	Metencephalon	Cerebellum, pons	
	Myelencephalon	Medulla	Fourth ventricle
Spinal cord		Spinal cord	Central canal

Key Point

Although different parts of the brain are specialized in various vertebrate groups, there is an evolutionary trend toward larger size and greater complexity of the cerebrum and cerebellum.

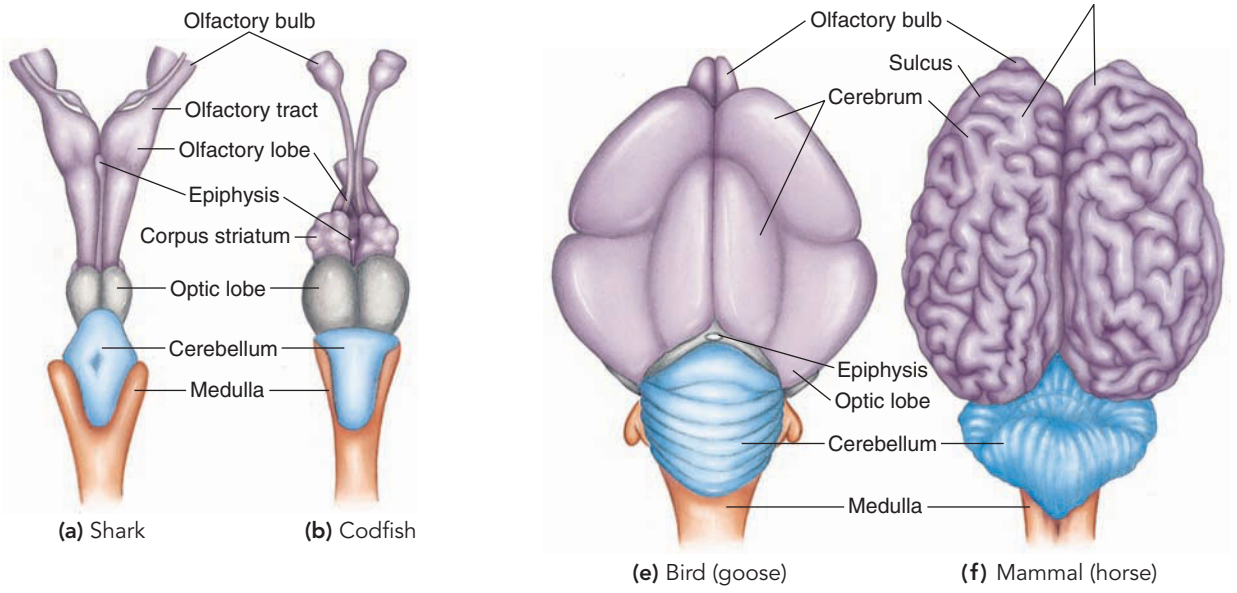

Figure 41-6 ***Animated*** Evolution of the vertebrate brain

Comparison of the brains of members of six vertebrate classes reveals basic similarities and evolutionary trends. (Brains are not drawn to scale.) Note that different parts of the brain are specialized in the various groups. The large olfactory lobes in the shark brain **(a)** are essential to this predator's highly developed sense of smell. **(b–f)** During the course of evolution, the cerebrum and cerebellum have become larger and more complex. In mammals **(f),** the cerebrum is the most prominent part of the brain; the cerebral cortex, the thin outer layer of the cerebrum, is highly convoluted (folded), which greatly increases its surface area.

smell—the dominant sense in most aquatic and terrestrial vertebrates. In fact, much of brain development in vertebrates appears to focus on integrating olfactory information. In fishes and amphibians, a large part of the cerebrum is devoted to this function.

Birds are an exception among the vertebrates in that their sense of smell is generally poor. A part of their cerebrum, the *corpus striatum,* however, is highly developed. This structure controls eating, flying, singing, and other action patterns.

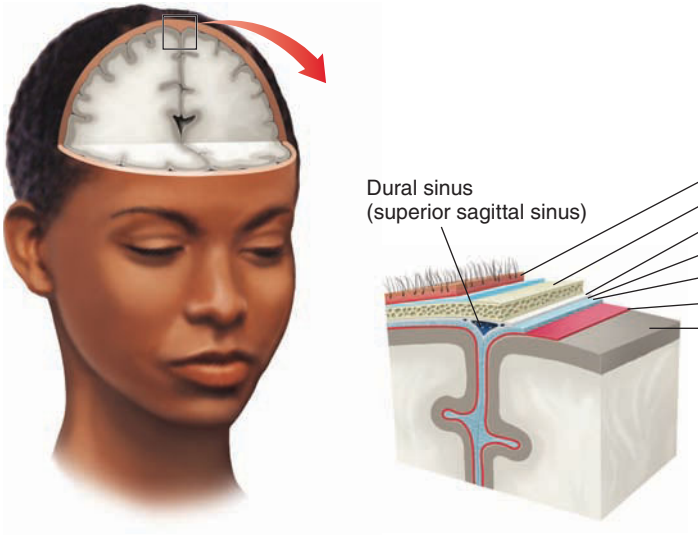
In most vertebrates, the cerebrum is divided into right and left **cerebral hemispheres.** Most of the cerebrum is made of **white matter,** which consists mainly of myelinated axons that connect various parts of the brain. In mammals and in the majority of reptiles, a layer of **gray matter,** the **cerebral cortex,** makes up the outer portion of the cerebrum. Gray matter is unmyelinated and contains cell bodies and dendrites.

Certain reptiles and all mammals have a type of cerebral cortex called the **neocortex.** The neocortex serves as an *association area*—a region that links sensory and motor functions and is responsible for higher functions, such as learning. The neocortex is very extensive in mammals, making up the bulk of the cerebrum. In humans, about 90% of the cerebral cortex is neocortex, which consists of six distinct cell layers.

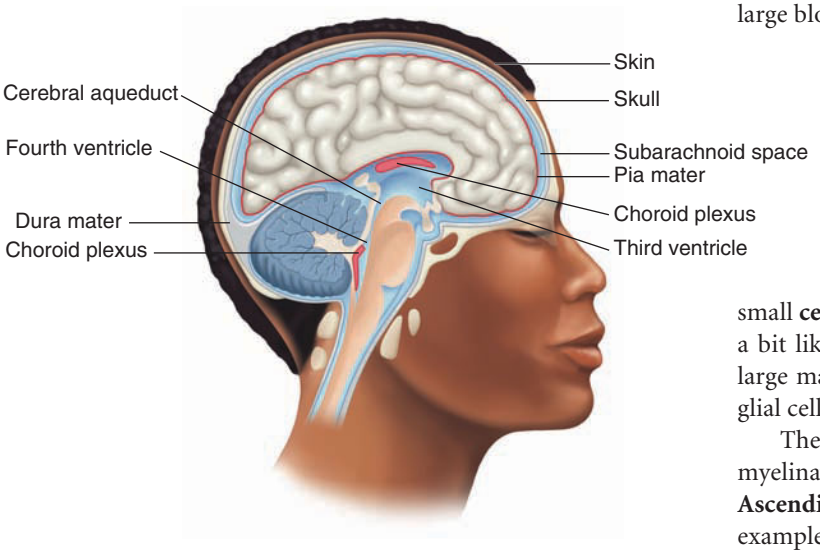
In mammals, the cerebrum is the most prominent part of the brain. During embryonic development, it expands and grows backward, covering many other brain structures. The surface area of the human cerebral cortex is greatly expanded by numerous folds called **convolutions.** The furrows between them are called **sulci** (sing., *sulcus*) if shallow and **fissures** if deep. The number of folds (not the size of the brain) has been associated with complexity of brain function. The cerebrum is responsible for numerous functions performed by other parts of the brain in other vertebrates. In addition, the mammalian cerebrum has highly developed association functions.

Review

- What are the functions of the structures derived from the vertebrate embryonic forebrain?
- How does the brain of a mammal differ from the brain of an amphibian?



(a) Frontal section through the superior part of the brain. Note the large dural sinus, a blood sinus, between two layers of the dura mater. Blood leaving the brain flows into such sinuses and then circulates to the large jugular veins in the neck.



(b) Sagittal section through brain. The CSF, which cushions the brain and spinal cord, is produced by the choroid plexi in the walls of the ventricles. This fluid circulates through the ventricles and subarachnoid space. It is continuously produced and reabsorbed into the blood of the dural sinuses.

Figure 41-7 Protection of the brain and spinal cord

The CNS is well protected by the skull and meninges and by cerebrospinal fluid (CSF).

THE HUMAN CENTRAL NERVOUS SYSTEM

Learning Objectives

5 Describe the structure and functions of the human spinal cord.
6 Describe the structure and functions of the human cerebrum.
7 Summarize the sleep–wake cycle, and contrast rapid-eye-movement (REM) sleep and non-REM sleep.
8 Describe the actions of the limbic system.

The soft, fragile human brain and spinal cord are well protected. Encased within bone, they are covered by three layers of connective tissue, the **meninges.** The three meningeal layers are the tough, outer **dura mater;** the middle **arachnoid;** and the thin, vascular **pia mater,** which adheres closely to the tissue of the brain and spinal cord (Fig. 41-7). *Meningitis* is a disease in which these coverings become infected and inflamed.

The space between the arachnoid and the pia mater is the subarachnoid space, which contains **cerebrospinal fluid (CSF).** CSF is a shock-absorbing fluid that cushions the brain and spinal cord against mechanical injury. It also serves as a medium for exchange of nutrients and waste products between the blood and brain. CSF is produced by special networks of capillaries, collectively called the **choroid plexus,** that extend from the pia mater into the ventricles. After circulating through the ventricles, CSF passes into the subarachnoid space. It is then reabsorbed into large blood sinuses within the dura mater.

The spinal cord transmits impulses to and from the brain

The tubular **spinal cord** extends from the base of the brain to the level of the second lumbar vertebra. A cross-section view through the spinal cord reveals a small **central canal** surrounded by an area of gray matter shaped a bit like the letter H (Fig. 41-8). The gray matter consists of large masses of cell bodies, dendrites, unmyelinated axons, and glial cells.

The white matter, found outside the gray matter, consists of myelinated axons arranged in bundles called **tracts** or **pathways. Ascending tracts** conduct impulses up the cord to the brain. For example, the spinothalamic tracts in the anterior and lateral columns of the white matter conduct pain and temperature information from sensory neurons in the skin. The pyramidal tracts are **descending tracts** that convey impulses from the cerebrum to motor nerves at various levels in the cord. We describe the spinal nerves later in this chapter.

In addition to transmitting impulses to and from the brain, the spinal cord controls many reflex activities. A **reflex action** is a relatively simple, involuntary motor response to a stimulus. Although most reflex actions are more complex, let us consider a **withdrawal reflex,** in which a neural circuit consisting of three

types of neurons carries out a response to a stimulus (Fig. 41-9). Suppose that your hand accidentally touches a flame. Almost instantly, and even before you become consciously aware of what has happened, you jerk your hand away. In this brief instant a sensory neuron transmits a message from pain receptors in the skin to the spinal cord.

Within the spinal cord, a sensory neuron transmits the signal to an interneuron. The interneuron integrates the information and signals an appropriate motor neuron, which conducts the information to groups of muscles. The muscles respond by contracting and moving the limb toward the midline of the body, that is, moving the hand away from the flame. Actually, many neurons in sensory, association, and motor nerves participate in such a reflex action. Generally, we are not even consciously aware that all these responding muscles exist. In summary, signals are transmitted through a withdrawal reflex in the following sequence:

Reception by sensory receptor in skin ⟶ sensory neuron transmits signal ⟶ CNS interneuron integrates information ⟶ motor neuron transmits signal ⟶ muscle contracts

At the same time the reflex pathway is activated, a message is sent up the spinal cord to the conscious areas of the brain. As you pull your hand away from the flame, you become aware of what has happened and feel the pain. This awareness, however, is not part of the reflex response.

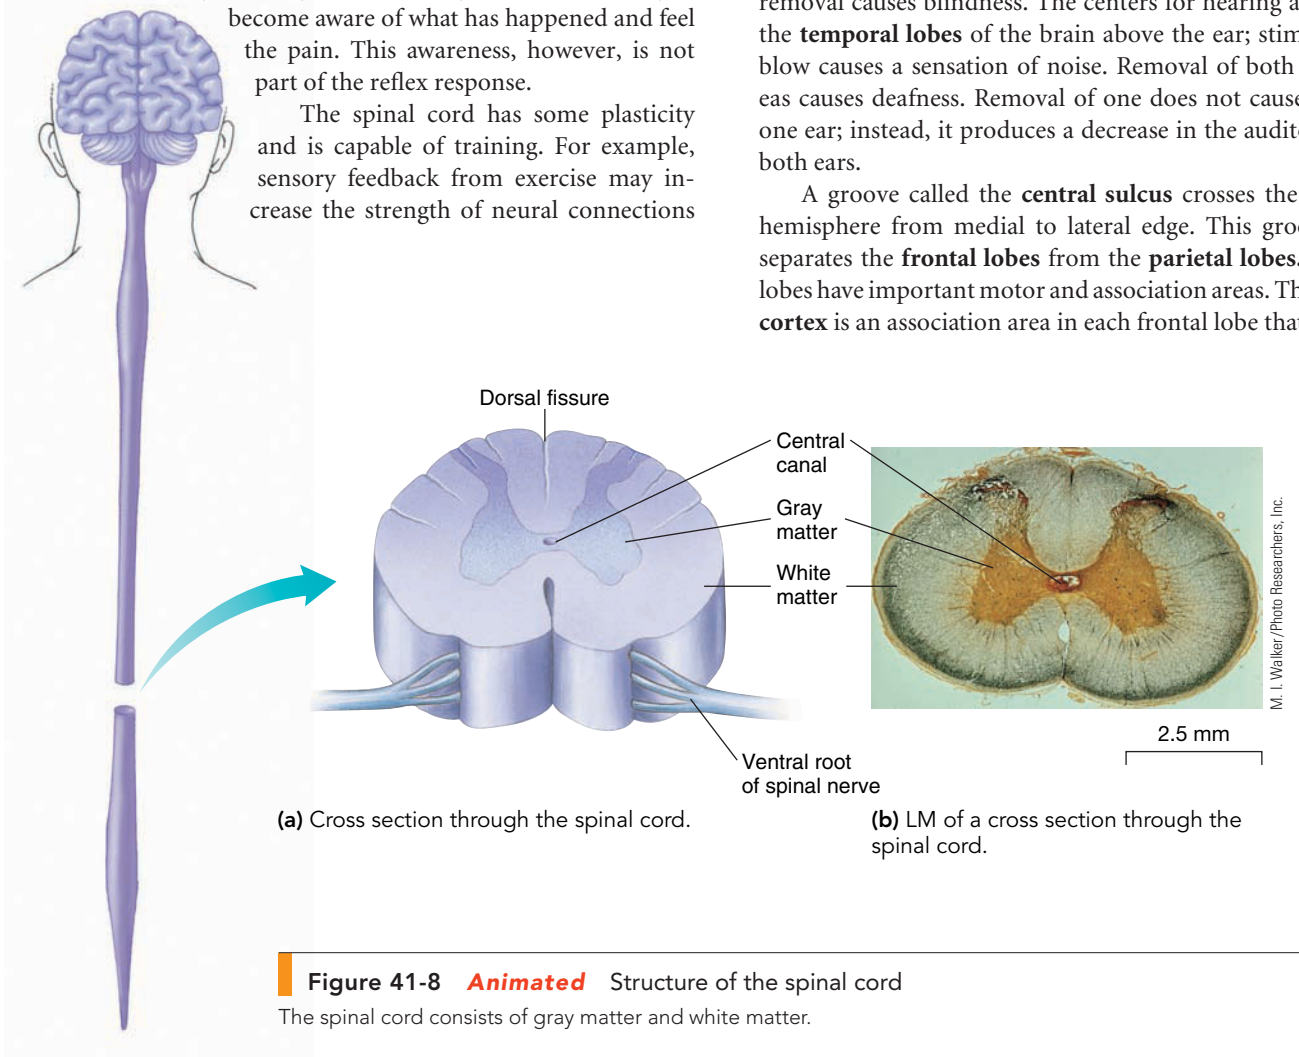
The spinal cord has some plasticity and is capable of training. For example, sensory feedback from exercise may increase the strength of neural connections in the spinal cord. If descending connections with the brain are intact, some victims of spinal cord injury (some 200,000 patients in the United States alone) could potentially develop at least some limited ability to walk again.

The most prominent part of the human brain is the cerebrum

The structure and functions of the main parts of the human brain are summarized in Table 41-2, and the brain is illustrated in Figures 41-10 and 41-11. As in other mammals, the human cerebral cortex consists of right and left *cerebral hemispheres* and is functionally divided into three areas: (1) **sensory areas** receive incoming signals from the sense organs; (2) **motor areas** control voluntary movement; and (3) **association areas** link the sensory and motor areas and are responsible for thought, learning, language, memory, judgment, and personality. You can see positron-emission tomography (PET) scans showing some functional areas of the cerebrum in Figure 41-12 on page 877.

Investigators have mapped the cerebral cortex, locating the areas responsible for different functions. The **occipital lobes** contain the visual centers. Stimulation of these areas, even by a blow on the back of the head, causes the sensation of light; their removal causes blindness. The centers for hearing are located in the **temporal lobes** of the brain above the ear; stimulation by a blow causes a sensation of noise. Removal of both auditory areas causes deafness. Removal of one does not cause deafness in one ear; instead, it produces a decrease in the auditory acuity of both ears.

A groove called the **central sulcus** crosses the top of each hemisphere from medial to lateral edge. This groove partially separates the **frontal lobes** from the **parietal lobes.** The frontal lobes have important motor and association areas. The **prefrontal cortex** is an association area in each frontal lobe that is crucial in



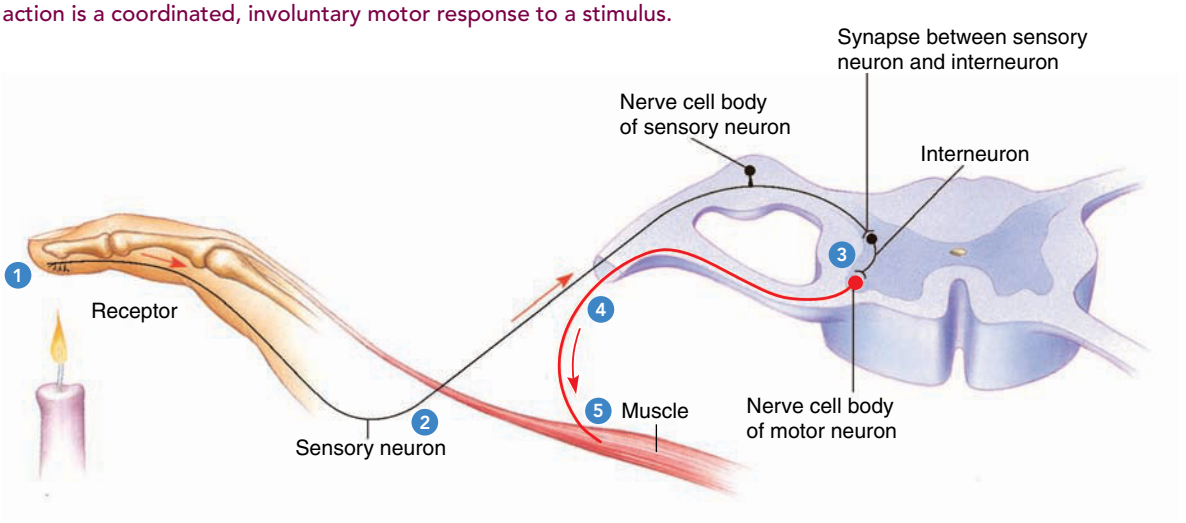
(a) Cross section through the spinal cord.

(b) LM of a cross section through the spinal cord.

Figure 41-8 ***Animated*** Structure of the spinal cord
The spinal cord consists of gray matter and white matter.

Key Point

A reflex action is a coordinated, involuntary motor response to a stimulus.



1 **Reception.** Sensory receptor signals sensory neuron.

2 **Transmission.** Sensory neuron transmits signal to CNS.

3 **Integration.** Interneuron integrates information.

4 **Transmission.** Appropriate motor neuron (*shown in red*) transmits impulses to muscle.

5 **Action by effector.** Muscle contracts, moving hand away from flame (actual response).

Figure 41-9 Withdrawal reflex

evaluating information, making judgments and decisions, planning, and organizing responses. The **motor areas** in the frontal lobes control the skeletal muscles. The **somatosensory area** in the anterior region of the parietal lobes receives information regarding touch, pressure, heat, cold, and pain from sense organs in the skin. This region also receives information regarding position of the body.

The size of the motor area in the brain for any given part of the body is proportional to the complexity of movement involved, not to the amount of muscle. Predictably, areas that control the hands and face are relatively large (Fig. 41-13 on page 878). A similar relationship exists between the sensory area and the sensitivity of the region of the skin from which it receives impulses. Neural fibers in the brain cross so that one side of the brain controls the opposite side of the body. As a result of another "reversal," the uppermost part of the cortex controls the lower limbs of the body.

When all the areas of known function are plotted, they cover almost all of the rat's cortex, a large part of the dog's, a moderate amount of the monkey's, and only a small part of the total surface of the human cortex. The remaining cortical areas are association areas. Somehow the association regions integrate the diverse impulses reaching the brain so that an appropriate response is made. When disease or accident destroys the functioning of one or more association areas, the ability to recognize certain kinds of symbols may be lost. For example, the names of objects may be forgotten, although their functions are remembered and understood.

The white matter of the cerebrum lies beneath the cerebral cortex. Nerve fibers of the white matter connect the cortical areas with one another and with other parts of the nervous system. A large band of white matter, the **corpus callosum,** connects the right and left hemispheres (see Fig. 41-11).

Deep within the white matter of the cerebrum lie the **basal ganglia,** paired groups of nuclei (gray matter). These nuclei play an important role in coordinating movement. The basal ganglia send signals to and receive signals from the **substantia nigra** in the midbrain. The neurons that project (extend) to the basal ganglia produce **dopamine,** a neurotransmitter that helps balance inhibition and excitation of neurons involved in motor function. Other neurons from the substantia nigra signal nuclei in the thalamus, which in turn relay information to the motor cortex. Neurons from the substantia nigra that signal the thalamus release the neurotransmitter **gamma-aminobutyric acid (GABA).** Just how these areas work together to coordinate motor function is not yet fully understood.

Brain activity cycles in a sleep–wake pattern

Brain activity can be studied by measuring and recording the electrical potentials, or "brain waves," generated by thousands of active neurons in various parts of the brain. This electrical activity can be recorded by a device known as an *electroencephalograph.* A recording of this electrical activity, called an **electroencephalogram (EEG),** can be obtained by taping electrodes to different parts of the scalp and measuring the activity of the

TABLE 41-2

The Human Brain

Structure	Description	Function
Brain stem		
Medulla	Continuous with spinal cord; primarily made up of nerves passing from spinal cord to rest of brain	Contains vital centers (clusters of neuron cell bodies) that control heartbeat, respiration, and blood pressure; contains centers that control swallowing, coughing, vomiting
Pons	Forms bulge on anterior surface of brain stem	Connects various parts of brain with one another; contains respiratory and sleep centers
Midbrain	Just above pons	Center for visual and auditory reflexes (e.g., pupil reflex, blinking, adjusting ear to volume of sound)
Thalamus	At top of brain stem	Main sensory relay center for conducting information between spinal cord and cerebrum; neurons in thalamus sort and interpret all incoming sensory information (except olfaction) before relaying messages to appropriate neurons in cerebrum
Hypothalamus	Just below thalamus; pituitary gland is connected to hypothalamus by stalk of neural tissue	Contains centers for control of body temperature, appetite, fat metabolism, and certain emotions; regulates pituitary gland
Cerebellum	Second-largest division of brain	Reflex center for muscular coordination and refinement of movements
Cerebrum	Largest, most prominent part of human brain; longitudinal fissure divides cerebrum into right and left hemispheres, each divided into lobes: frontal, parietal, temporal, and occipital lobes	Center of intellect, memory, consciousness, and language; also controls sensation and motor functions
Cerebral cortex (outer gray matter)	Arranged into convolutions (folds) that increase surface area; functionally, cerebral cortex is divided into	
	1. Motor areas	Control movement of voluntary muscles.
	2. Sensory areas	Receive incoming information from eyes, ears, pressure and touch receptors, etc.
	3. Association areas	Sites of intellect, memory, language, and emotion; interpret incoming sensory information
White matter	Consists of myelinated axons of neurons that connect various regions of brain; axons are arranged into bundles (tracts)	Connects the following: 1. Neurons within same hemisphere 2. Right and left hemispheres 3. Cerebrum with other parts of brain and spinal cord

cerebral cortex. The EEG shows that the brain is continuously active. The most regular indication of activity appears to be **alpha waves,** which occur rhythmically at the rate of about 10 per second (Fig. 41-14 on page 880).

Alpha waves are generated mainly from the visual areas in the occipital lobes when the person being tested is resting quietly with eyes closed. When the eyes are opened, alpha waves disappear and are replaced by more rapid, irregular waves. As you are reading this biology text, your brain is emitting **beta waves.** These waves have a fast-frequency rhythm that represents heightened mental activity, such as information processing. During sleep, the brain emits waves with a lower frequency and a higher amplitude. The slow, large waves associated with certain stages of sleep are called **theta waves** and **delta waves.** During dreaming, flurries of irregular waves occur.

Certain brain diseases change the pattern of brain waves. Individuals with epilepsy, for example, exhibit a distinctive, recognizable, abnormal wave pattern. The location of a brain tumor or the site of brain damage caused by a blow to the head can sometimes be determined by noting the part of the brain that emits abnormal waves.

The reticular activating system regulates consciousness

The **reticular activating system (RAS)** is a neural pathway within the brain stem and thalamus. The RAS receives messages from neurons in the spinal cord and from many other parts of the nervous system and communicates with the cerebral cortex by complex neural circuits. Components of the RAS help regulate **consciousness**—a state of awareness of the external world and of self, including thoughts and perceptions. When certain neurons of the RAS bombard the cerebral cortex with stimuli, the individual feels alert and can focus on specific thoughts. If the

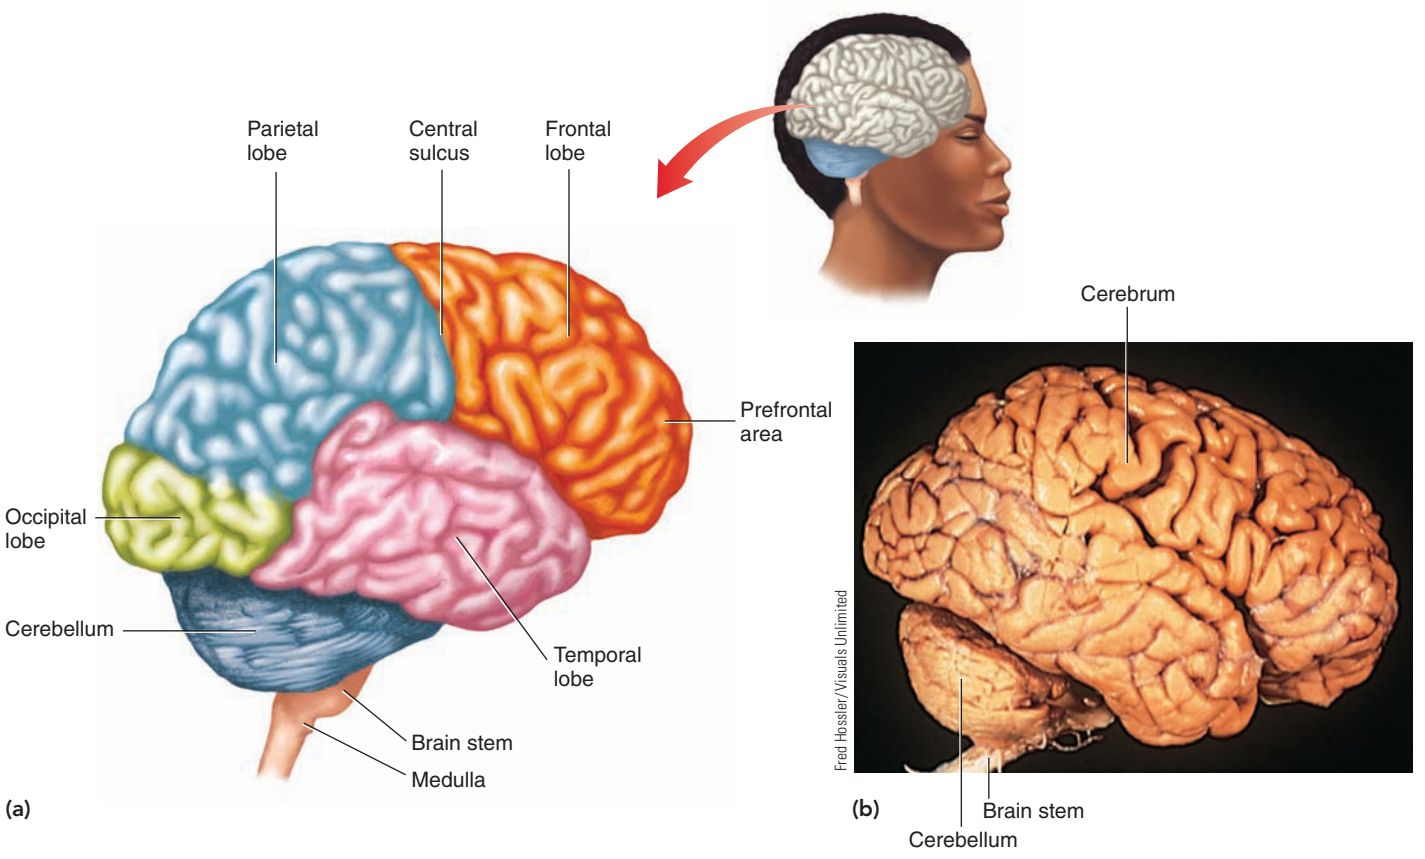


Figure 41-10 ***Animated*** The human brain

Human brain, lateral view. Each cerebral hemisphere is divided into four major lobes. The diencephalon and part of the brain stem are covered by the cerebrum. Compare the diagram **(a)** with the photograph of the human brain **(b).**

RAS is severely damaged, the individual may pass into a deep, permanent coma.

Sleep has two main stages

Sleep is an alteration of consciousness during which there is decreased electrical activity in the cerebral cortex and from which a person can be aroused. Two main stages of sleep are **non-REM** and **REM.** *REM* is an acronym for *rapid eye movement.* During non-REM sleep, sometimes called normal sleep, metabolic rate decreases, breathing slows, and blood pressure decreases. Slower-frequency, higher-amplitude waves (theta and delta waves) are characteristic of non-REM sleep. This electrical activity is thought to be generated spontaneously by the cerebral cortex when it is not driven by impulses from other parts of the brain.

Every 90 minutes or so, a sleeping person enters the REM stage for a time. During this stage (about 20% of total sleep time), the eyes move about rapidly beneath the closed but fluttering lids. Brain waves change to a desynchronized pattern. Everyone dreams, especially during REM sleep. PET scans of sleeping subjects indicate that during REM sleep, blood flow in the frontal lobes is reduced. In contrast, blood flow increases in areas that produce visual scenes and emotion. During REM sleep, neurons in the RAS release the neurotransmitter **norepinephrine,** which stimulates heightened activity in certain regions of the brain.

The hypothalamus and brain stem regulate the sleep–wake cycle

Using rats, researchers have demonstrated that stimulation of the *preoptic nucleus* of the hypothalamus results in non-REM sleep. The preoptic nucleus is located near the **suprachiasmatic nucleus,** the most important of the body's biological clocks. The suprachiasmatic nucleus receives information about the duration of light and dark from the retina of the eye and apparently transmits this information to the preoptic nucleus.

Melatonin, a hormone released by the *pineal gland,* also plays a role in regulating the sleep–wake cycle. The suprachiasmatic nucleus signals the pineal gland about light and dark. This gland secretes up to 10 times as much melatonin during darkness as during daylight. The fatigue and decreased physical and mental performance referred to as *jet lag* occur when we fly to a different time zone where the body is no longer synchronized with the light–dark cycle.

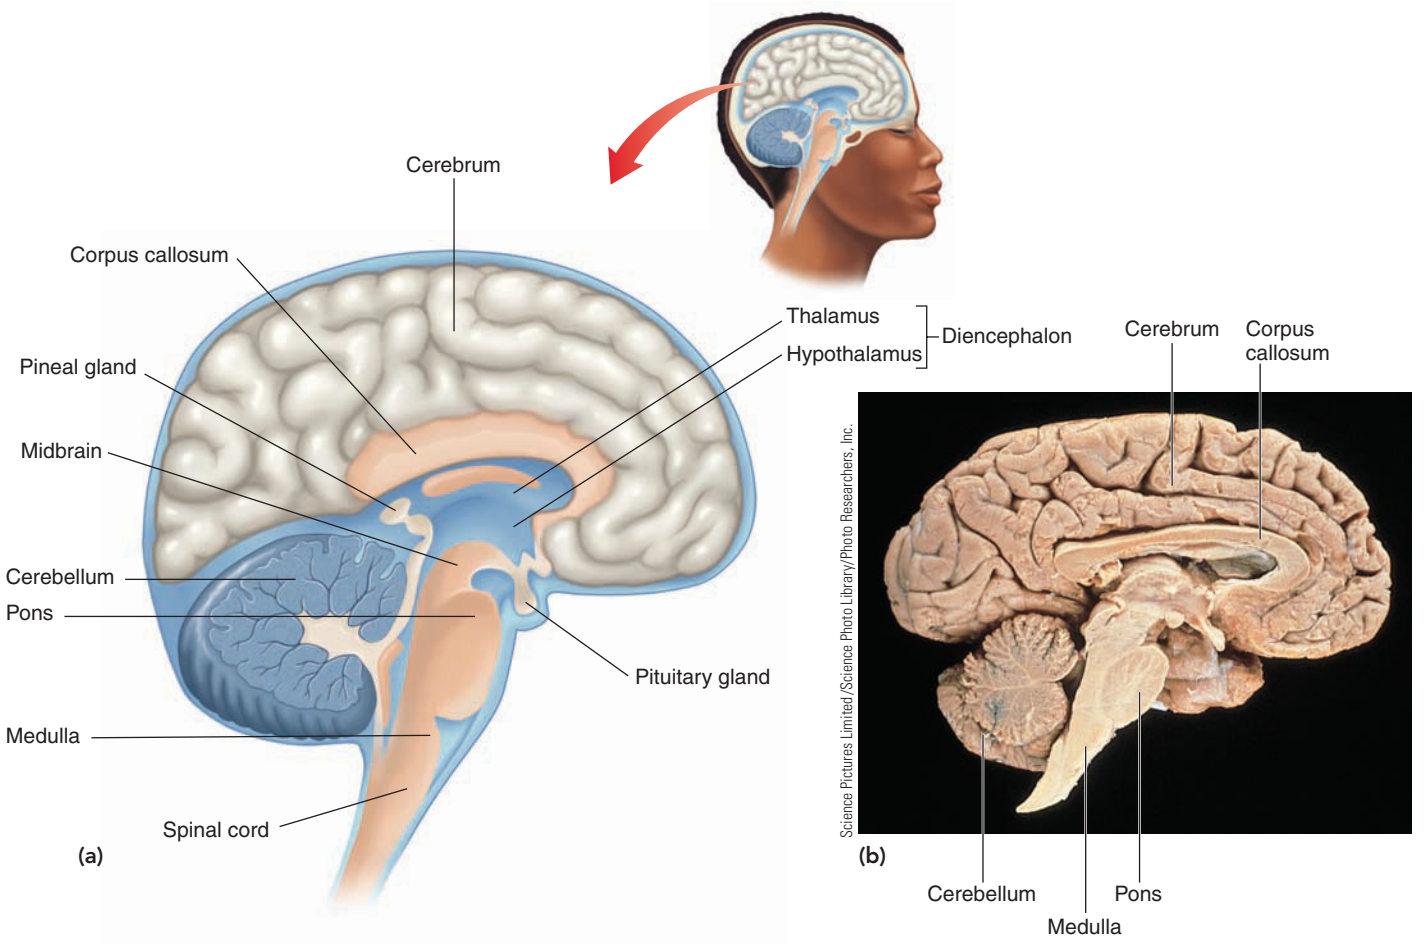

Figure 41-11 ***Animated*** Midsagittal section through the human brain

Half of the brain has been cut away, exposing structures normally covered by the cerebrum. Compare the diagram **(a)** with the photograph of the human brain **(b).**

The *raphe nuclei* in the brain stem (lower pons and medulla) appear important in producing REM sleep. Many neurons that project from the raphe nuclei release **serotonin,** a neurotransmitter involved in sleep. After many hours of activity, the sleep–wake cycle may be affected by fatigue of the RAS. Sleep centers are then activated, and their neurons release serotonin. After sufficient rest, the inhibitory neurons of the sleep centers become less excitable, and the excitatory neurons of the RAS become more excitable.

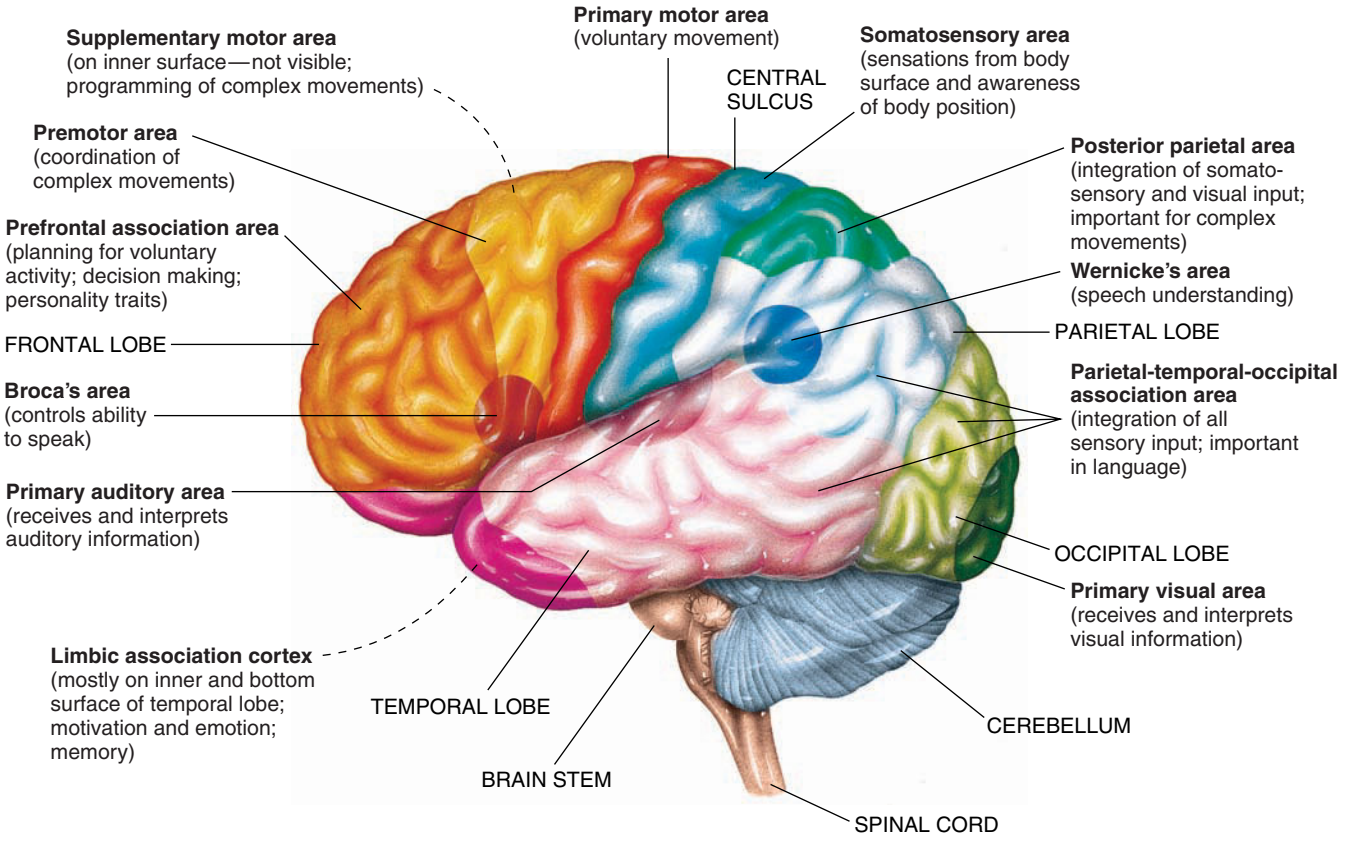
The function of sleep is not known

Although birds, mammals, and many other animals have a sleep–wake cycle, neurophysiologists do not know why sleep is necessary. When a person stays awake for unusually long periods, fatigue and irritability result, and even routine tasks are not performed well. Non-REM sleep may provide time for the brain to restore itself. For example, the brain may repair damage caused by free radicals produced during metabolism. REM sleep may be important in learning and in processing memories.

In sleep-deprivation experiments with human volunteers, lack of REM sleep makes the participants anxious and irritable. When they are permitted to sleep normally again, they spend more time than usual in the REM stage for a while. Many types of drugs, such as amphetamines, alter sleep patterns and affect the amount of REM sleep. Certain drugs that induce sleep may increase total sleeping time but decrease REM time. When a person stops taking such a drug, several weeks may be required before normal sleep patterns are re-established.

The limbic system affects emotional aspects of behavior

The **limbic system** influences the emotional aspects of behavior, evaluates rewards, and is important in motivation. It plays a role



(a) Various areas of the cerebral cortex are responsible for specific types of neural processing. (Lateral view of the brain).

Figure 41-12 Functional areas of the cerebrum

in sexual behavior, biological rhythms, and autonomic responses. The limbic system, present in all mammals, includes regions of the cerebrum (parts of the frontal lobe, temporal lobe, hippocampus, amygdala, and olfactory bulb), regions of the thalamus, hypothalamus, several nuclei in the midbrain, and the neural pathways that connect these structures (Fig. 41-15 on page 880). The limbic system influences the endocrine system and the autonomic division of the nervous system.

The **hippocampus** functions in the formation and retrieval of verbal and emotional memories. It helps place our experiences in categories so that they can be stored along with similar memories. The **amygdala** filters incoming sensory information and interprets it in the context of emotional needs and survival. **Emotions** are feeling states that we experience spontaneously; they involve the mind and the body. Humans are born with the capacity to express emotions such as fear, anger, sadness, and happiness. When it perceives danger, the amygdala sends information to other parts of the brain so that appropriate responses can be made. This part of the limbic system is important in the experiences of fear and aggression. The amygdala becomes hy-

The homunculus is proportioned to reflect the relative amount of cerebral cortex that receives sensory information from each body part.

(b) Motor homunculus. This cross section through the posterior part of the frontal lobe shows which area of cerebral cortex controls each body part. Note that more of the cerebral cortex is devoted to controlling those body structures capable of skilled, complex movement. The primary motor area is involved in coordinated movement of many muscle groups.

Figure 41-13 ***Animated*** Maps of the primary sensory and motor areas

persensitive to possible danger following a traumatic experience (see *Focus On: The Neurobiology of Traumatic Experience*).

Structures of the limbic system are essential in an infant's bonding with a caregiver during the first year of life. The development of a secure attachment bond between infant and caregiver is the foundation for all future emotional and social connections between the child and other human beings. The quality of early attachment between child and caregiver affects brain develop-

THE NEUROBIOLOGY OF TRAUMATIC EXPERIENCE

In recent years, the 9/11 attack on the World Trade Center, civilian deaths by suicide bombers, the experiences of hundreds of thousands of troops at war in Iraq, and a host of natural disasters have heightened our awareness of the effects of traumatic experiences. A *traumatic experience* is an event that causes intense fear, helplessness, or horror and that overwhelms normal coping and defense mechanisms. Whether you are a combat veteran; a survivor of childhood abuse; or the victim of a robbery, rape, hurricane, or domestic violence, you may have experienced the effects of trauma.

Most of us have strategies for processing moderately disturbing experiences. For example, if you were one of the millions of people who were glued to their television sets on 9/11 or watched as people were wounded in Iraq, you may have been disturbed by the events you witnessed. You probably processed what you saw and heard by thinking and talking about it, perhaps even writing about it. You may have dreamed about your experience. As the brain actively reviews and sorts out a disturbing experience, we make sense of what happened, its emotional intensity decreases, and we store the memory along with other memories of more ordinary past events. The memory of the uncomfortable experience fades in importance.

Traumatic events are more difficult to process. If you are one of the survivors who actually ran for your life as the World Trade Center fell, or if you are a combat veteran, your body's response to the danger is more intense. Years later, your brain may still be secreting abnormally high amounts of stress hormones and neurotransmitters, and you may remain on red alert for possible danger.

How does the brain respond in a traumatic experience, and how does the experience affect the brain? When danger threatens, the amygdala sends messages to both the hypothalamus (which signals the autonomic division of the nervous system and the endocrine system) and the neocortex (which allows us to be conscious of our experience).The amygdala is programmed to remember the smells, sounds, and sensations that are part of the experience. Until the memories of the experience are fully processed, similar smells, sounds, and sensations remind us of the traumatic event and trigger the body to prepare for danger. The traumatized individual experiences fear and anxiety. Some trauma survivors develop posttraumatic stress disorder (PTSD), a condition in which they experience (1) intrusive thoughts, images, sensory experiences, memories, and dreams; (2) an urge to avoid reminders of the traumatic event; and (3) physiological hyperarousal, a condition in which the body remains on high-alert status, continuously scanning the environment for potential danger.

Because they are so overwhelming, traumatic memories are very difficult to process. They cause us so much discomfort and anxiety that we tend to avoid them rather than intentionally focus on them and sort them out. As a result, traumatic memories seem to stay "stuck" in the limbic system, and when triggered, the experience is replayed with its original emotional intensity (a flashback).

Several neuroimaging studies have shown an association between prolonged trauma (for example, severe child abuse) and long-term changes in the brain. These changes include EEG abnormalities, significantly smaller total brain and cerebral volumes, decreased right–left hemisphere integration, decreased size of the corpus callosum, and decreased volume of the hippocampus and amygdala.

Neuroimaging studies have also demonstrated changes in brain function, including increased amygdalar response and decreased cortical response. Investigators have used functional magnetic resonance imaging (fMRI) to measure amygdalar response to masked, fearful face targets. They found exaggerated amygdalar responses in subjects with PTSD. The investigators suggested that these intense responses occurred because the normal mediating influence of the medial prefrontal cortex was absent.

When researchers presented subjects with reminders of their traumatic experience, they observed decreased activity in the anterior cingulate cortex (ACC). This area, part of the medial prefrontal cortex, normally inhibits the amygdala so that it does not respond too strongly. When the ACC does not function normally, cerebral blood flow to the amygdala increases (and can be seen on neuroimages). The amygdala overresponds, and the individual experiences anxiety, distress, and physiological hyperarousal, which may lead to intense emotional responses that are rooted in the traumatic experience.

Broca's area, a region in the posterior part of the left frontal cortex, is also affected by trauma. Broca's area is critically important in generating words and thus in expressing language. Researchers have shown that when subjects are exposed to accounts of their traumatic experiences, activity in Broca's area decreases. This deactivation appears to be the physiological basis for the difficulty that trauma survivors have describing their experience in words. Trauma survivors have described flashbacks of their experience by saying that they are in a state of "speechless terror." Without words, it is difficult to process and resolve a traumatic experience.

Given these and other studies, we can conclude that traumatic experience can cause both structural and functional changes in the brain and that many trauma survivors respond strongly to triggers that remind them of their experience. The exaggerated responses of the amygdala to harmless stimuli perceived as threatening are dissociated from cortical (medial prefrontal) activation. Responses generated by the limbic system are rooted in emotion rather than in rationality and judgment.

ment and future behavior. Healthy attachment allows the baby to express emotions and provides the basis for learning how to regulate emotions. Attachment also determines how vulnerable (or resilient) the individual will be to traumatic experiences later in life.

Researchers first discovered in the 1950s that the limbic system is part of an important motivational system when they implanted electrodes in certain areas of the brains of laboratory animals. They found that a rat quickly learns to press a lever that

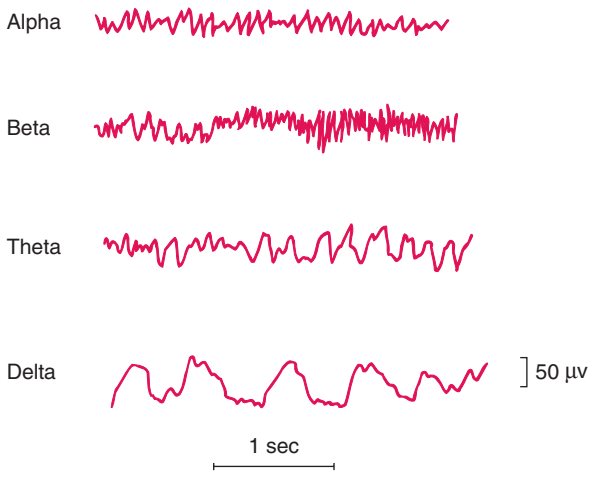

Figure 41-14 EEGs showing electrical activity in the brain

The regular waves characteristic of the relaxed state are alpha waves. During mental activity, rapid, low-amplitude beta waves are dominant. Recordings made in various stages of sleep show theta and delta waves, which have a lower frequency and greater amplitude.

stimulates a **reward center** in the brain. In fact, the rat will press the lever as many as 5000 times per hour, choosing this self-stimulation over food and water, until it drops from exhaustion.

We now know that the brain has reward centers that give us pleasure when we carry out vital activities such as eating, drinking, and sexual activity. These centers are important in experiencing emotion and in motivation. When stimulated, they activate reward circuits that allow us to feel pleasure in response to certain experiences.

The **mesolimbic dopamine pathway,** a major reward circuit, includes two important areas in the midbrain, the substantia nigra and the adjacent ventral tegmental area. These areas, which extend into behavioral control centers in the limbic system, contain the largest group of neurons that release dopamine in the brain. Dopamine neurons are activated by novel stimuli associated with reward or pleasure. These neurons signal us about surprising events or stimuli that predict rewards. Dopamine may motivate us to act when something important is happening.

As researchers continue to unravel the mechanisms of dopamine pathways, we may better understand such disorders as attention deficit disorder (ADD) and schizophrenia, conditions associated with excessive amounts of dopamine and other neurotransmitters in the brain. People with these disorders have difficulty filtering out sensory stimuli. The presence of excess dopamine may drive them to divert their attention to so many sensory stimuli that they have difficulty focusing on the most important stimuli.

Review

- How is the human CNS protected? What is the function of the cerebrospinal fluid?
- What are two main functions of the vertebrate spinal cord?
- What are the functions of each of the major lobes of the cerebrum?
- What is the function of the reticular activating system? of the limbic system?

INFORMATION PROCESSING

Learning Objectives

9 Relate neural plasticity to synaptic plasticity, and give three examples of neural plasticity.

10 Summarize how the brain processes information.

Neurobiologists are beginning to understand how the nervous system functions—how neurons signal one another; connect; and carry out basic functions such as regulating heart rate, respiration, and sleep–wake cycles; as well as how we learn and remember. An interesting question has been, To what extent are these functions **hard-wired,** that is, preset? Even animals with very simple nervous systems can learn. They learn to repeat behaviors associated with reward and to avoid behaviors that cause pain. Such changes in behavior are possible because of **neural plasticity,** the ability of the nervous system to change in response to experience. Such change modifies structure and function.

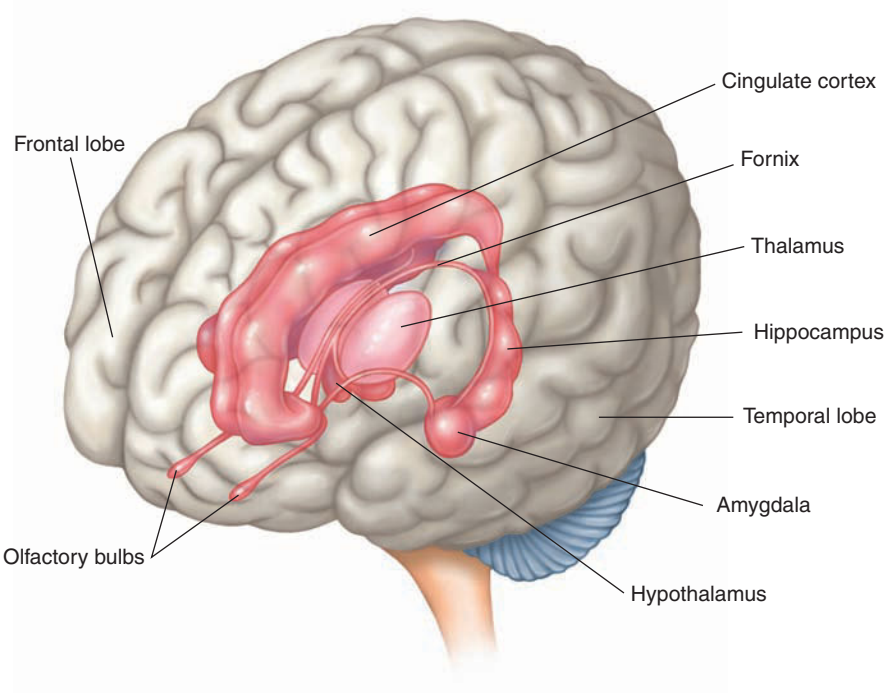

Figure 41-15 The limbic system

The limbic system consists of a ring of forebrain structures that surround the brain stem and are interconnected by complex neural pathways. This system is critical in regulation of emotional aspects of behavior and in motivation.

Many areas of the brain once thought to be hard-wired are now known to be flexible and capable of change. Familiar examples of neural plasticity in human motor skills include learning to walk, ride a bicycle, or catch a baseball. At first you were probably clumsy, but with practice your performance became smoother and more precise. For that to happen, changes must occur in the brain. Similarly, the ability to learn languages, solve problems, and perform scientific experiments depends on neural plasticity.

What are the mechanisms by which neurons signal one another to learn diverse activities, such as skilled movement and the study of biology? Canadian psychologist Donald O. Hebb proposed in 1949 that when two neurons connected by a *synapse* (that is, presynaptic and postsynaptic neurons) are active simultaneously, the synapse is strengthened. In 1973, British researchers T. V. P. Bliss and T. J. Lomo found experimental evidence for Hebb's hypothesis. Investigating rabbit brains, these researchers applied a series of high-frequency electrical stimuli to neurons in the hippocampus (a region that converts information into memories). The result was a long-term increase in synaptic strength. We can also credit Hebb for the axiom "neurons that fire together, wire together." Experience influences how neural circuits in our brains organize themselves.

Because neurons signal one another at synapses, these junctions between neurons are currently the focus of intense research. Neural plasticity may, in fact, be **synaptic plasticity,** because changes that occur during learning and remembering appear to take place at synapses. As the brain matures, it loses some of its plasticity. Neurobiologists are looking for molecules that inhibit the brain's ability to change.

Learning involves the storage of information and its retrieval

Learning is the process by which we acquire knowledge or skills as a result of experience. For learning to occur, we must be able to remember what we experience. **Memory** is the process of encoding, storing, and retrieving information or learned skills.

Implicit memory, also called *procedural memory,* is unconscious memory for perceptual and motor skills, such as riding a bicycle. Implicit memory is about "how" to do something and involves repeating the behavior until it becomes routine. **Explicit memory,** also called *declarative memory,* involves factual knowledge of people, places, or objects and requires conscious recall of the information. The hippocampus is critical in forming and retrieving explicit memories.

Information processing involves short- and long-term memory

At any moment you are bombarded with thousands of bits of sensory information. At this very moment, your eyes are receiving information about the words on this page, the objects around you, and the intensity of the light in the room. At the same time you may be hearing a variety of sounds—music, your friends talking in the next room, the hum of an air conditioner. Your olfactory epithelium may sense cologne or the smell of coffee. Maybe you are eating as you read. Sensory receptors in your hands may be receiving information regarding the weight and position of your book. Most sensory stimuli are not important to remember and so are filtered out.

When we select information to remember, we must process it. When we begin to process information, we *encode* it. We recognize patterns and meaningfully associate the stimuli to past experience or knowledge. Information processing involves both **short-term memory,** which lasts only minutes, and **long-term memory,** which may last for many years.

Typically, we can hold only about seven chunks of information (a chunk is some unit such as a word, syllable, or number) at a time in short-term memory. Short-term memory lets us recall information for a few minutes. When we look up a phone number, for example, we usually remember it only long enough to dial. If we need the same number an hour later, most of us have to look it up again. One hypothesis of short-term memory suggests that reverberating circuits are involved (see Fig. 40-13). A memory circuit may continue to reverberate for several minutes until it fatigues or until new signals interfere with the old.

The hippocampus temporarily holds new information and may integrate various aspects of an experience, including odors, sounds, and other information. **Memory consolidation,** which depends on the hippocampus, allows memories to be *stored* for long periods. Consolidation involves expression of genes and protein synthesis and depends on new neural connections at synapses. Time (several minutes, hours, or even longer) is required for the brain to *consolidate* a new memory.

When information is selected for long-term storage, the brain rehearses the material and then stores it in long-term memory in association with similar memories. We integrate new information with other knowledge already stored in the brain.

If a person suffers a brain concussion, memory of what happened immediately before the incident may be completely lost. This is known as *retrograde amnesia.* When the hippocampus is damaged, short-term memory may be unimpaired and the patient can still recall information stored in the past. However, new short-term memories can no longer be converted to long-term memories.

Where are memories stored? When large areas of the mammalian cerebral cortex are destroyed, information is lost somewhat in proportion to the extent of lost tissue. No specific area can be labeled the "memory bank." Rather, memories seem to be stored within many areas of the brain. For example, visual memories may be stored in the visual centers of the occipital lobes, and auditory memories may be stored in the temporal lobes. Researchers think that memories are integrated in many areas of the brain, including the amygdala and the hippocampus, association areas of the cerebral cortex, and the thalamus and hypothalamus. *Wernicke's area* in the temporal lobe has been identified as a very important association area for complex thought processes. Neurons within the association areas form interconnected pathways that permit complicated reverberation.

Retrieval of information stored in long-term memory is of considerable interest—especially to students! The challenge is

to find information when you need it. When you seem to forget something, the problem may be that you have not searched effectively for the memory. Information retrieval can be improved by careful encoding, for example, by forming strong associations between items.

Neurobiological changes occur during learning

Short-term memory involves changes in the neurotransmitter receptors of postsynaptic neurons. These changes strengthen synaptic connections. The receptors are linked by second messengers (for example, cyclic AMP) to ion channels in the plasma membrane.

In some types of learning, changes take place in presynaptic terminals or postsynaptic neurons that permanently enhance or inhibit the transmission of impulses. In some cases, specific neurons may become more sensitive to neurotransmitter. Neurons typically transmit action potentials in bursts, and the amount of neurotransmitter released by each action potential may increase or decrease.

Repeated electrical stimulation of neurons causes a functional change at synapses. When a presynaptic neuron continues to transmit action potentials at a high rate for a minute or longer, there is a long-lasting strengthening of the connection between the presynaptic and postsynaptic neurons. This increased strength of the synaptic connection is known as **long-term potentiation (LTP).** *Potentiation* means "to strengthen or make more potent." In contrast, low-frequency stimulation of neurons results in a long-lasting *decrease* in the strength of their synaptic connections, called **long-term depression (LTD).** Information storage and forgetting depend on the strengthening and weakening of synaptic connections brought about by LTP and LTD.

Induction of LTP and LTD requires activation of two types of receptors: **NMDA receptors** and **AMPA receptors.** These receptors, present on the plasma membranes of postsynaptic neurons, control the passage of calcium ions into neurons. NMDA receptors respond to the neurotransmitter *glutamate* by opening Ca^{2+} channels. However, when the postsynaptic neuron is at its resting potential, NMDA ion channels are blocked by Mg^{2+}.

A model for the mechanism of LTP is illustrated in Figure 41-16. A presynaptic neuron releases glutamate, which binds with AMPA receptors. The postsynaptic neuron becomes depolarized. If depolarization of the postsynaptic neuron is sufficiently strong, Mg^{2+} move away from the NMDA receptors, unblocking them. Glutamate can then bind with these receptors, opening Ca^{2+}channels and letting Ca^{2+} move into the cell. Calcium ions appear to be an important trigger for LTP.

Calcium ions act as second messengers that initiate long-term changes ultimately responsible for LTP. For example, calcium ions activate a Ca^{2+}-dependent second-messenger pathway that results in the insertion of more AMPA receptors in the postsynaptic membrane. This is important because additional AMPA receptors increase sensitivity to glutamate. More EPSPs are produced, which strengthens the synapse (that is, helps maintain the LTP).

Calcium ions also activate a pathway that leads to release of a **retrograde signal,** a signal that moves backward, from the postsynaptic neuron to the presynaptic neuron. The soluble gas *nitric oxide (NO)* has been identified as a retrograde signal. This signal enhances neurotransmitter release by the presynaptic neuron. Note that this is a positive feedback loop that strengthens the connection between the two neurons.

Long-term memory involves gene expression

Gene expression and protein synthesis take place during the process of establishing long-term memory. This process involves slower, but longer-lasting, changes in synaptic connections. Long-term memory depends on activated receptors linked to G proteins. Cyclic AMP acts as a second messenger.

A high level of cyclic AMP activates a protein kinase that enters the nucleus, leading to gene activation and protein synthesis. In this process, protein kinase phosphorylates a transcription factor known as **CREB** (for *cyclic AMP response element binding protein*). CREB then turns on the transcription process of certain genes. CREB has been shown to be a signaling molecule in the memory pathway in many animals, including fruit flies and mice. The molecules and processes involved in learning and memory have been highly conserved during evolution.

Experience affects development and learning

Many studies have demonstrated neural plasticity in rats and other laboratory animals exposed to enriched environments. In contrast with rats housed in standard cages and provided with the basic necessities, those exposed to enriched environments are given toys and other stimulating objects, as well as the opportunity to socially interact with other rats. Animals reared in an enriched environment exhibit increased synaptic contacts and process and remember information more quickly than animals lacking such advantages. Mice exposed to enriched environments develop significantly greater numbers of neurons in the hippocampus and learn mazes faster than control animals.

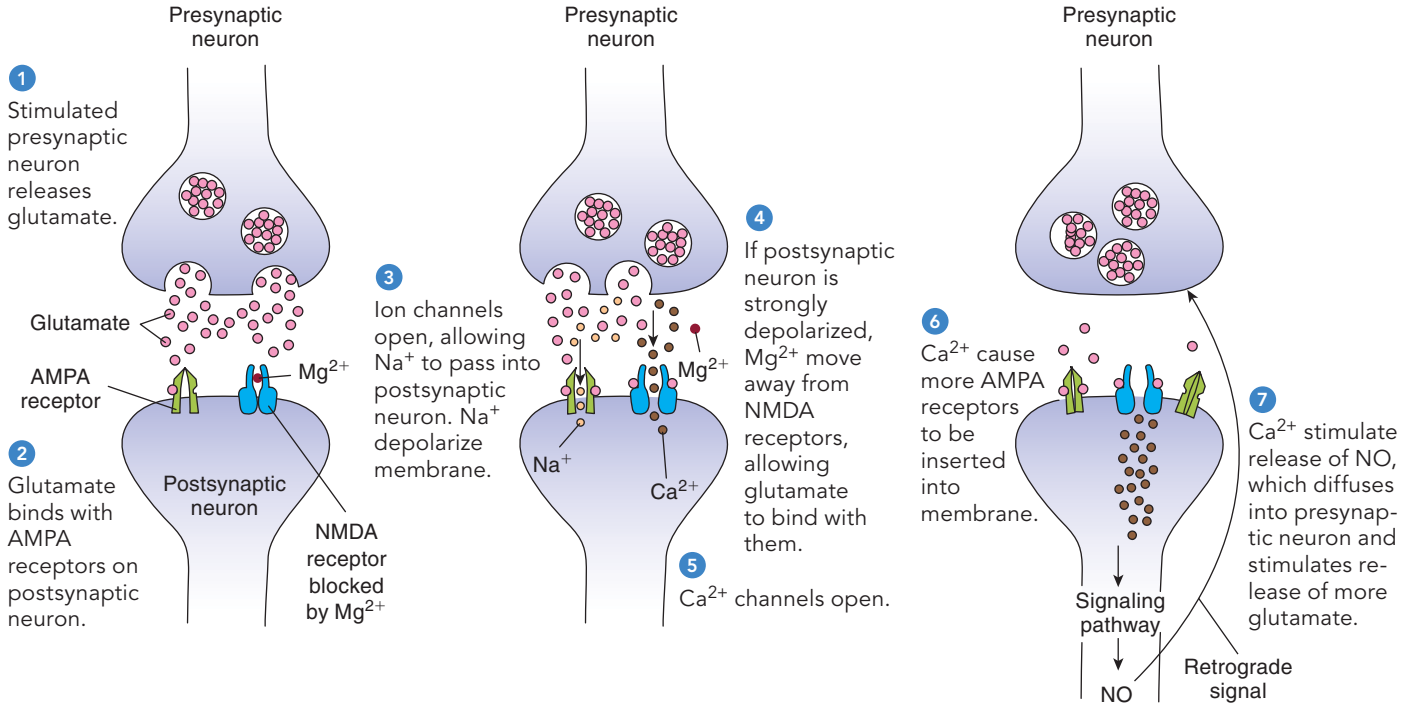
Early environmental stimulation can also enhance the development of motor areas in the brain. For example, the brains of rats encouraged to exercise become slightly heavier than those of control animals. Characteristic changes occur within the cerebellum, including the development of larger dendrites.

Apparently, during early life certain critical or sensitive periods of nervous system development occur that are influenced by environmental stimuli. For example, when the eyes of young mice first open, neurons in the visual cortex develop large numbers of dendritic spines (structures on which synaptic contact takes place). If the animals are kept in the dark and deprived of visual stimuli, fewer dendritic spines form. If the mice are exposed to light later in life, some new dendritic spines form but never as many as develop in a mouse reared in a normal environment.

Studies linking the development of the brain with environmental experience have demonstrated that early stimulation is important for the sensory, motor, and intellectual development of children. Such studies led to a greatly expanded educational

Key Point

When glutamate binds to NMDA receptors, Ca^{2+} enter the postsynaptic neuron and activate intracellular signaling systems that lead to changes responsible for LTP.



(a) Activation of AMPA receptors. Glutamate released by a presynaptic neuron binds with AMPA receptors on the postsynaptic neuron. Note that NMDA receptors are blocked by Mg^{2+}.

(b) Activation of NMDA receptors. The combination of strong stimulation and glutamate binding activates NMDA receptors.

(c) Long-term potentiation. Calcium ions activate pathways, leading to changes that are ultimately responsible for LTP.

Figure 41-16 A proposed model for the mechanism of long-term potentiation (LTP)

toy market and to widespread acceptance of early-education programs. Researchers have also suggested that continuing environmental stimulation is needed to maintain the status of the cerebral cortex in later life.

Review

- What is synaptic plasticity?
- How is information processed? How might short-term memory be adaptive?

Language involves comprehension and expression

Language is a form of communication in which we use words to symbolize objects and convey ideas. In most people, the areas of the brain responsible for language are located only in the left hemisphere. **Wernicke's area,** located in the temporal lobe, is an important center for language comprehension (see Fig. 41-12). This area helps us recognize and interpret both spoken and written words. Wernicke's area also helps us formulate the choice and sequence of words and transfers information to **Broca's area.** Located near motor areas in the left frontal lobe, Broca's area controls our ability to speak. Broca's area is also important in language processing and speech comprehension.

THE PERIPHERAL NERVOUS SYSTEM

Learning Objectives

11 Describe the organization of the peripheral nervous system, and compare its somatic and autonomic divisions.

12 Contrast the sympathetic and parasympathetic divisions of the autonomic system, and give examples of the effects of these systems on specific organs such as the heart and intestine.

The peripheral nervous system consists of the sensory receptors, the nerves that link these receptors with the central nervous system, and the nerves that link the CNS with effectors (muscles and glands). The somatic division of the PNS helps the body respond

to changes in the external environment. The nerves and receptors that maintain homeostasis despite internal changes make up the autonomic division.

The somatic division helps the body adjust to the external environment

The **somatic division** of the PNS includes the receptors that react to changes in the external environment, the sensory neurons that inform the CNS of those changes, and the motor neurons that adjust the positions of the skeletal muscles that help maintain the body's posture and balance. In mammals, 12 pairs of **cranial nerves** emerge from the brain. They transmit information regarding the senses of smell, sight, hearing, and taste from the special sensory receptors, as well as information from the general sensory receptors, especially in the head region. For example, cranial nerve II, the optic nerve, transmits signals from the retina of the eye to the brain. The cranial nerves also bring orders from the CNS to the voluntary muscles that control movements of the eyes, face, mouth, tongue, pharynx, and larynx. Cranial nerve VII, the facial nerve, transmits signals to the muscles used in facial expression and to the salivary glands.

In humans, 31 pairs of **spinal nerves** emerge from the spinal cord. Named for the general region of the vertebral column from which they originate, they comprise 8 pairs of cervical, 12 pairs of thoracic, 5 pairs of lumbar, 5 pairs of sacral, and 1 pair of coccygeal spinal nerves. The ventral branches of several spinal nerves form tangled networks called *plexi* (sing., *plexus*). Within a plexus, the fibers of a spinal nerve may separate and then regroup with fibers that originated in other spinal nerves. Thus, nerves emerging from a plexus consist of neurons from several different spinal nerves.

The autonomic division regulates the internal environment

The **autonomic division** helps maintain homeostasis in the internal environment. For example, it regulates the heart rate and helps maintain a constant body temperature. The autonomic system works automatically and without voluntary input. Its effectors are smooth muscle, cardiac muscle, and glands. Like the somatic system, it is functionally organized into reflex pathways. Receptors within the viscera relay information via afferent nerves to the CNS. The information is integrated at various levels. Then the decision is transmitted along efferent nerves to the appropriate muscles or glands.

Afferent and efferent neurons of the autonomic division lie within cranial or spinal nerves. For example, afferent fibers of cranial nerve X, the vagus nerve, transmit signals from many organs of the chest and upper abdomen to the CNS. Its efferent fibers transmit signals from the brain to the heart, stomach, small intestine, and several other organs.

The efferent portion of the autonomic division is subdivided into **sympathetic** and **parasympathetic systems.** Many organs are innervated by both types of nerves. In general, sympathetic and parasympathetic systems have *opposite* effects (Figs. 41-17 and 41-18). For example, the heart rate is speeded up by messages from sympathetic nerve fibers and slowed by impulses from its parasympathetic nerve fibers. In many cases sympathetic nerves operate to stimulate organs and to mobilize energy, especially in response to stress; whereas the parasympathetic nerves influence organs to conserve and restore energy, particularly during quiet, calm activities.

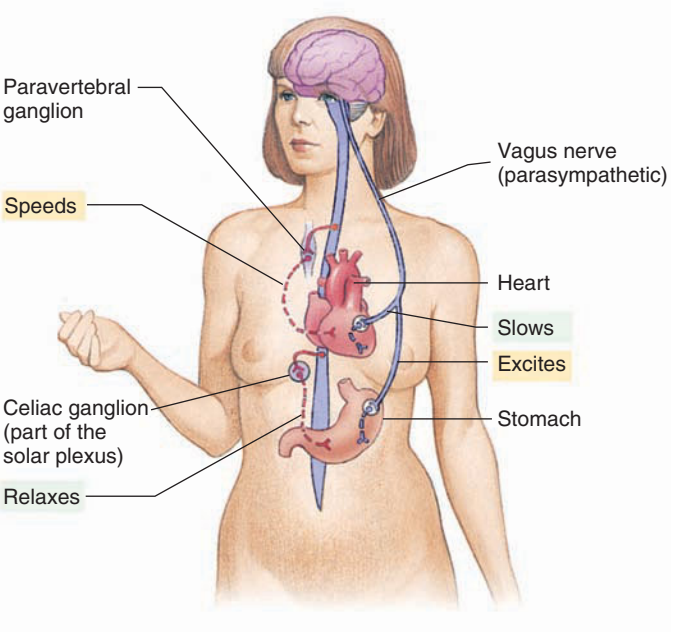


Figure 41-17 Dual innervation of the heart and stomach

A sympathetic nerve increases the heart rate, whereas the vagus nerve, a parasympathetic nerve, slows the heartbeat. In contrast, sympathetic nerves slow contractions of the stomach and intestine, whereas the vagus nerve stimulates contractions of the digestive organs. Sympathetic nerves are shown in red; postganglionic fibers are shown as dotted lines.

Instead of using a single efferent neuron, as in the somatic system, the autonomic system uses a relay of two neurons between the CNS and the effector. The first neuron, called the **preganglionic neuron,** has a cell body and dendrites within the CNS. Its axon, part of a peripheral nerve, ends by synapsing with a **postganglionic neuron.** The dendrites and cell body of the postganglionic neuron are in a ganglion outside the CNS. Its axon terminates near or on the effector. The sympathetic ganglia are paired, and a chain of them, the **paravertebral sympathetic ganglion chain,** runs on each side of the spinal cord from the neck to the abdomen. Some sympathetic preganglionic neurons do not end in these ganglia but pass on to **collateral ganglia** in the abdomen, close to the aorta and its major branches. Parasympathetic preganglionic neurons synapse with postganglionic neurons in **terminal ganglia** near or within the walls of the organs they innervate.

The sympathetic and parasympathetic systems also differ in the neurotransmitters they release at the synapse with the effector. Both preganglionic and postganglionic parasympathetic neurons secrete acetylcholine. Sympathetic postganglionic neurons

Key Point

Most organs are innervated by both sympathetic and parasympathetic nerves.

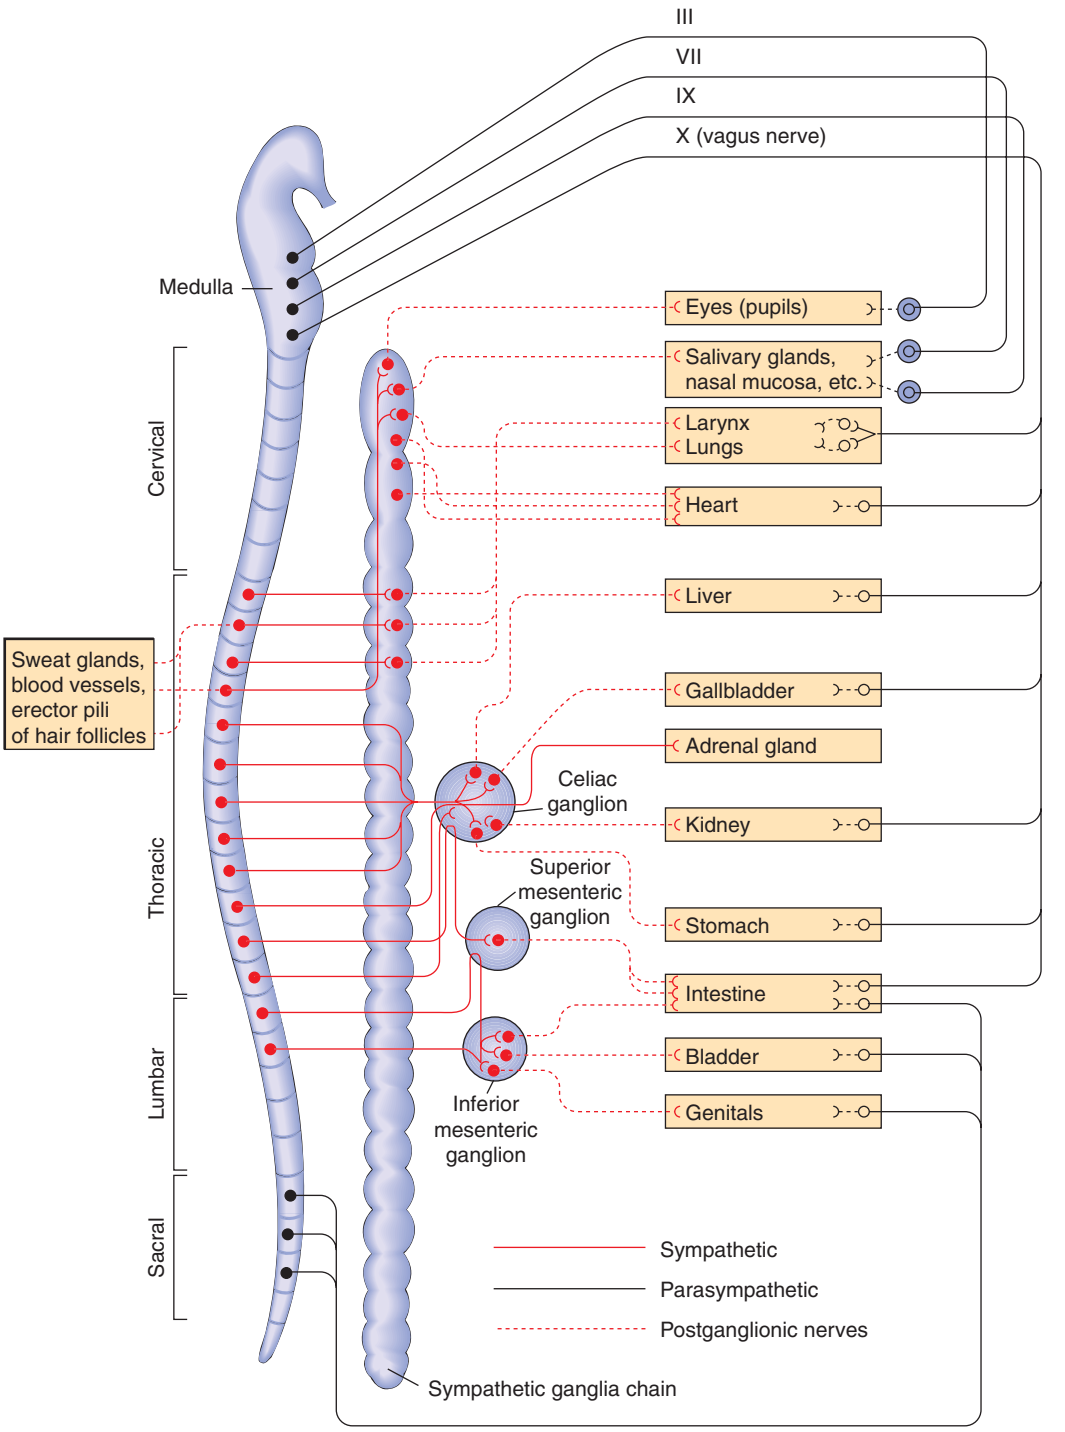

Figure 41-18 The sympathetic and parasympathetic systems

Complex as it appears, this diagram has been greatly simplified. Red lines represent sympathetic nerves, black lines represent parasympathetic nerves, and dotted lines represent postganglionic nerves.

release norepinephrine (although preganglionic sympathetic neurons secrete acetylcholine).

The autonomic division got its name from the original idea that it was independent of the CNS, that is, autonomous. Neurobiologists have disproved this and shown that the hypothalamus and many other parts of the CNS help regulate the autonomic system. Although the autonomic system usually functions automatically, its activities can be consciously influenced. Biofeedback provides a person with visual or auditory evidence concerning the status of an autonomic body function. For example, a tone may be sounded when blood pressure reaches a desirable level. Using such techniques, individuals have learned to control autonomic activities such as blood pressure, brain wave pattern, heart rate, and blood sugar level. Even certain abnormal heart rhythms can be consciously modified.

Review

- What are some functions of the PNS?
- What are some differences between the somatic division and the autonomic division?
- What are some differences in structure and function of the sympathetic system and the parasympathetic system?

EFFECTS OF DRUGS ON THE NERVOUS SYSTEM

Learning Objective

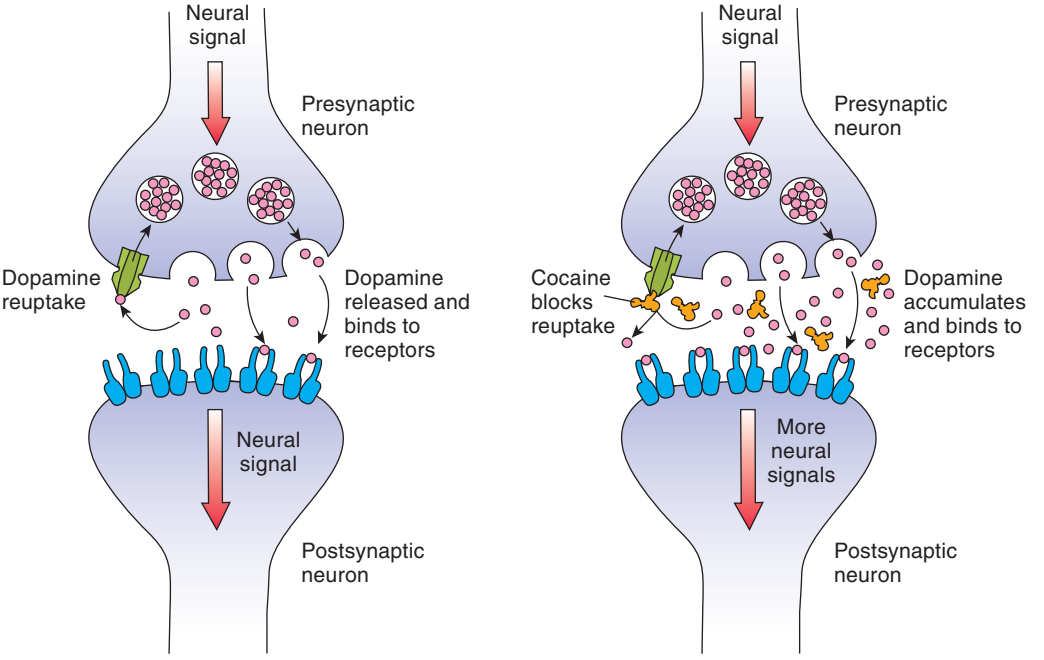
13 Discuss the biological actions and effects on mood of the following types of drugs: alcohol, antidepressants, barbiturates, anti-anxiety drugs, antipsychotic drugs, opiates, stimulants, hallucinogens, and marijuana.

About 25% of all prescribed drugs are taken to alter psychological conditions, and almost all the commonly abused drugs affect mood. Many act by changing the levels of neurotransmitters within the brain. In particular, levels of norepinephrine, serotonin, and dopamine influence mood.

According to the Substance Abuse and Mental Health Services Administration, an estimated 22.5 million individuals in the United States suffer from substance abuse or substance dependence. The report states that 19.1 million people in the United States were current users of illicit drugs in 2004, meaning they used an illicit drug at least once during the 30 days prior to the interview. More than 9 million children live with a parent who is dependent on alcohol and/or illicit drugs. Table 41-3 lists several commonly used and abused drugs and gives their effects. Also see *Focus On: Alcohol: The Most Abused Drug.*

Habitual use of almost any mood-altering drug can result in **psychological dependence,** in which the user becomes emotionally dependent on the drug. When deprived of it, the user craves the feeling of euphoria (well-being) the drug induces. Some drugs induce **tolerance** after several days or weeks. Response to the drug decreases, and greater amounts are required to obtain the desired effect. Tolerance often occurs because the liver cells are stimulated to produce more of the enzymes that metabolize and inactivate the drug. It can also occur when the number of postsynaptic receptors that bind with the drug decrease (*down-regulation*).

Drug addiction is a serious societal problem that involves compulsive use of a drug despite negative health consequences and negative effects on the ability to function socially and occupationally. Use of some drugs, such as heroin, tobacco, alcohol, and barbiturates, may also result in physical dependence, in which physiological changes occur that make the user dependent



(a) Reuptake of the neurotransmitter dopamine. Dopamine binds with a transporter (*green*) that shuttles it back into the presynaptic terminal.

(b) Cocaine blocks the reuptake of dopamine by binding competitively with the dopamine reuptake transporter. As a result, more dopamine is available to bind with postsynaptic receptors.

Figure 41-19 Mechanism of cocaine action

focus on

ALCOHOL: THE MOST ABUSED DRUG

After tobacco, alcohol is the leading cause of premature death in the United States. It is linked to approximately 100,000 deaths every year and costs our society more than $185 billion annually. According to the 2004 National Survey on Drug Use and Health, an estimated 16.7 million Americans (6.9%) engaged in binge drinking (five or more drinks) on five or more days during the month preceding the survey. The highest prevalence of binge and heavy drinking was for young adults aged 18 to 25 years.

More than half of men and women in the United States report that one or more of their close relatives have a drinking problem. Alcohol abuse is not limited to adults. About 4.6 million adolescents, or nearly one of every three high school students, experience negative consequences from alcohol use, including difficulty with parents, poor performance at school, and trouble with the law.

Alcohol abuse results in physiological, psychological, and social impairment and has serious negative consequences for family, friends, and society. Alcohol abuse has been linked to the following statistics:

- More than 40% of all traffic fatalities
- More than 50% of violent crimes and more than 60% of child-abuse and spouse-abuse cases
- More than 50% of suicides
- More than 15,000 babies born each year with serious birth defects because their mothers drank alcohol during pregnancy; fetal alcohol syndrome is the leading cause of preventable mental retardation in the United States
- Increased risk for certain cancers, especially those of the liver, esophagus, throat, and larynx

A single drink, that is, 12 oz of beer, 5 oz of wine, or 1.5 oz of 80-proof liquor, results in a blood-alcohol concentration of approximately 20 mg/dL (milligrams per deciliter). This represents about 0.5 oz of pure alcohol in the blood. Alcohol accumulates in the blood because absorption occurs more rapidly than do oxidation and excretion. Every cell in the body can take in alcohol from the blood. At first the drinker may feel stimulated, but alcohol actually depresses the CNS.

As blood-alcohol concentration rises, information processing, judgment, memory, sensory perception, and motor coordination all become progressively impaired. Depression and drowsiness generally occur. Contrary to popular belief, alcohol decreases sexual performance. Some individuals become loud, angry, or violent. A blood-alcohol concentration of 80 mg/dL (or 0.08 gm/100 mL) legally defines driving while intoxicated (DWI). A 170-pound man typically reaches this level by drinking four drinks in an hour on an empty stomach.

Alcohol metabolism occurs at a fixed rate in the liver, so only time, not coffee, decreases its effects. Because alcohol inhibits water reabsorption in the kidneys, more fluid is excreted as urine than is consumed. This results in dehydration that, together with low blood sugar level, may cause the stupor produced by excessive drinking.

In chronic drinkers, cells of the CNS adapt to the presence of the drug. This causes *tolerance* (more and more alcohol is needed to experience the same effect) and physical dependence. Abrupt withdrawal can result in sleep disturbances, severe anxiety, tremors, seizures, hallucinations, and psychoses.

The *A1* allele of the D2 dopamine receptor gene increases the risk for alcoholism. Individuals with this allele have fewer D2 dopamine receptors in their brain. Alcohol, like cocaine, heroin, amphetamines, and nicotine, enhances dopamine activity in the *mesolimbic dopamine pathway* of the brain. Individuals with the *A1* allele may compensate for their low dopamine levels by using alcohol and other drugs. However, the mechanisms underlying alcohol addiction are complex. Evidence suggests that many neurotransmitters are involved, including glutamate, serotonin, GABA, and opioid peptides. Recently, researchers used microarray techniques to identify a number of genes that may be associated with alcohol dependence.

Treatment for alcohol problems includes various forms of psychotherapy and use of drugs such as Disulfiram (Antabuse), which causes immediate symptoms of a "hangover" after alcohol intake. The group support offered by Alcoholics Anonymous (AA) has proved effective for many struggling with alcohol dependence.

on the drug. For example, when heroin or alcohol is withheld, the addict suffers characteristic withdrawal symptoms. Physical addiction can occur when a drug, for example, morphine, has components similar to substances that body cells normally manufacture on their own. Some highly addictive drugs, such as crack cocaine and methamphetamine, do not cause serious withdrawal symptoms.

The neurophysiological mechanisms for drug addiction involve the *mesolimbic dopamine pathway*. Neurons in this pathway signal neurons in an area of the limbic system (the nucleus accumbens). Effects on neurons in the mesolimbic dopamine pathway have been demonstrated in nicotine, heroin, amphetamine, and cocaine addiction. For example, amphetamines stimulate dopamine release. Cocaine blocks the reuptake of dopamine into presynaptic neurons, thus prolonging the stimulation (Fig. 41-19). Amphetamines or cocaine can increase dopamine concentration in the limbic system by up to 1000 times normal amounts! Prolonged drug use alters gene expression and changes neuron structure.

Review

- How does each of the following drugs affect the CNS: (1) alcohol, (2) antipsychotic drugs, (3) antidepressants, (4) amphetamines, and (5) MDMA ("Ecstasy")?

TABLE 41-3

Effects of Some Commonly Used Drugs

Name of Drug	Effect on Mood	Actions on Body	Side Effects/Dangers Associated with Abuse
Antidepressants			
Tricyclic antidepressants (e.g., Elavil, Anafranil)	Elevate mood; relieve depression; used to treat obsessive-compulsive behavior	Most block reuptake of biogenic amines (especially norepinephrine), increasing their concentration in synapses	Sedation, weight gain, sexual dysfunction
Selective serotonin reuptake inhibitors (SSRIs) (e.g., Prozac, Zoloft, Lexapro)	Relieve depression; used to treat obsessive-compulsive behavior	Block serotonin reuptake	Nausea, headache, insomnia, anxiety
MAO inhibitors (e.g., Parnate, Nardil)	Relieve depression	Block enzymatic breakdown of biogenic amines, increasing their concentration in synapses	Liver toxicity, excessive CNS stimulation; overdose may affect blood pressure, cause hallucinations
Anti-anxiety Medications			
Benzodiazepines (e.g., Xanax, Valium, Librium)	Sedation; induce sleep	Bind to GABA receptors on postsynaptic neuron; increase effectiveness of GABA in opening chloride channels, causing hyperpolarization; cause relaxation of skeletal muscles	Drowsiness, confusion; psychological dependence, addiction; effects additive with alcohol
Barbiturates ("downers") (e.g., phenobarbital)	Sedation; induce sleep	Bind to receptor adjacent to GABA receptor on chloride channels; chloride channels open so more chloride ions move in, causing hyperpolarization	Drowsiness, confusion; psychological dependence, tolerance, addiction; severe CNS depression, resulting in coma and death (especially lethal in combination with alcohol)
Antipsychotic Medications			
Phenothiazines (e.g., Thorazine, Mellaril, Stelazine)	Relieve symptoms of schizophrenia; reduce impulsive and aggressive behavior	Block dopamine receptors	Muscle spasms, shuffling gait, and other symptoms of Parkinson's disease
Newer antipsychotic medications (e.g., Abilify, Risperdal)	Similar to phenothiazines, but also increase motivation	Block dopamine receptors and other neurotransmitter receptors	Fewer side effects than with the phenothiazines
Narcotic Analgesics			
Opiates (e.g., morphine, codeine, Demerol, heroin)	Euphoria; sedation; relieve pain	Mimic actions of endorphins; bind to opiate receptors	Depress respiration; constrict pupils; impair coordination; tolerance, psychological dependence, addiction; convulsions, death from overdose
Cocaine	Brief, intense high with euphoria, followed by fatigue and depression	Stimulates release and inhibits reuptake of norepinephrine and dopamine, leading to CNS stimulation followed by depression; autonomic stimulation; dilation of pupils; local anesthesia	Mental impairment, convulsions, hallucinations, unconsciousness; death from overdose
Marijuana	Euphoria	Impairs coordination; impairs depth perception and alters sense of timing; impairs short-term memory (probably by decreasing acetylcholine levels in the hippocampus); inflames eyes; causes peripheral vasodilation	In large doses, sensory distortions, hallucinations, evidence of lowered sperm counts and testosterone levels
Amphetamines			
"Uppers," "pep pills," "crystal meth" (e.g., Dexedrine); methamphetamine is a popular club drug	Euphoria, stimulation, hyperactivity	Stimulate release and block reuptake of dopamine and norepinephrine; enhance flow of impulses in RAS, leading to increased heart rate, blood pressure; pupil dilation	Tolerance, physical dependence; hallucinations; increased blood pressure; psychotic episodes; death from overdose

TABLE 41-3

(Continued)

Name of Drug	Effect on Mood	Actions on Body	Side Effects/Dangers Associated with Abuse
Amphetamines (*continued*)			
Methylphenidate Amphetamine-like prescription stimulant commonly used to treat attention deficit hyperactivity disorder (ADHD) (e.g., Ritalin, Concerta)	CNS stimulation, but has calming effect on many children and adults who have ADHD; increases focus	Increases heart rate, blood pressure, and body temperature; like amphetamines and cocaine, blocks dopamine transporter so increases dopamine concentration in synapses	Not addictive at prescribed doses; used illegally and abused by some high school and college students who use them in higher doses than would be prescribed; can cause irregular heartbeat and respiration, hallucinations, delusions, and convulsions; abuse can lead to tolerance and physical addiction
MDMA (3,4-methylenedioxymethamphetamine) "Ecstasy" (most popular of club drugs)	Stimulation, sense of pleasure, self-confidence, feelings of closeness to others; mild hallucinogenic	CNS stimulant; damages serotonin pathways in rat and monkey brains	Hyperthermia (excessive body heat); overdose causes rapid heartbeat, high blood pressure, panic attacks, and seizures; long-term neurological changes; cognitive impairment
Rohypnol (flunitrazepam) "Date rape" drug, "roofies," "roach"	Sedative-hypnotic	Muscle relaxation; amnesia	Physical and psychological dependence; withdrawal may cause seizures; may be lethal when mixed with alcohol and/or other depressants
PCP (phencyclidine) "Angel dust," "ozone"	Feelings of strength, power, invulnerability, and a numbing effect on the mind	Increase in blood pressure and heart rate; shallow respiration; flushing, profuse sweating; numbness of extremities; muscular incoordination; changes in body awareness, similar to those associated with alcohol intoxication	Psychological dependence, craving; in adolescents, interferes with hormones related to growth and development; may interfere with learning; causes hallucinations, delusions, disordered thinking; high doses cause drop in blood pressure and heart rate, seizures, coma, and death; chronic use causes memory loss, difficulties with speech and thinking, and depression
LSD (lysergic acid diethylamide)	Overexcitation; sensory distortions, hallucinations	Alters levels of neurotransmitters in brain; potent CNS stimulator; dilates pupils, sometimes unequally; increases heart rate; raises blood pressure	Irrational behavior
Methaqualone (e.g., Quaalude, Sopor)	Hypnotic	Depresses CNS; depresses certain spinal reflexes	Tolerance, physical dependence; convulsions, death
Caffeine	Increases mental alertness; decreases fatigue and drowsiness	Acts on cerebral cortex; relaxes smooth muscle; stimulates cardiac and skeletal muscle; increases urine volume	Very large doses stimulate centers in the medulla (may slow the heart); toxic doses may cause convulsions
Nicotine	Lessens psychological tension	Stimulates sympathetic nervous system; increases dopamine in mesolimbic pathway	Tolerance, physical dependence; stimulates development of atherosclerosis by stimulating synthesis of lipid in arterial wall
Alcohol	Euphoria, relaxation, release of inhibitions	Depresses CNS; impairs vision, coordination, judgment; lengthens reaction time	Physical dependence; damage to pancreas and liver (e.g., cirrhosis); brain damage

SUMMARY WITH KEY TERMS

Learning Objectives

1 Contrast nerve nets and radial nervous systems with bilateral nervous systems (page 866).

- Nerve nets and radial nervous systems are typical of radially symmetrical invertebrates. Bilateral nervous systems are characteristic of bilaterally symmetrical animals.
- Cnidarians have a **nerve net** of nerve cells scattered throughout the body; they have no central control organ. Echinoderms typically have a **radial nervous system** consisting of a nerve ring and nerves that extend to various parts of the body.
- In a **bilateral nervous system,** nerve cells concentrate to form **nerves, nerve cords, ganglia,** and **brain;** typically, sense organs are concentrated in the head region. An increased number of interneurons and more complex synaptic contacts permit a wide range of responses.
- In planarian flatworms the bilateral nervous system includes **cerebral ganglia** and, usually, two solid ventral nerve cords connected by transverse nerves. Annelids and arthropods typically have a ventral nerve cord and numerous ganglia. The cerebral ganglia of arthropods have specialized regions. Octopods and other cephalopod mollusks have highly developed nervous systems with neurons concentrated in a central region.

ThomsonNOW™ Learn more about various nervous systems by clicking on the figures in ThomsonNOW.

2 Identify trends in the evolution of the invertebrate nervous system (page 866).

- Trends in nervous system evolution include increased numbers and concentration of nerve cells; specialization of function; increased number of association neurons; more complex synaptic contacts; and **cephalization,** formation of a head.

3 Describe the two main divisions of the vertebrate nervous system (page 867).

- The vertebrate nervous system consists of the **central nervous system (CNS)** and **peripheral nervous system (PNS).** The CNS consists of the brain and dorsal, tubular **spinal cord.** The PNS consists of sensory receptors and nerves.

ThomsonNOW™ Learn more about the vertebrate nervous system by clicking on the figure in ThomsonNOW.

4 Trace the development of the principal vertebrate brain regions from the hindbrain, midbrain, and forebrain; and compare the brains of fishes, amphibians, reptiles, birds, and mammals (page 868).

- In the vertebrate embryo, the brain and spinal cord arise from the **neural tube.** The anterior end of the tube differentiates into **hindbrain, midbrain,** and **forebrain.**
- The hindbrain subdivides into the **metencephalon** and **myelencephalon.** The myelencephalon develops into the **medulla,** which contains vital centers and other reflex centers. The **fourth ventricle,** the cavity of the medulla, communicates with the central canal of the spinal cord. The metencephalon gives rise to the **cerebellum,** which is responsible for muscle tone, posture, and equilibrium, and to the **pons,** which connects various parts of the brain.
- The midbrain is the largest part of the brain in fishes and amphibians. It is their main association area, linking sensory input and motor output. In reptiles, birds, and mammals, the midbrain serves as a center for visual and auditory reflexes. The medulla, pons, and midbrain make up the **brain stem.**
- The forebrain differentiates to form the **diencephalon** and **telencephalon.** The diencephalon develops into the thalamus and hypothalamus. The **thalamus** is a relay center for motor and sensory information. The **hypothalamus** controls autonomic functions; links nervous and endocrine systems; controls temperature, appetite, and fluid balance; and is involved in some emotional and sexual responses.
- The telencephalon develops into the cerebrum and **olfactory bulbs.** In most vertebrates the **cerebrum** is divided into right and left **hemispheres.** In fishes and amphibians, the cerebrum mainly integrates incoming sensory information. In birds, the corpus striatum controls complex behavior patterns, such as flying and singing.
- In mammals, the **neocortex** accounts for a large part of the **cerebral cortex,** the **gray matter** of the brain. The cerebrum has complex association functions.

ThomsonNOW™ Explore the early development of the vertebrate nervous system and the evolution of the vertebrate brain by clicking on the figures in ThomsonNOW.

5 Describe the structure and functions of the human spinal cord (page 871).

- The human brain and spinal cord are protected by bone and three **meninges**—the **dura mater, arachnoid,** and **pia mater;** the brain and spinal cord are cushioned by **cerebrospinal fluid (CSF).**
- The spinal cord transmits impulses to and from the brain and controls many **reflex actions.** The spinal cord consists of **ascending tracts,** which transmit information to the brain, and **descending tracts,** which transmit information from the brain. Its gray matter contains nuclei that serve as reflex centers.

ThomsonNOW™ Learn more about the spinal cord by clicking on the figure in ThomsonNOW.

- A **withdrawal reflex** involves sensory receptors; sensory neurons, interneurons, and motor neurons; and effectors, such as muscles.

6 Describe the structure and functions of the human cerebrum (page 871).

- The human cerebral cortex consists of gray matter, which forms folds or **convolutions.** Deep furrows between the folds are called **fissures.**
- The cerebrum is functionally divided into **sensory areas** that receive incoming sensory information; **motor areas** that control voluntary movement; and **association areas** that link sensory and motor areas and are responsible for learning, language, thought, and judgment. The cerebrum consists of lobes, including the **frontal lobes, parietal lobes, temporal lobes,** and **occipital lobes.**
- The **white matter** of the cerebrum lies beneath the cerebral cortex. The **corpus callosum,** a large band of white matter, connects right and left hemispheres. The **basal ganglia,** a cluster of nuclei within the white matter, are important centers for motor function.

ThomsonNOW™ Learn more about the human brain by clicking on the figures in ThomsonNOW.

7 Describe the sleep–wake cycle, and contrast rapid-eye-movement (REM) sleep and non-REM sleep (page 871).

- Brain activity cycles in a sleep–wake pattern that is regulated by the hypothalamus and brain stem. **Alpha wave** patterns are characteristic of relaxed states. **Beta wave** patterns accompany heightened mental activity; and slower-frequency, higher-amplitude **theta** and **delta waves** are characteristic of non-REM sleep.
- The **reticular activating system (RAS)** is an arousal system; its neurons filter sensory input, selecting which information is transmitted to the cerebrum.
- Electrical activity of the cerebral cortex and metabolic rate slow during **non-REM sleep,** whereas dreaming characterizes **REM sleep.**
- The body's main biological clock—the **suprachiasmatic nucleus**—receives information about light and dark and apparently transmits it to other nuclei that regulate sleep. When sleep centers are activated, they release **serotonin.**

8 Describe the actions of the limbic system (page 871).

- The **limbic system** of the brain affects the emotional aspects of behavior, motivation, sexual activity, autonomic responses, and biological rhythms. The **hippocampus** is important in categorizing information and consolidating memories. The **amygdala** evaluates incoming information and signals danger.

9 Relate neural plasticity to synaptic plasticity, and give three examples of neural plasticity (page 880).

- Changes in behavior are possible because of **neural plasticity,** the ability of the nervous system to change in response to experience. Examples include learning to walk, ride a bicycle, or speak a new language. **Synaptic plasticity** is the ability of the nervous system to modify synapses, which allows learning and remembering. Synaptic plasticity appears to be the major form of neural plasticity.

10 Summarize how the brain processes information (page 880).

- **Learning** is the process by which we acquire knowledge or skills as a result of experience. **Memory** is the process by which information is encoded, stored, and retrieved. **Implicit memory** is unconscious ("how-to") memory for perceptual and motor skills. **Explicit memory** is factual memory of people, places, or objects.
- **Short-term memory** lets us recall information, such as a telephone number, for a few minutes. Information can be transferred from short-term memory to **long-term memory.**
- Learning and memory involve long-term functional changes at synapses. Known as **long-term potentiation (LTP),** such changes involve increased sensitivity to an action potential by a postsynaptic neuron. **Long-term depression (LTD)** is a long-lasting decrease in the strength of synaptic connections. Long-term memory storage involves gene activation. The transcription factor **CREB** is an important signaling molecule in the memory pathway. The physical structure and chemistry of the brain can be altered by environmental experience.

11 Describe the organization of the peripheral nervous system, and compare its somatic and autonomic divisions (page 883).

- The PNS consists of sensory receptors and nerves, including the **cranial nerves** and **spinal nerves** and their branches. The **somatic division** of the PNS responds to changes in the external environment. The **autonomic division** regulates the internal activities of the body.

12 Contrast the sympathetic and parasympathetic divisions of the autonomic system, and give examples of the effects of these systems on specific organs such as the heart and intestine (page 883).

- The **sympathetic system** permits the body to respond to stressful situations. The **parasympathetic system** influences organs to conserve and restore energy. Many organs are innervated by sympathetic and parasympathetic nerves, which function in opposite ways. For example, the sympathetic system increases heart rate, whereas the parasympathetic system decreases heart rate.

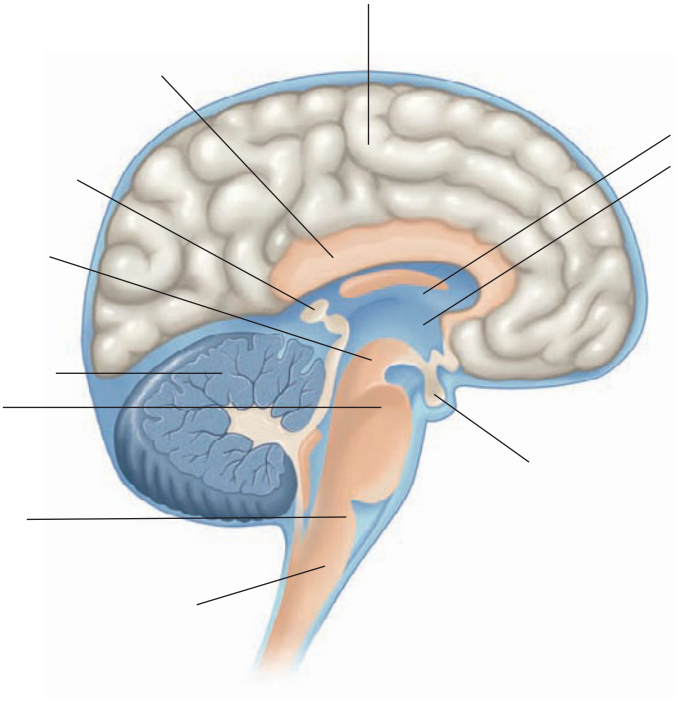
13 Discuss the biological actions and effects on mood of the following types of drugs: alcohol, antidepressants, barbiturates, anti-anxiety drugs, antipsychotic drugs, opiates, stimulants, hallucinogens, and marijuana (page 886).

- Many drugs alter mood by increasing or decreasing the concentrations of specific neurotransmitters within the brain. See Table 41-3 for a summary of these drugs.
- Habitual use of mood-altering drugs can result in **psychological dependence** or **drug addiction.** Many drugs induce **tolerance,** in which the body's response to the drug decreases so that greater amounts are needed to obtain the desired effect.

TEST YOUR UNDERSTANDING

1. A radially symmetrical animal such as *Hydra* is likely to have (a) a forebrain (b) a nerve net (c) cerebral ganglia (d) a ventral nerve cord (e) cerebral ganglia and a nerve net
2. In vertebrate embryos the brain develops from the (a) spinal cord (b) sympathetic nervous system (c) parasympathetic nervous system (d) neural tube (e) forebrain
3. Which part of the brain maintains posture, muscle tone, and equilibrium? (a) cerebrum (b) medulla (c) cerebellum (d) neocortex (e) thalamus
4. Which part of the brain controls autonomic functions and regulates body temperature? (a) cerebrum (b) hypothalamus (c) cerebellum (d) pons (e) thalamus
5. In a withdrawal reflex, following reception a signal is transmitted by (a) a motor neuron to an association neuron in the CNS (b) an association neuron in the CNS to an afferent neuron (c) an afferent neuron in the CNS to a motor neuron (d) a sensory neuron to an interneuron in the CNS (e) a sensory neuron to an interneuron in the PNS
6. Association areas in the human brain are concentrated in the (a) cerebral cortex (b) medulla (c) ventricle (d) hippocampus (e) meninges
7. The human brain is protected by (a) meninges, cerebrospinal fluid, and skull bones (b) meninges and skull bones only (c) dura mater and fourth ventricle (d) pia mater and skull bones (e) arachnoid, pia mater, cerebrospinal fluid, and ganglia
8. Which of the following is *not* a function of the spinal cord? (a) controls many reflex actions (b) transmits information to the brain (c) transmits information from the brain (d) regulates sleep–wake cycles (e) controls the withdrawal reflex

9. The most prominent part of the amphibian brain is the (a) midbrain (b) medulla (c) cerebellum (d) neocortex (e) cerebrum
10. The visual centers are located in the (a) parietal lobes (b) thalamus (c) occipital lobes (d) limbic lobes (e) frontal lobes
11. As you are answering these questions, what is the predominant type of wave your brain is emitting? (a) REM (b) alpha (c) theta (d) delta (e) beta
12. Implicit memory is (a) short-term memory (b) long-term memory (c) factual knowledge of people, places, or objects (d) unconscious memory for perceptual or motor skills (e) learning that depends on long-term depression (LTD)
13. Long-term potentiation (LTP) (a) is mainly the responsibility of cranial nerve X (b) is a long-lasting increase in synaptic strength (c) is associated with short-term memory (d) is a long-lasting decrease in synaptic strength (e) occurs mainly during REM sleep
14. The heart rate is slowed by (a) sympathetic nerves (b) parasympathetic nerves (c) corpus callosum (d) both sympathetic and parasympathetic nerves (e) the hippocampus working together with sympathetic nerves
15. After taking a mood-altering drug for several weeks, a patient notices it no longer works as effectively. This is an example of (a) psychological dependence (b) withdrawal (c) addiction (d) tolerance (e) neurotransmitter increases
16. Amphetamines (a) affect neurons in the mesolimbic dopamine pathway (b) decrease the amount of dopamine secreted (c) do not result in tolerance (d) are sometimes referred to as *downers* (e) are CNS depressants
17. Label the diagram. Use Figure 41-11a to check your answers.



CRITICAL THINKING

1. Imagine that you have just become a parent. What kinds of things can you do to enhance the development of your child's intellectual abilities?
2. What is the adaptive function of the limbic system when you are in danger?
3. Hypothesize a possible relationship between inheritance and intelligence based on gene activation during information processing.
4. **Evolution Link.** What general trends can you identify in the evolution of the vertebrate brain?
5. **Evolution Link.** CREB has been shown to be a signaling molecule in the memory pathway in many animals, including fruit flies and mice. What does this suggest about the evolution of learning and memory?

Sensory Systems

Merlin D. Tuttle/Bat Conservation International/Photo Researchers, Inc.

Bats are guided by echoes. This California leaf-nosed bat (*Macrotus californicus*) has located an insect.

KEY CONCEPTS

Sensory receptors detect information about changes in the internal or external environment.

Steps that take place in sensory processing include sensory reception, energy transduction, transmission of signals, and interpretation in the brain.

Mechanoreceptors respond to touch, pressure, gravity, stretch, or movement.

Most animals have mechanoreceptors that detect motion and position; in vertebrates, the vestibular apparatus in the inner ear helps maintain equilibrium.

In vertebrates, the organ of Corti within the cochlea of the inner ear contains auditory receptors.

Most organisms have chemoreceptors for taste and smell that detect chemical substances in food, water, and air.

Almost all organisms respond to light; in vertebrates, the retina contains the photoreceptor cells, rods and cones.

Have you heard dolphins make clicking sounds? Humans can hear only a limited number of the wide range of sound frequencies that dolphins emit. Dolphins, bats, and a few other vertebrates detect distant objects by *echolocation,* sometimes called biosonar. Echolocation works something like radar but uses sound rather than radio waves. For example, a bat emits high-pitched sounds that bounce off objects in its path and echo back. By rapidly responding to the echo, the bat skillfully avoids obstacles and captures prey (see photograph). Using echolocation, bats and dolphins determine the size, shape, texture, and density of an object, as well as its location. Certain moths and other insect prey have evolved the ability to detect sounds emitted by some foraging bats. Through the course of evolution, some species of bats have adapted to this ability of their prey and now emit even higher-frequency sounds that their prey cannot detect.

By informing an animal about its environment, *sensory systems* are the link between the animal and the outside world. The kinds of sensory receptors an animal has and the way in which the brain *perceives* incoming sensory information determine what the animal's world is like. We humans live in a world of rich colors, numerous shapes, and varied sounds. But we cannot hear the high-pitched whistles that are audible to dogs and cats or the ultrasonic echoes by which bats navigate. Nor do we ordinarily recognize our friends by their distinctive odors! And although vision is our dominant and most refined sense, we are blind to the ultraviolet (UV) hues that light up the world for insects.

We are most familiar with the senses of sight, hearing, smell, taste, and touch, but there are other senses. In fact, touch is a compound sense that allows us to detect pressure, pain, and temperature. Some sensory receptors allow us to sense balance, muscle tension, and joint position, so we have an awareness of our bodies. Birds and some other animals can detect changes in magnetic fields. Sharks, rays, and several other species of fishes detect electric fields.

In this chapter we will first examine how sensory systems function. Next we will introduce the major types of sensory receptors. We then discuss several types of sensory receptors with emphasis on auditory and visual receptors. ■

HOW SENSORY SYSTEMS WORK

Learning Objective

1 Describe sensory system function, including sensory reception, energy transduction, receptor potential, sensory adaptation, and perception.

Sensory receptors detect information about changes in the internal or external environment. These receptors consist of specialized neuron endings or specialized cells in close contact with neurons. Sensory receptors, along with other types of cells, make up complex **sense organs,** such as eyes, ears, nose, and taste buds. A human taste bud, for example, consists of modified epithelial cells that detect chemicals dissolved in saliva.

Several steps take place in sensory processing, including sensory reception, energy transduction, transmission of the signal, and interpretation in the brain. With minor variations, this is how all sensory systems operate.

Sensory receptors receive information

Sensory receptors receive stimuli from the external or internal environment. In the process of reception, they absorb a small amount of energy from some stimulus. Each kind of sensory receptor is especially sensitive to one particular form of energy. The photoreceptors of the human eye are stimulated by an extremely faint beam of light, and taste receptors are stimulated by a minute amount of a chemical compound.

Sensory receptors transduce energy

Sensory receptors *transduce,* or convert, the energy of the stimulus into electrical signals, the information currency of the nervous system. This process is known as **energy transduction.** When unstimulated, a sensory receptor maintains a *resting potential,* that is, a difference in charge between the inside and outside of the cell (see Chapter 40). Transduction couples a stimulus with the opening or closing of ion channels in the plasma membrane of sensory receptors. The permeability of the plasma membrane to various ions is altered.

A change in ion distribution causes a change in voltage across the membrane. If the difference in charge increases, the receptor becomes hyperpolarized. If the potential decreases, the receptor becomes depolarized. A change in membrane potential is a **receptor potential.** A receptor potential does not directly trigger an action potential. Like an excitatory postsynaptic potential, or EPSP (see Chapter 40), the receptor potential is a **graded response** in which the magnitude of change depends on the energy of the stimulus.

The function of a receptor potential is to generate action potentials that transmit information to the central nervous system (CNS). If the receptor is a separate cell, receptor potentials stimulate the release of a neurotransmitter, which flows across the synapse and binds to sites on sensory neurons (▮ Fig. 42-1). When a sensory neuron becomes sufficiently depolarized to reach its threshold level, an action potential is generated.

Many receptors are specialized neurons rather than separate cells. In these neurons, the specialized region of the plasma membrane that transduces energy does not generate action potentials. Current generated by receptor potentials flows to a region along the axon where an action potential can be generated.

As we discussed in Chapter 40, **sensory neurons,** also known as *afferent neurons,* transmit information from receptors to the CNS. The action potential travels along the axon of the sensory neuron to the CNS. In summary,

> Stimulus (such as light energy) ⟶ receptor transduces energy of stimulus into electrical energy ⟶ receptor potential ⟶ action potential in sensory neuron ⟶ signal transmitted to CNS

Sensory input is integrated at many levels

Sensory integration begins in the receptor itself. For example, receptor potentials produced by various stimuli are integrated by summation. Integration also occurs in the spinal cord and at various locations in the brain.

Sensory receptors adapt to stimuli

Many sensory receptors do not continue to respond at the initial rate, even if the stimulus continues at the same intensity. This process, called **sensory adaptation,** occurs for two reasons. First, during a sustained stimulus, the receptor sensitivity decreases and produces a smaller receptor potential (resulting in a lower frequency of action potentials in the sensory neurons). Second, changes take place at synapses in the neural pathway activated by the receptor. For example, the release of neurotransmitter from a presynaptic terminal may decrease in response to a series of action potentials.

Some receptors, such as those for pain or cold, adapt so slowly that they continue to trigger action potentials as long as

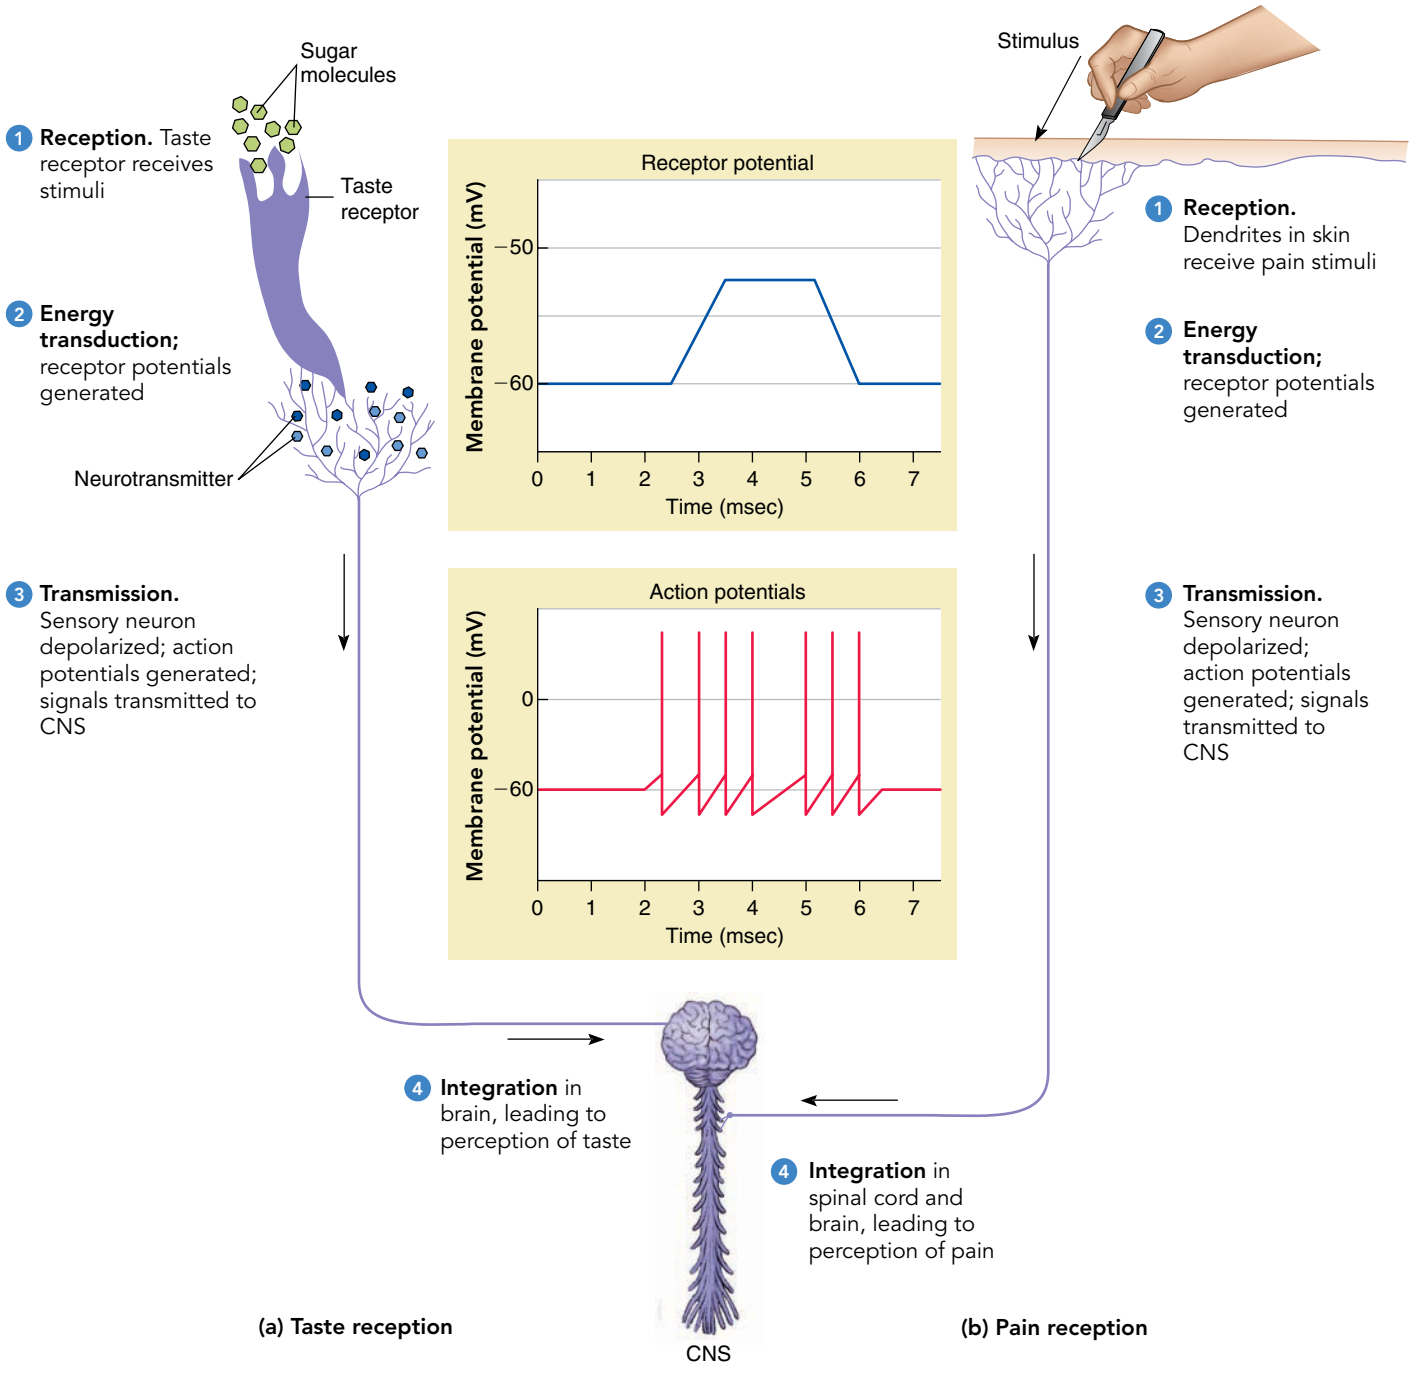

Figure 42-1 How sensory systems work

Sensory receptors receive stimuli, transduce stimulus energy to electrical energy, and thus generate receptor potentials. Action potentials are generated in sensory neurons that transmit signals to the CNS, where they are integrated.

the stimulus persists. Other receptors adapt rapidly, permitting us to ignore persistent unpleasant or unimportant stimuli. For example, when you first pull on a pair of tight jeans, your pressure receptors let you know that you are being squished, and you may feel uncomfortable. Soon, though, these receptors adapt, and you hardly notice the sensation of the tight fit. In the same way, people quickly adapt to odors that at first seem to assault their senses. Sensory adaptation enables an animal to discriminate between unimportant background stimuli that can be ignored and new or important stimuli that require attention.

Sensation depends on transmission of a coded message

How do you know whether you are seeing a blue sky, tasting a doughnut, or hearing a note played on a piano? All action poten-

tials are qualitatively the same. Light of the wavelength 450 nm (blue), sugar molecules (sweet), and sound waves of 440 hertz (Hz) (A above middle C) all cause transmission of similar action potentials. Our ability to differentiate stimuli depends on both the sensory receptor itself and on the brain. We can distinguish the color of a blue sky from the scent of cologne; a sweet taste from a light breeze; or the sound of a piano from the heat of the sun because cells of each sensory receptor are connected to specific neurons in particular parts of the brain. Because a receptor normally responds to only one type of stimulus (for example, light), the brain interprets a message arriving from a particular receptor as meaning that a certain type of stimulus occurred (such as a flash of color).

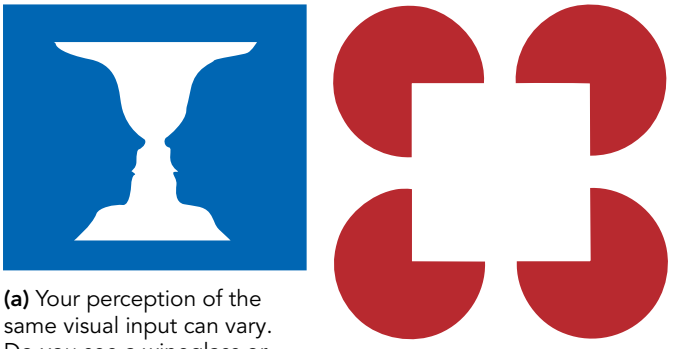
When stimulated, a sensory receptor initiates what might be considered a coded message, composed of action potentials transmitted by sensory neurons. This coded message is later decoded in the brain. Impulses from the sensory receptor may differ in the (1) total number of sensory neurons transmitting the signal, (2) specific neurons transmitting action potentials and their targets, (3) total number of action potentials transmitted by a given neuron, and (4) frequency of the action potentials transmitted by a given fiber. The intensity of a stimulus is coded by the frequency of action potentials fired by sensory neurons during the stimulus. A strong stimulus results in a greater depolarization of the receptor membrane, so the sensory neuron fires action potentials with greater frequency than would a weak stimulus. This variation is possible because as a graded response, the receptor potential can vary in magnitude.

The difference in sound intensity between the gentle rustling of leaves and a clap of thunder depends on the number of neurons transmitting action potentials as well as the frequency of the action potentials transmitted by each neuron. Just how the sensory receptor initiates different codes and how the brain analyzes and interprets them to produce various sensations are not yet completely understood.

Sensation takes place in the brain. Interpretation of the message and the type of sensation depends on which interneurons receive the message. The rods and cones of the eye do not see. When stimulated, they send a message to the brain that interprets the signals and translates them into a rainbow, an elephant, or a child. Artificial (for example, electrical) stimulation of brain centers can also result in sensation. In contrast, many sensory messages never give rise to sensations at all. For example, certain chemoreceptors sense internal changes in the body but never stir our consciousness.

Sensory perceptions are constructed by the mind

The brain interprets sensations by converting them to perceptions of stimuli. Sensory **perception** is the process of selecting, interpreting, and organizing sensory information. Sensory perceptions are constructed by the mind by comparing present sensory experience with our memories of past experiences. You may perceive the incoming visual and auditory input of a hissing snake very differently than does your friend or a herpetologist who studies snakes. Perceptions are also influenced by our state of mind at the time we receive sensory information. Optical illusions demonstrate that the brain can interpret sensory stimuli in various ways (Fig. 42-2a). The brain also modifies stimuli to make them more complete, familiar, or logical (Fig. 42-2b).



(a) Your perception of the same visual input can vary. Do you see a wineglass or the profiles of two faces?

(b) Do you "see" a white square? If so, your brain is completing a familiar pattern suggested by the right-angle wedges taken out of each of the four red circles.

TYPES OF SENSORY RECEPTORS

Learning Objective

2 Classify sensory receptors according to the location of stimuli to which they respond and according to the types of energy they transduce.

Sensory receptors can be classified according to the location of the stimuli to which they respond. **Exteroceptors** receive stimuli from the outside environment, enabling an animal to know and explore the world, search for food, find and attract a mate, recognize friends, and detect enemies. **Interoceptors** are sensory receptors within body organs that detect changes in pH, osmotic pressure, body temperature, and the chemical composition of the blood. You are not usually aware of messages sent to the CNS by these receptors as they work continuously to maintain homeostasis. You become aware of their activity when they signal certain internal conditions such as thirst, hunger, nausea, pain, and orgasm.

We can also classify sensory receptors based on the type of energy they transduce (Table 42-1). *Thermoreceptors* respond to heat and cold. *Electroreceptors* sense differences in electrical potential. Some electroreceptors are sensitive enough to detect Earth's magnetic field. *Nociceptors* (pain receptors) respond to mechanical, temperature, and other stimuli that could be damaging. *Mechanoreceptors* transduce mechanical energy—touch, pressure, gravity, stretching, and movement. These receptors

TABLE 42-1

Classification of Receptors by Type of Energy They Transduce

Type of Receptor	Type of Energy Transduced	Examples
Thermoreceptors	Heat	Temperature receptors in blood-sucking insects and ticks; pit organs in pit vipers; nerve endings and receptors in skin and tongues of many animals
Electroreceptors and electromagnetic receptors	Electrical; receptors sense differences in electrical potential; electromagnetic receptors detect magnetic fields	Electrical currents in water used to navigate by many fish and some amphibian species; magnetic fields used for orientation and migration
Nociceptors (pain receptors)	Mechanical; physical force such as strong touch, pressure; heat, temperature extremes; damaging chemicals	Neuron endings in skin and other tissues
Mechanoreceptors	Mechanical; change shape as a result of being pushed or pulled	Tactile receptors (free nerve endings, Merkel discs, Meissner corpuscles, Ruffini corpuscles, Pacinian corpuscles); respond to touch and pressure Proprioceptors; respond to movement and body position Muscle spindles; respond to muscle contraction Golgi tendon organs; respond to stretch of a tendon Joint receptors; respond to movement in ligaments Statocysts in invertebrates; have hair cells that respond to gravity Lateral line organs in fish; detect vibrations in the water; respond to waves and currents Vestibular apparatus Hair cells in saccule and utricle; respond to gravity, linear acceleration Hair cells in semicircular canals; respond to angular acceleration Hair cells in organ of Corti in cochlea; respond to pressure waves (sound)
Chemoreceptors	Specific chemical compounds	Taste buds; olfactory epithelium
Photoreceptors	Light	Eyespots; ommatidia in compound eye of arthropods; rods and cones in retina of vertebrates

convert mechanical forces directly into electrical signals. *Chemoreceptors* transduce the energy of certain chemical compounds, and *photoreceptors* transduce light energy.

Review

- Name five kinds of sensory receptors based on the type of energy they transduce. What is the specific function of each?

THERMORECEPTORS

Learning Objective

3 Identify three functions of thermoreceptors.

Thermoreceptors respond to heat and cold. Mosquitoes, ticks, and other blood-sucking arthropods use thermoreception in their search for an endothermic host. Some have temperature receptors on their antennae that are sensitive to changes of less than 0.5°C. At least two types of snakes—pit vipers and boas—use thermoreceptors to locate their prey (Fig. 42-3).

In mammals, which are endothermic, free nerve endings (and perhaps, specialized receptors) in the skin and tongue detect temperature changes in the outside environment. However,

Carmela Lesczynski/Animals Animals

Figure 42-3 Thermoreception

The pit organ of this bamboo viper (*Trimeresurus stejnegeri*) is a sense organ located between each eye and nostril. The pit organ of many snakes can detect the heat from an endothermic animal up to a distance of 1 to 2 m.

pain receptors sense extreme temperatures that pose a threat to the body. Thermoreceptors in the hypothalamus detect internal changes in temperature and receive and integrate information from receptors on the body surface. The hypothalamus then initiates homeostatic mechanisms that ensure a constant body temperature.

- What are the functions of thermoreceptors in mosquitoes, snakes, and mammals?

ELECTRORECEPTORS AND ELECTROMAGNETIC RECEPTORS

Learning Objective

4 Describe the functions of electroreceptors and electromagnetic receptors.

Electroreceptors sense differences in electrical potential. Some predatory species of sharks, rays, and bony fishes detect electric fields generated in the water by the muscle activity of their prey. Several groups of fishes have electric organs, specialized muscle or nerve cells that emit electrical signals and receive a feedback signal. In species that produce a weak electric current, electroreceptors may help in navigation. This mechanism is particularly useful in murky water, where visibility and olfaction are poor.

Electroreception also appears important in communication, for example, in recognizing a potential mate. Males and females have different frequencies of electric discharge. A few fishes, such as electric eels or electric rays, have electric organs in their heads capable of delivering powerful shocks (up to several hundred volts) that stun prey or predators. Weaker electrical signals are emitted continuously to help in assessing the environment, orienting themselves, and communicating.

Some electroreceptors, called **electromagnetic receptors,** are sensitive enough to detect Earth's magnetic field. When a shark, ray, or skate swims across one of Earth's magnetic field lines, its electromagnetic receptors detect changes that occur in electric currents. This information, which is integrated in the brain, helps the animal orient itself. Many other organisms, including some bacteria, insects, amphibians, fishes, reptiles, birds, and a few mammals, can also detect magnetic fields and use this information to orient themselves. Migratory birds and sea turtles are well-known examples of animals that use magnetic fields to navigate (discussed further in Chapter 51).

Review

- What are two functions of electroreceptors?
- What is the function of electromagnetic receptors?

NOCICEPTORS

Learning Objective

5 Describe the functions of nociceptors, and identify the roles of glutamate and substance P.

Pain receptors, called **nociceptors** (from the Latin *nocere,* meaning "to injure"), are free nerve endings (dendrites) of certain sensory neurons found in almost every tissue. Three main types of nociceptors have been identified. Mechanical nociceptors respond to strong tactile stimuli such as cutting, crushing, or pinching. Thermal nociceptors respond to temperature extremes (temperatures above 45°C or below 5°C). Other nociceptors respond to a variety of damaging stimuli, including certain chemicals.

When stimulated, nociceptors transmit signals through sensory neurons to interneurons in the spinal cord. The sensory neurons release the neurotransmitter **glutamate,** as well as several neuropeptides, including **substance P,** that enhance and prolong the actions of glutamate. The interneuron transmits the message to the opposite side of the spinal cord and then upward to the thalamus, where pain perception begins. From the thalamus, impulses are sent into the parietal lobes and several other cortical regions, including areas of the limbic system where the emotional aspects of the pain are processed. When pain signals reach the cerebrum, we become fully aware of the pain and can evaluate the situation.

Review

- What is the function of each main type of nociceptor?
- What is the function of substance P?

MECHANORECEPTORS

Learning Objectives

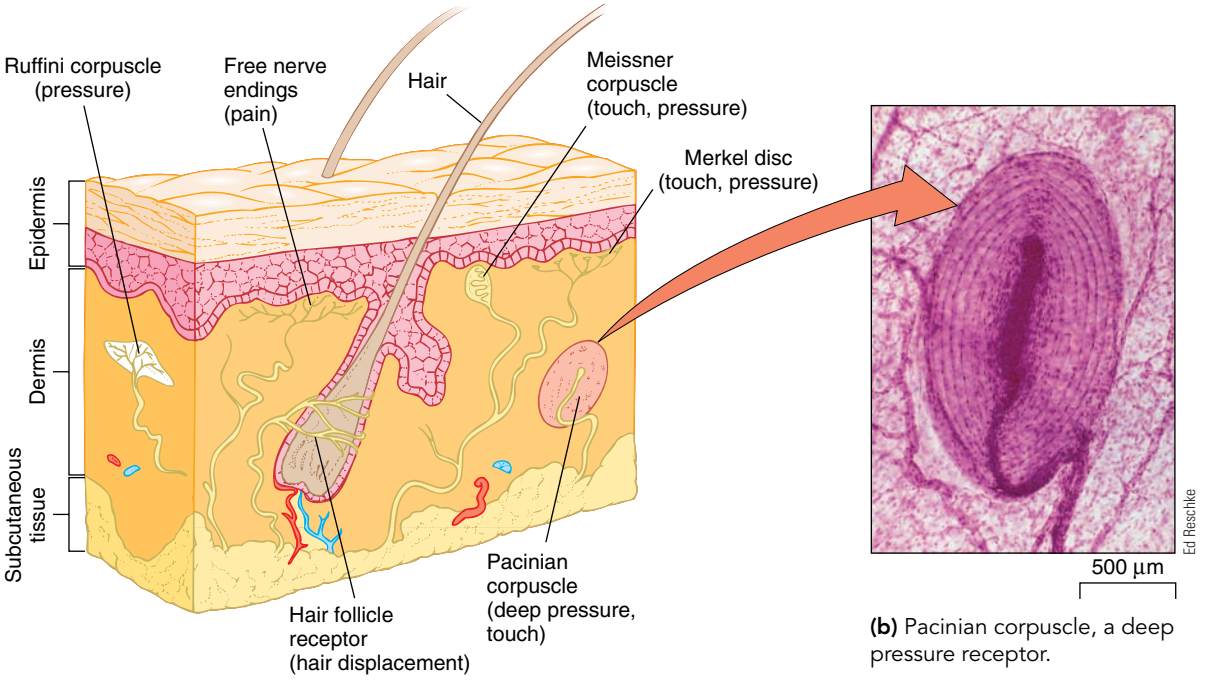
6 Compare the functions and mechanisms of action of the following mechanoreceptors: tactile receptors, proprioceptors, statocysts, hair cells, and lateral line organs.

7 Compare the structure and function of the saccule and utricle with that of the semicircular canals in maintaining equilibrium.

8 Trace the path taken by sound waves through the structures of the ear, and explain how the organ of Corti functions as an auditory receptor.

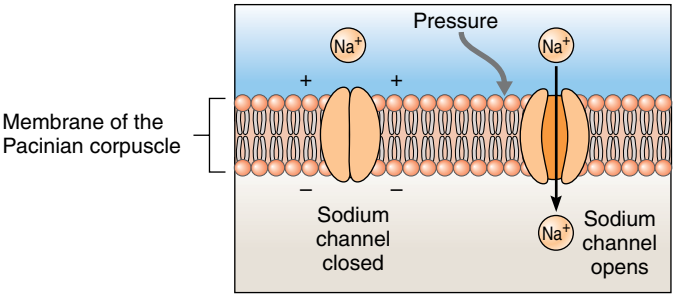
Mechanoreceptors are activated when they change shape as a result of being mechanically pushed or pulled. They transduce mechanical energy, permitting animals to feel, hear, and maintain balance. These receptors provide information about the shape, texture, weight, and topographic relations of objects in the external environment. Some mechanoreceptors are extremely sensitive. For example, alligators have pressure receptors on their faces that can detect the movement in the surrounding water caused by a single drop of falling water.

Certain mechanoreceptors enable an organism to maintain its body position with respect to gravity (for us, head up and feet down; for a dog, dorsal side up and ventral side down; for a tree sloth, ventral side up and dorsal side down).When displaced from its normal position, the animal quickly adjusts its body to reassume normal orientation. Mechanoreceptors continuously send information to the CNS regarding the position and movements of the body. Mechanoreceptors also provide information about the operation of internal organs. For example, they inform us about the presence of food in the stomach, feces in the rectum, urine in the bladder, and a fetus in the uterus.



(a) This diagrammatic section through the human skin illustrates several mechanoreceptors that respond to touch and pressure. Also shown are free nerve endings that respond to pain.

(b) Pacinian corpuscle, a deep pressure receptor.



(c) The mechanical forces these receptors sense cause Na^+ channels to open, depolarizing the axon.

Figure 42-4 ***Animated*** Sensory reception in human skin

Touch receptors are located in the skin

The simplest mechanoreceptors are free nerve endings in the skin. They detect touch, pressure, and pain when stimulated by objects that contact the body surface. In many invertebrates and vertebrates, **tactile** (touch) **receptors** lie at the base of a hair or bristle. These receptors may sense the body's orientation in space with respect to gravity. They may also detect air and water vibrations and contact with other objects. The tactile receptor is stimulated indirectly when the hair is bent or displaced. A receptor potential develops, and a few action potentials may be generated. This type of receptor responds only when the hair is moving. Even though the hair may be maintained in a displaced position, the receptor is not stimulated unless there is motion.

Thousands of specialized tactile receptors are located in mammalian skin (Fig. 42-4). **Merkel discs** sense touch and pressure. They adapt slowly, permitting us to know that an object continues to touch the skin. Three types of mechanoreceptors in the skin have encapsulated endings: Meissner corpuscles, Ruffini corpuscles, and Pacinian corpuscles. **Meissner corpuscles** are sensitive to light touch and pressure and adapt quickly to a sustained stimulus. **Ruffini corpuscles,** which adapt very slowly, inform us of heavy, continuous touch and pressure.

Pacinian corpuscles are sensitive to deep pressure that causes rapid movement of the tissues. They are especially sensitive to stimuli that vibrate. The Pacinian corpuscle consists of a neuron ending surrounded by concentric connective tissue layers interspersed with fluid. Compression causes displacement of the layers, which stimulates the axon. Even though the displacement is maintained under steady compression, the receptor potential rapidly falls to zero, and action potentials cease—an excellent example of sensory adaptation.

Proprioceptors help coordinate muscle movement

Proprioceptors help animals maintain postural relations—the position of one part of the body with respect to another. Located within muscles, tendons, and joints, proprioceptors continuously respond to tension and movement. With their continuous input, an animal can perceive the positions of its arms, legs, head,

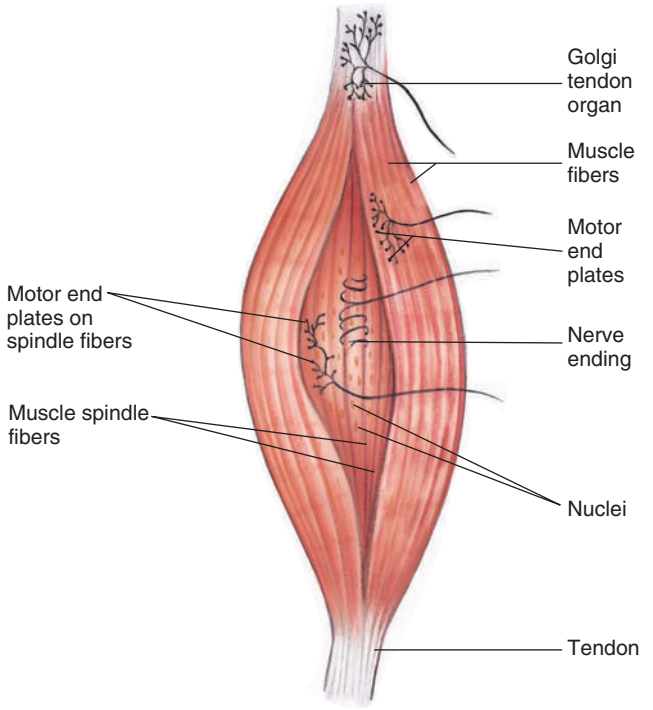


Figure 42-5 Proprioceptors

Muscle spindles detect muscle movement. A muscle spindle consists of an elongated bundle of specialized muscle fibers. Golgi tendon organs respond to tension in muscles and their associated tendons.

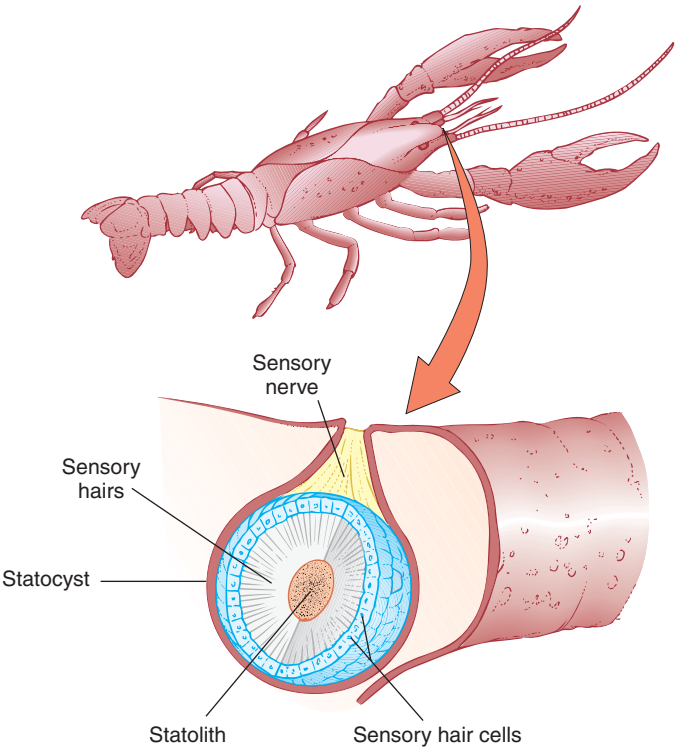

Figure 42-6 A statocyst

Many invertebrates have statocysts, receptors that sense gravitational force and provide information about orientation of the body with respect to gravity.

and other body parts, along with the orientation of its body as a whole. This information is essential for all forms of locomotion and for all coordinated and skilled movements, from spinning a cocoon to completing a reverse one-and-a-half dive with twist. With the help of proprioceptors, we carry out activities such as dressing or playing the piano even in the dark.

Vertebrates have three main types of proprioceptors: **muscle spindles,** which detect muscle movement (Fig. 42-5); **Golgi tendon organs,** which respond to tension in contracting muscles and in the tendons that attach muscle to bone; and **joint receptors,** which detect movement in ligaments. Impulses from proprioceptors help coordinate the contractions of the several distinct muscles involved in a single movement. Without such receptors, complicated, skilled acts would be impossible. Proprioceptors are also important in maintaining balance.

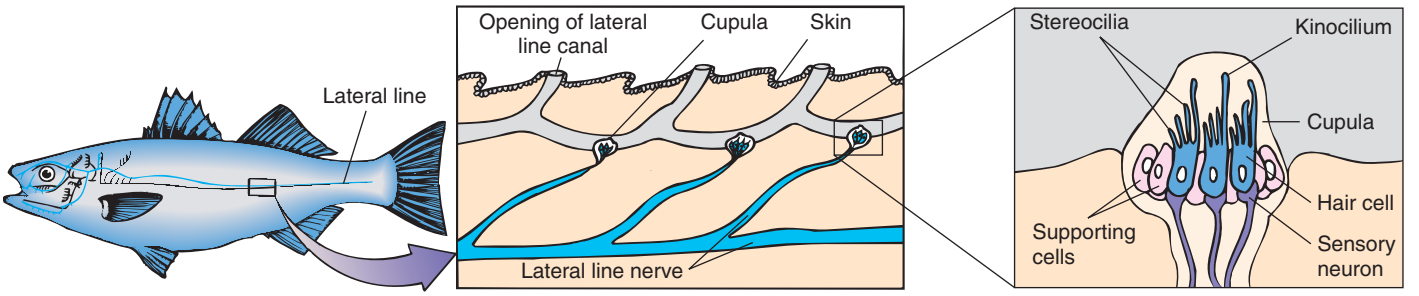
Proprioceptors are probably more numerous and more continually active than any of the other sensory receptors, although we are less aware of them than of most of the others. As long as the stimulus is present, receptor potentials are maintained (although not at constant magnitude) and action potentials continue to be generated. Proprioceptors continuously send signals to inform the brain about position.

The mammalian muscle spindle, one of the more versatile stretch receptors, helps maintain muscle tone. It is a bundle of specialized muscle fibers, with a central region encircled by sensory neuron endings. These neurons continue to transmit signals for a prolonged period, in proportion to the degree of stretch.

Many invertebrates have gravity receptors called statocysts

Many invertebrates—from jellyfish to crayfish—have gravity receptors called **statocysts** (Fig. 42-6). Statocysts are the simplest organs of equilibrium. A statocyst is basically an infolding of the epidermis lined with receptor cells, called sensory hair cells, equipped with sensory hairs (not true hairs). The cavity contains one or more **statoliths,** tiny granules of loose sand grains or calcium carbonate held together by an adhesive material secreted by cells of the statocyst. Normally the particles are pulled downward by gravity and stimulate the sensory cells.

When the animal changes position, the statocyst tilts and the statolith moves in the same direction. This movement bends the sensory hairs. Each sensory hair cell responds maximally when the animal is at a particular position with respect to gravity. The mechanical displacement results in receptor potentials and action potentials that inform the CNS of the change in position. By "knowing" which sensory cells are firing, the animal knows where "down" is and can correct any abnormal orientation.



(a) The lateral line organ is a canal that extends the length of the body.

(b) The canal has numerous groupings of hair cells and openings to the outside environment.

(c) The receptor cells are hair cells. Each hair cell has stereocilia and a kinocilium that are covered with a gelatinous cupula. The hair cells respond to waves, currents, and other disturbances in the water, informing the fish of obstacles or moving objects.

Figure 42-7 Lateral line organ

In a classic experiment, the function of the statocyst was demonstrated by substituting iron filings for sand grains in the statocysts of crayfish. The force of gravity was overcome by holding magnets above the animals. The iron filings were attracted upward toward the magnets, and the crayfish began to swim upside down in response to the new information provided by their gravity receptors.

Hair cells are characterized by stereocilia

Vertebrate **hair cells** are mechanoreceptors that detect movement. They are the sensory receptors, located in the lateral line of fishes, that detect water movements (Fig. 42-7). Hair cells help maintain position and equilibrium and are important in hearing.

The surface of a vertebrate hair cell typically has a single long **kinocilium** and many shorter **stereocilia,** hairlike projections that increase in length from one side of the hair cell to the other (see Fig. 42-7c). A kinocilium is a true cilium with a 9×2 arrangement of microtubules (see Chapter 4). In contrast, stereocilia are not really cilia. They are microvilli that contain actin filaments.

Mechanical stimulation of the stereocilia causes voltage changes. Mechanical stimulation in one direction causes depolarization and release of neurotransmitter, whereas mechanical stimulation in the opposite direction results in hyperpolarization. However, hair cells have no axons and do not produce their own action potentials. Rather, they release neurotransmitters that depolarize associated neurons.

Lateral line organs supplement vision in fishes

Lateral line organs of fishes and aquatic amphibians detect vibrations in the water. They inform the animal of obstacles in its way and of moving objects such as prey, enemies, and others in its school. Typically, the lateral line organ is a long canal running the length of the body and continuing into the head. The canal is lined with sensory hair cells. The tips of the stereocilia are enclosed by a **cupula,** a mass of gelatinous material secreted by the hair cells.

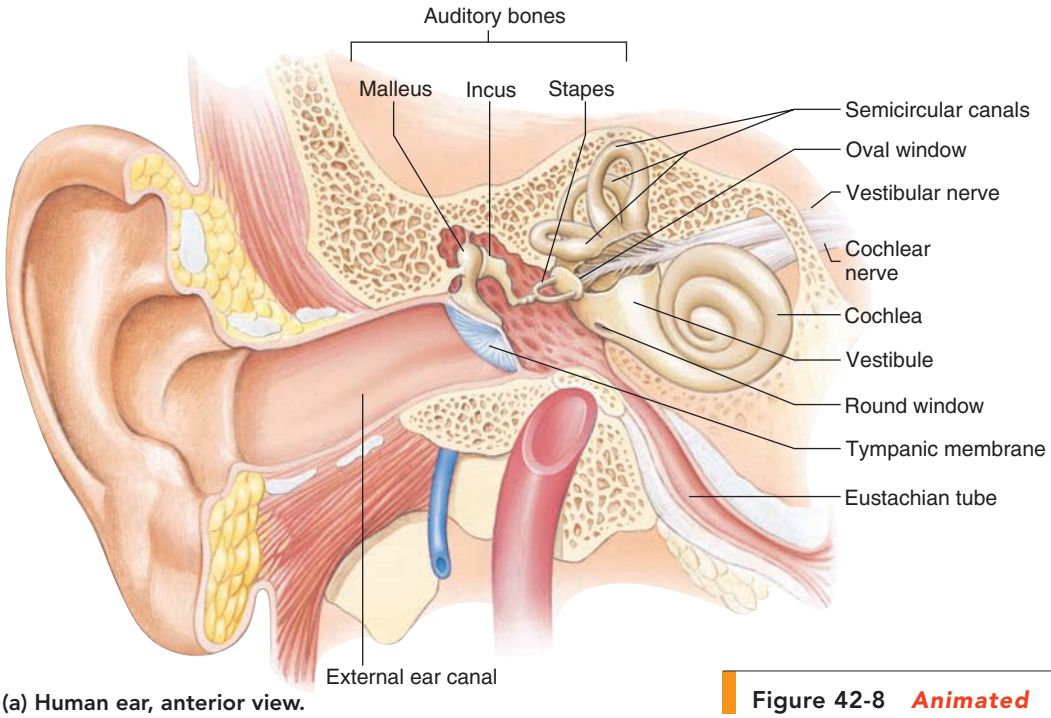
Pressure waves, currents, and even slight movement in the water cause vibrations in the lateral line organ. As the water moves the cupula, the stereocilia bend. This changes the membrane potential of the hair cell, which may then release neurotransmitter. If an associated sensory neuron is sufficiently stimulated, an action potential may be dispatched to the CNS.

The vestibular apparatus maintains equilibrium

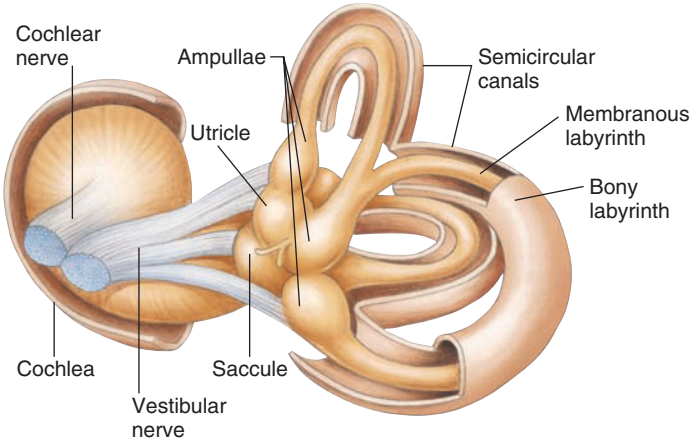
When you think of the ear, you probably think of hearing. However, in vertebrates its main function is to help maintain equilibrium. Many vertebrates do not have outer or middle ears, but all have inner ears (Fig. 42-8). The mammalian **inner ear** includes organs of equilibrium equipped with hair cells that sense the position of the body with respect to gravity.

The inner ear is a group of interconnected canals and sacs, called the **labyrinth,** which includes a membranous labyrinth that fits inside a bony labyrinth. In mammals the membranous labyrinth has two saclike chambers—the **saccule** and the **utricle**—and three **semicircular canals.** Collectively, the saccule, utricle, and semicircular canals are called the **vestibular apparatus** (see Fig. 42-8b). Destruction of these organs leads to a considerable loss of the sense of equilibrium. A pigeon whose vestibular apparatus has been destroyed cannot fly but in time can relearn how to maintain equilibrium by using visual stimuli.

The sensory cells of the saccule and utricle are hair cells similar to those of the lateral line organ (Fig. 42-9). The stereocilia projecting from the hair cells are covered by a gelatinous cupula



(a) Human ear, anterior view.



(b) Vestibular apparatus consists of saccule, utricle, and semicircular canals. The utricle and saccule are best seen in the posterior view shown here.

Figure 42-8 ***Animated*** The human ear

in which calcium carbonate ear stones, called **otoliths,** are embedded. The hair cells in the saccule and utricle lie in different planes.

Normally, the pull of gravity causes the otoliths to press against the stereocilia, stimulating them to initiate impulses. Sensory neurons at the bases of the hair cells transmit these signals to the brain. When the head is tilted or in linear acceleration (increasing speed when the body is moving in a straight line), otoliths press on the stereocilia of different cells, deflecting them. Deflection of the stereocilia toward the kinocilium depolarizes the hair cell. Deflection in the opposite direction hyperpolarizes the hair cell. Thus, depending on the direction of movement, the hair cells release more or less neurotransmitter. The brain interprets the neural messages so the animal is aware of its full body position relative to the ground regardless of how its head is positioned.

Information about turning movements, referred to as angular acceleration, is provided by the three semicircular canals. Each canal, a hollow ring connected with the utricle, lies at right angles to the other two and is filled with fluid called **endolymph.** At one of the openings of each canal into the utricle, there is a small, bulblike enlargement, the **ampulla.** Within each ampulla lies a clump of hair cells called a **crista** (pl., *cristae*), similar to the groups of hair cells in the utricle and saccule. No otoliths are present. The stereocilia of the hair cells of the cristae are stimulated by movements of the endolymph in the canals (Fig. 42-10).

When the head is turned, there is a lag in the movement of the fluid within the canals. The stereocilia move in relation to the fluid and are stimulated by its flow. This stimulation produces not only the consciousness of rotation but also certain reflex movements in response to it. These reflexes cause the eyes and head to move in a direction opposite that of the original rotation. Because the three canals are in three different planes, head movement in any direction stimulates fluid movement in at least one of the canals.

We humans are used to movements in the horizontal plane but not to vertical movements (parallel to the long axis of the upright body). The motion of an elevator or of a ship pitching in a rough sea stimulates the semicircular canals in an unusual way and may cause seasickness or motion sickness, with resultant nausea or vomiting. When a seasick person lies down, the movement stimulates the semicircular canals in a more familiar way and nausea is less likely to occur.

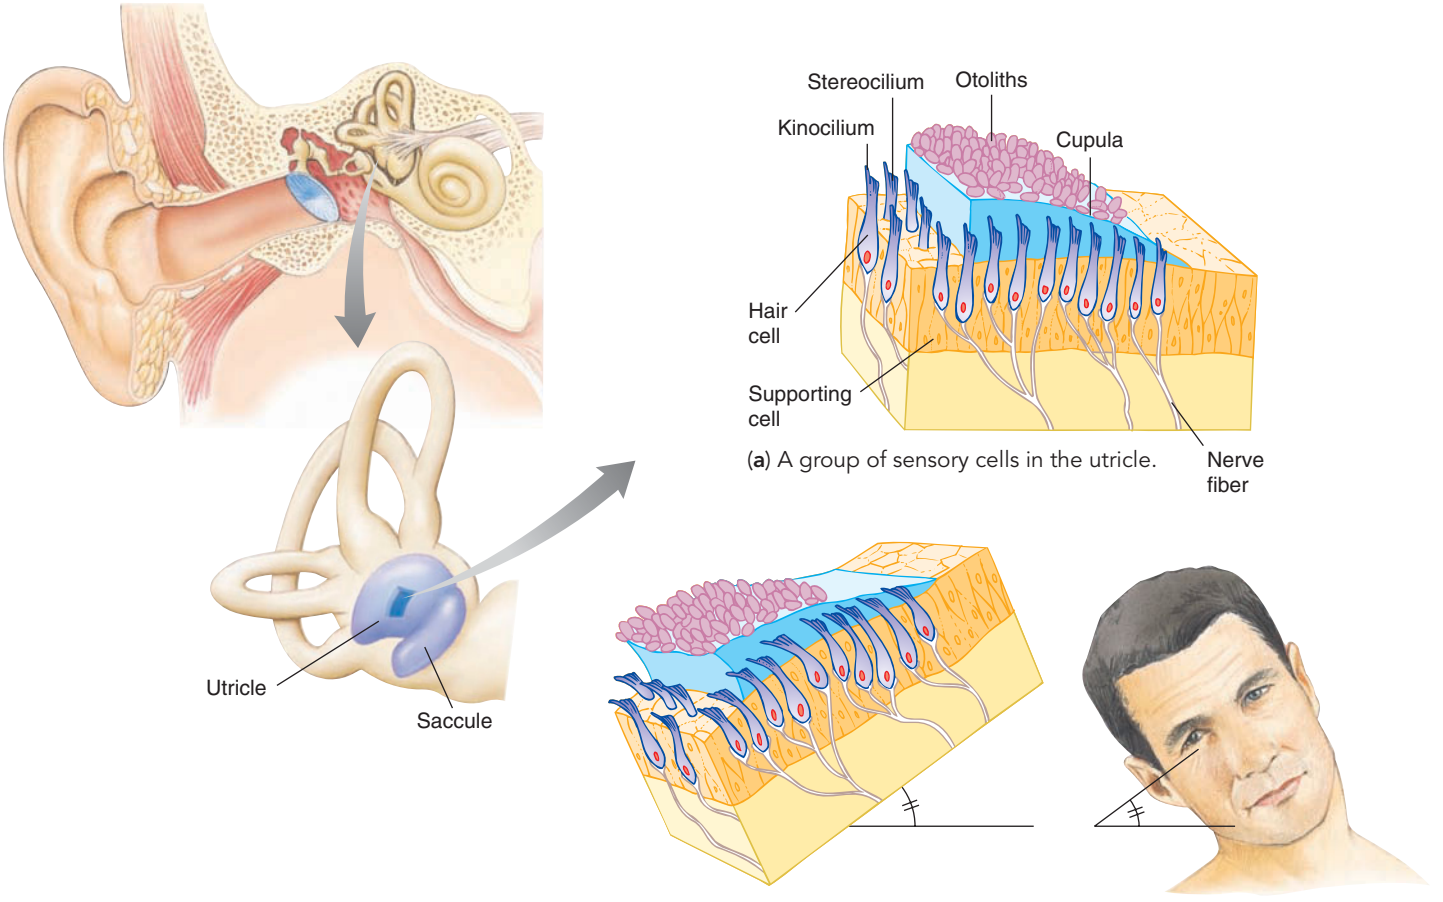


Figure 42-9 ***Animated*** Function of the saccule and utricle in maintaining equilibrium

The saccule and utricle sense linear acceleration, allowing us to know our position relative to the ground. Compare the positions of the otoliths and hair cells in **(a)** with those in **(b).** Changes in head position cause the force of gravity to distort the cupula, which in turn distorts the stereocilia of the hair cells. The hair cells respond by releasing neurotransmitters. Impulses are transmitted along the vestibulocochlear nerve to the brain.

Auditory receptors are located in the cochlea

Many arthropods and most vertebrates have sound receptors, but for many of them hearing does not seem to be a sensory priority. It is important in tetrapods, however, and both birds and mammals have a highly developed sense of hearing. Their auditory receptors, located in the **cochlea** of the inner ear, contain mechanoreceptor hair cells that detect pressure waves.

The cochlea is a spiral tube that resembles a snail's shell (Fig. 42-11). If the cochlea were uncoiled, you would see that it consists of three canals separated from one another by thin membranes. The canals come almost to a point at the apex. Two of these canals, the **vestibular canal** and the **tympanic canal,** connect at the apex of the cochlea and are filled with a fluid known as **perilymph.** The middle canal, the **cochlear duct,** is filled with endolymph and contains the auditory organ, the **organ of Corti.**

Each organ of Corti contains about 18,000 hair cells, in rows that extend the length of the coiled cochlea. The stereocilia of each hair cell extend into the cochlear duct. The hair cells rest on the **basilar membrane,** which separates the cochlear duct from the tympanic canal. Another membrane, the **tectorial membrane,** overhangs and is in contact with the hair cells.

In terrestrial vertebrates, sound waves in the air are transformed into pressure waves in the cochlear fluid. In the human ear, for example, sound waves pass through the **external auditory canal** and vibrate the **tympanic membrane,** or eardrum, which separates the outer ear and the middle ear. The vibrations are transmitted across the middle ear by three tiny bones—the **malleus, incus,** and **stapes** (or hammer, anvil, and stirrup, so called because of their shapes). The malleus is in contact with the eardrum, and the stapes is in contact with a thin, membranous region of the cochlea called the **oval window.** The **eustachian tube,** which connects the middle ear with the pharynx (throat

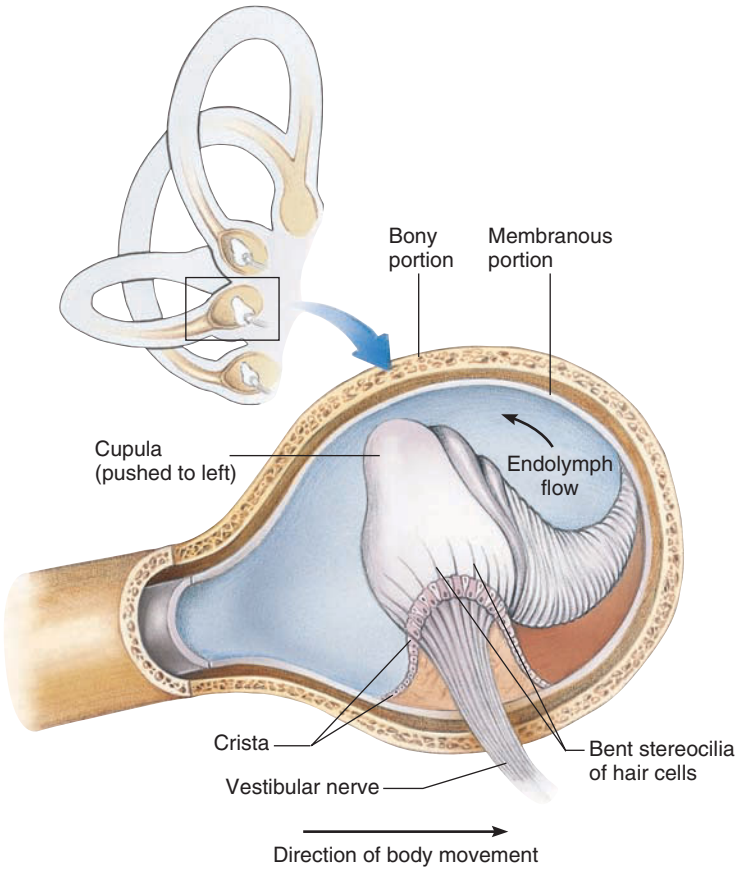

Figure 42-10 Semicircular canals and equilibrium

When the head changes its rate of rotation, endolymph within the ampulla of the semicircular canal distorts the cupula. The stereocilia of the hair cells bend, increasing the frequency of action potentials in sensory neurons. Information is transmitted to the brain via the vestibular nerve.

region), helps equalize pressure between the middle ear and the atmosphere.

The malleus, incus, and stapes act as three interconnected levers that amplify vibrations. A small movement in the malleus causes a larger movement in the incus and a very large movement in the stapes. The vibrations pass through the oval window to the perilymph in the vestibular canal. If sound waves were conducted directly from air to the oval window, much energy would be lost. The middle ear functions to couple sound waves in the air with the pressure waves conducted through the fluid in the cochlea.

Because liquids cannot be compressed, the oval window could not cause movement of the fluid in the vestibular canal if there were no escape valve for the pressure. This valve is provided by the membranous **round window** at the end of the tympanic canal. The pressure wave presses on the membranes separating the three ducts, is transmitted to the tympanic canal, and makes the round window bulge. The movements of the basilar membrane produced by these pulsations cause the stereocilia of the organ of Corti to rub against the overlying tectorial membrane.

Stereocilia are bent by their contact with the tectorial membrane. As a result, ion channels in the plasma membrane of the hair cells open. Calcium ions move into the hair cell, causing the release of *glutamate.* This neurotransmitter binds to receptors on sensory neurons that synapse with each hair cell, leading to depolarization of these sensory neurons. Axons of the sensory neurons join to form the **cochlear nerve,** a component of the vestibulocochlear nerve (cranial nerve VIII; also referred to as the *auditory nerve*). We can summarize the sequence of events involved in hearing as follows:

> Sound waves enter external auditory canal ⟶ tympanic membrane vibrates ⟶ malleus, incus, and stapes amplify vibrations ⟶ oval window vibrates ⟶ vibrations are conducted through fluid ⟶ basilar membrane vibrates ⟶ hair cells in organ of Corti are stimulated ⟶ cochlear nerve transmits impulses to brain

Sounds differ in pitch, loudness, and tone quality. **Pitch** depends on frequency of sound waves, or number of vibrations per second, and is expressed as hertz (Hz). Low-frequency vibrations result in the sensation of low pitch, whereas high-frequency vibrations result in the sensation of high pitch. Sounds of a given frequency set up resonance waves in the cochlear fluid that cause a particular section of the basilar membrane to vibrate. High frequencies are detected by hair cells located near the base of the cochlea, whereas low frequencies are sensed by hair cells near the apex of the cochlea. The brain infers the pitch of a sound from the particular hair cells that are stimulated.

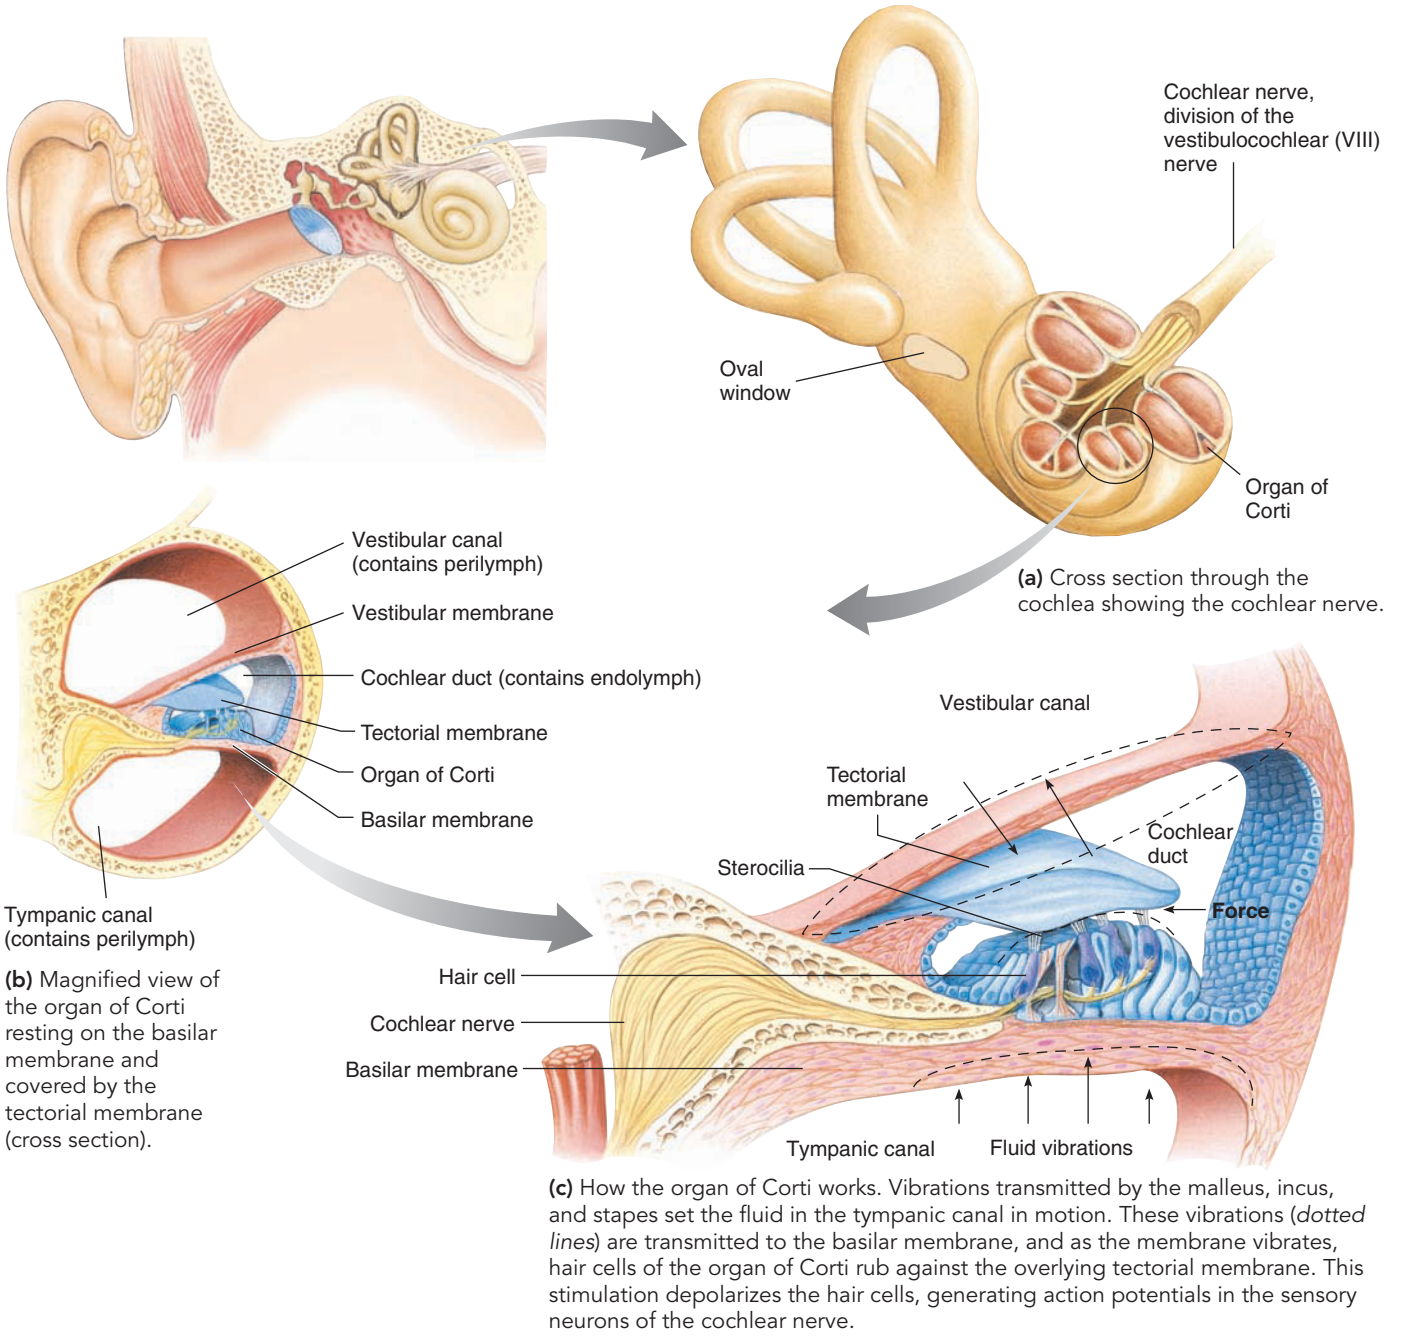
The human ear typically registers sound frequencies between about 20 and 20,000 Hz (also expressed as 20 kilohertz), and is most sensitive to sounds between 1000 and 4000 Hz (Fig. 42-12). Comparing the energy of audible sound waves with the energy of visible light waves, your ear is 10 times as sensitive as your eye. Dogs can hear sounds up to 40,000 Hz, and bats can detect frequencies as high as 100,000 Hz.

Loud sounds cause resonance waves of greater amplitude (height). The hair cells are more intensely stimulated, and the cochlear nerve transmits a greater number of impulses per second. Variations in tone quality, or timbre, such as when an oboe, a cornet, and a violin play the same note, depend on the number and kinds of overtones, or harmonics, produced. Many hair cells along the basilar membrane are stimulated and vibrate simultaneously, in addition to the main vibration common to all three instruments. Thus, differences in tone quality are recognized in the pattern of the hair cells stimulated.

Deafness may be caused by injury to, or malformation of, either the sound-transmitting mechanism of the outer, middle, or inner ear or the sound-perceiving mechanism of the inner ear. Efferent neurons from the brain stem protect the hair cells of the organ of Corti by dampening their response. Even so, exposure to high-intensity sound, such as heavily amplified music, damages hair cells in the organ of Corti.

Key Point

The hair cells in the organs of Corti in the cochlea are the receptors for hearing.



(a) Cross section through the cochlea showing the cochlear nerve.

(b) Magnified view of the organ of Corti resting on the basilar membrane and covered by the tectorial membrane (cross section).

(c) How the organ of Corti works. Vibrations transmitted by the malleus, incus, and stapes set the fluid in the tympanic canal in motion. These vibrations (*dotted lines*) are transmitted to the basilar membrane, and as the membrane vibrates, hair cells of the organ of Corti rub against the overlying tectorial membrane. This stimulation depolarizes the hair cells, generating action potentials in the sensory neurons of the cochlear nerve.

Review

- Which sensory receptors permit you to perform actions such as getting dressed or finding your way into bed in the dark?
- How do hair cells work?
- What are otoliths, and what is their role in maintaining equilibrium?
- What is the sequence of events involved in hearing?

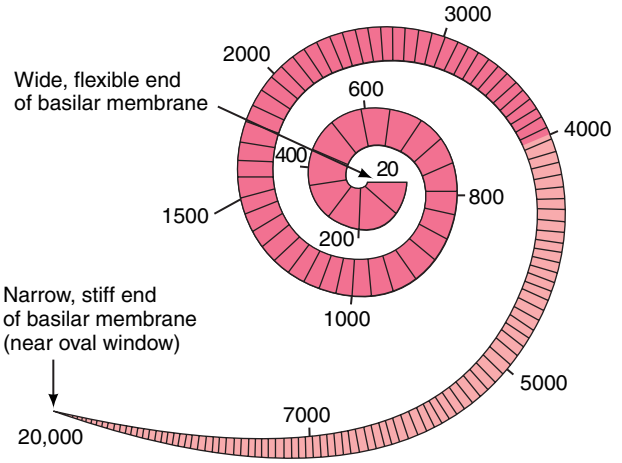

Figure 42-12 Distinguishing pitch

The basilar membrane is shown here coiled as it would be within the cochlea. Various parts of the basilar membrane vibrate in response to specific frequencies. The narrow, stiff end of the basilar membrane responds to higher frequencies, whereas the wide, flexible end responds to lower frequencies. Pitch depends on frequency of sound waves expressed as hertz (Hz). The human ear is most sensitive to sounds between 1000 and 4000 Hz.

CHEMORECEPTORS

Learning Objective

9 Compare the structure and function of the receptors of taste and smell, and describe the function of the vomeronasal organ.

Two highly sensitive chemoreceptive systems have evolved for **gustation,** or taste, and **olfaction,** or smell. These chemical senses, found throughout the animal kingdom, allow animals to detect chemical substances in food, water, and air. Evaluating such chemical cues allows animals to find food and mates and to avoid predators. Members of the same species use chemoreception to communicate about these critical issues.

For terrestrial vertebrates, the sense of smell involves gaseous substances that reach olfactory receptors through the air. The sense of taste involves materials dissolved in water (or saliva) in the mouth. For aquatic animals, these distinctions blur. Does a catfish smell or taste the water?

The organs of taste and smell in insects are sensory hairs called **sensilla** (sing., *sensillum*), which project from the end of the leg and from the mouthparts. In ants, bees, and some other insect species, receptors located on the antennae sense odors. In the blowfly, each sensillum contains four chemoreceptors (Fig. 42-13). Dendrites from each cell extend to an opening at the tip, and axons transmit sensory signals to the brain. Recent findings suggest that insects can distinguish among various bitter tastes more precisely than mammals can. This ability is important in discriminating tastes associated with spoiled, bacteria-laden foods or toxins.

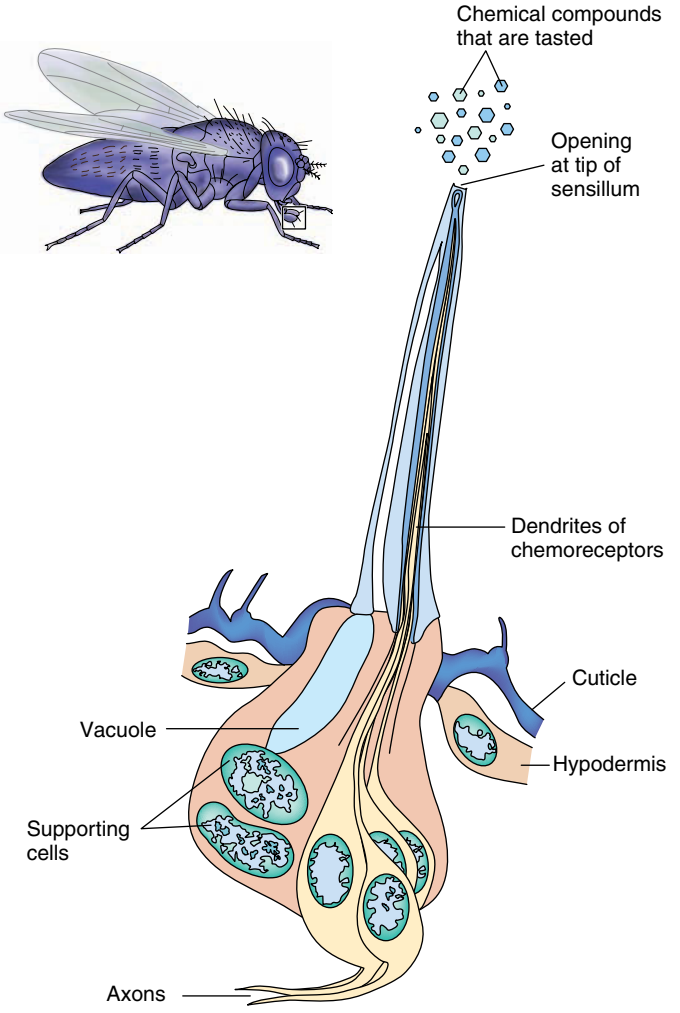

Figure 42-13 An insect taste receptor

Insects respond to a wide variety of chemical substances found in foods. Each sensillum in the blowfly contains four chemoreceptors. Dendrites that extend to an opening at the tip sense taste. The other end of each chemoreceptor is an axon that transmits sensory signals to the brain.

Taste receptors detect dissolved food molecules

The ability to discriminate among tastes has survival value. For example, foods with a high caloric value often taste sweet, whereas poisons are generally bitter. Mammals sense taste with **taste buds** located in the mouth. In humans, taste buds lie mainly in tiny elevations, or papillae, on the tongue. Each of the thousands of taste buds is an oval epithelial capsule containing about 100 taste receptor cells interspersed with supporting cells (Fig. 42-14).

The plasma membrane at the tip of each taste receptor cell has microvilli that extend into a taste pore on the surface of the tongue, where they are bathed in saliva. The taste receptors detect chemical substances dissolved in saliva. Certain molecules, such as those perceived as sweet, activate a signal transduction pro-

2 G protein is activated, and activates adenylyl cyclase.

3 ATP is converted to cyclic AMP (cAMP).

4 Cyclic AMP activates a protein kinase that closes K^+ channels.

(c) A sugar molecule activates a signal transduction process that leads to a decrease in K^+ permeability. The membrane becomes depolarized, resulting in action potentials in sensory neurons.

cess involving a G protein (see Fig. 42-14c). Adenylyl cyclase activity increases, elevating cyclic AMP levels. A protein kinase is activated that phosphorylates and closes K^+ channels. This decrease in K^+ permeability sets up a depolarizing receptor potential. Action potentials are then generated in sensory neurons that synapse with the taste receptor cell. One sensory neuron can innervate several taste buds.

Traditionally, four basic tastes have been recognized: sweet, sour, salty, and bitter. In 2000, physiologists reported a fifth taste, glutamate. Although the idea of a fifth taste is still somewhat controversial, it was first suggested almost a century ago by the Japanese physiologist Kikunae Ikeda. In 1908, Ikeda identified glutamate as the compound that triggers the taste he called umami, responsible for the savoriness of certain aged cheeses, soy sauce, anchovy, and some types of seafood.

Flavor depends on the four or five basic tastes in combination with smell, texture, and temperature. Smell affects flavor because odors pass from the mouth to the nasal chamber. No doubt you have observed that when your nose is congested, food seems to have little "taste." The taste buds are not affected, but the blockage of nasal passages severely reduces the participation of olfactory reception in the composite sensation of flavor.

Awareness of the genetic component of taste can be traced to 1931 when Arthur L. Fox, a chemist at the DuPont Company, synthesized a compound called *phenylthiocarbamide (PTC)*. Some PTC blew into the air and was inhaled by a colleague, who experienced it as very bitter. Because Fox himself could not taste it, he became intrigued and asked other people to taste it. Fox found that about 25% of people were nontasters. Everyone else experienced PTC as bitter. Further research showed that the ability to taste PTC is inherited as a dominant trait.

Since that time, taste researchers have found that some tasters are especially sensitive to bitter tastes. In fact, about 25% of

3. ATP converted to cyclic AMP.
4. Gated Na^+ channels open, leading to depolarization.

(c) An odorant activates a signal transduction process that leads to an increase in Na^+ permeability. The membrane becomes depolarized, resulting in transmission of action potentials to the brain.

Figure 42-15 ***Animated*** Olfactory epithelium

The olfactory epithelium is responsible for the sense of smell

Most invertebrates depend on **olfaction,** the detection of odors, as their main sensory modality. Recent findings indicate that the mechanisms for chemoreception have been highly conserved throughout the animal kingdom.

In terrestrial vertebrates, olfaction occurs in the nasal epithelium. In humans, the **olfactory epithelium** is found in the roof of the nasal cavity (Fig. 42-15). It contains about 100 million olfactory receptor cells with ciliated tips. The long, nonmotile cilia extend into a layer of mucus on the epithelial surface of the nasal passageway. Receptor molecules on the cilia bind with compounds dissolved in the mucus. The other end of each olfactory receptor cell is an axon that projects directly to the brain. These axons make up the **olfactory nerve** (cranial nerve I), which extends to the olfactory bulb in the brain. From there, information is transmitted to the **olfactory cortex,** which is in the limbic system, a part of the brain also associated with emotional behavior. (Odors are often associated with feelings and memories.)

When an *odorant,* a molecule that can be smelled, binds with a receptor on a cilium of an olfactory receptor cell, a signal transduction process is initiated (see Fig. 42-15c). A G protein is activated, leading to the synthesis of cyclic AMP, which opens gated channels in the plasma membrane. These channels permit Na^+ and other cations to enter the cell, causing depolarization, which is the receptor potential. The number of odorous molecules determines the intensity, which in turn determines the magnitude of the receptor potential.

Humans can detect at least seven groups of odors: camphor, musk, floral, peppermint, ethereal, pungent, and putrid. About 1000 genes code for 1000 types of olfactory receptors. Each odor consists of several component chemical groups, and each type of receptor may bind with a particular component. The combination of receptors activated determines what odor you perceive. You are capable of perceiving about 10,000 scents.

The olfactory receptors respond to remarkably small amounts of a substance. For example, most people can detect ionone, the synthetic substitute for the odor of violets, when it is present in a

the U.S. population are supertasters, 50% are regular tasters, and 25% are nontasters. Supertasters avoid broccoli, brussels sprouts, cabbage, and many other vegetables and fruits that taste bitter. These foods contain flavonoids and other compounds that are thought to protect against cancer. Continuing investigation of taste preferences and their nutritional consequences may lead to more effective approaches to improving nutrition and to a better understanding of the relative importance of genetics and learning in food selection.

concentration of only 1 part to more than 30 billion parts of air. Smell is perhaps the sense that adapts most quickly. The olfactory receptors adapt about 50% in the first second or so after stimulation, so even offensively odorous air may seem odorless after only a few minutes.

Many animals communicate with pheromones

Animals within many species communicate with one another by releasing **pheromones,** small, volatile molecules that are secreted into the environment. For example, female moths release pheromones that attract males. Dogs and wolves use pheromones to mark territory.

Mammals have specialized chemoreceptor cells that detect pheromones. These cells make up the **vomeronasal organ** located in the epithelium of the nose (separate from the main olfactory epithelium). The vomeronasal sensory neurons send signals to areas of the hypothalamus, which serves as a link with the endocrine system. (We discuss pheromones further in Chapter 51.)

Review

- How is signal transduction similar in taste buds and olfactory receptor cells? How is it different?

PHOTORECEPTORS

Learning Objectives

10 Contrast simple eyes, compound eyes, and vertebrate eyes.
11 Describe the functions of each structure of the verterate eye.
12 Describe the events that take place in human vision; compare the two types of photoreceptors, and describe the signal transduction pathway as part of your explanation.

Most animals have photoreceptors that use pigments to absorb light energy. **Rhodopsins** are the photopigments in the eyes of cephalopod mollusks (squids and octopods), arthropods, and vertebrates. Light energy striking a light-sensitive receptor cell containing these pigments triggers chemical changes in the pigment molecules that result in receptor potentials.

Invertebrate photoreceptors include eyespots, simple eyes, and compound eyes

The simplest light-sensitive structures in animals are found in certain cnidarians and flatworms (Fig. 42-16). They are **eyespots,** called **ocelli,** that detect light but do not form images. Eyespots are often bowl-shaped clusters of light-sensitive cells within the epidermis. They may detect the direction of the light source and distinguish light intensity.

Effective image formation requires a more complex **eye,** usually with a lens. A **lens** is a structure that concentrates light on a group of photoreceptors. Vision also requires a brain that can interpret the action potentials generated by the photoreceptors. The brain integrates information about movement, brightness, location, position, and shape of the visual stimulus. Two fundamentally different types of eyes evolved: the compound eye of arthropods and the camera eye of vertebrates and cephalopod mollusks.

The **compound eyes** of crustaceans and insects differ structurally and functionally from vertebrate eyes. The surface of a compound eye appears faceted, which means "having many faces," like a diamond (Fig. 42-17). Each **facet** is the convex *cornea* of one of the eye's visual units, called **ommatidia** (sing., *ommatidium*). The number of ommatidia varies with the species. For example, each eye of certain crustaceans has only 20 ommatidia, whereas the dragonfly eye has as many as 28,000.

The optical part of each ommatidium includes a biconvex lens and a **crystalline cone.** The lens and crystalline cone focus light onto photoreceptor cells called **retinular cells.** These cells have a light-sensitive membrane made up of microvilli that contain rhodopsin. The membranes of several retinular cells may fuse to form a central rod-shaped **rhabdome** that is sensitive to light.

Compound eyes do not perceive form well. Although the lens system of each ommatidium is adequate to focus a small inverted image, there is little evidence that the animal actually perceives them as images. However, all the ommatidia together produce a composite image, or **mosaic** picture. Each ommatidium, in gath-

Figure 42-17 Compound eyes

ering a point of light from a narrow sector of the visual field, is in fact sampling a mean intensity from that sector. All these points of light taken together form a mosaic picture (see Fig. 42-17d).

Arthropod eyes usually adapt to different intensities of light. A sheath of pigmented cells envelops each ommatidium, and screening pigments are present in *iris cells* and in retinular cells. In nocturnal and crepuscular (active at dusk) insects and many crustaceans, pigment migrates proximally and distally within each pigmented cell. When the pigment is in the proximal position, each ommatidium is shielded from its neighbor, and only light entering directly along its axis can stimulate the receptors. When the pigment is in the distal position, light striking at any angle can pass through several ommatidia and stimulate many retinal units. As a result, sensitivity is increased in dim light and the eye is protected from excessive stimulation in bright light. Pigment migration is under neural control in insects and under hormonal control in crustaceans. In some species it follows a daily rhythm.

Although the compound eye can form only coarse images, it compensates by following flickers to higher frequencies. Flies can detect up to about 265 flickers per second. In contrast, the human eye can detect only 45 to 53 flickers per second; for us, flickering lights fuse above these values, so we see light provided by an ordinary bulb as steady and the movement in motion pictures as smooth. To an insect, both room lighting and motion pictures must flicker horribly. The insect's high critical flicker fusion threshold permits immediate detection of even slight movement by prey or enemy. The compound eye is an important adaptation to the arthropod's way of life.

Compound eyes differ from our eyes in another respect. They are sensitive to wavelengths of light in the range from red to ultraviolet (UV). Accordingly, an insect can see UV light well, and its world of color is very different from ours. Because they reflect UV light to various degrees, flowers that appear identically colored to humans may appear strikingly dissimilar to insects (see Fig. 36-5).

Vertebrate eyes form sharp images

The position of the eyes in the front of the head of primates and certain birds allows both eyes to focus on the same object. The

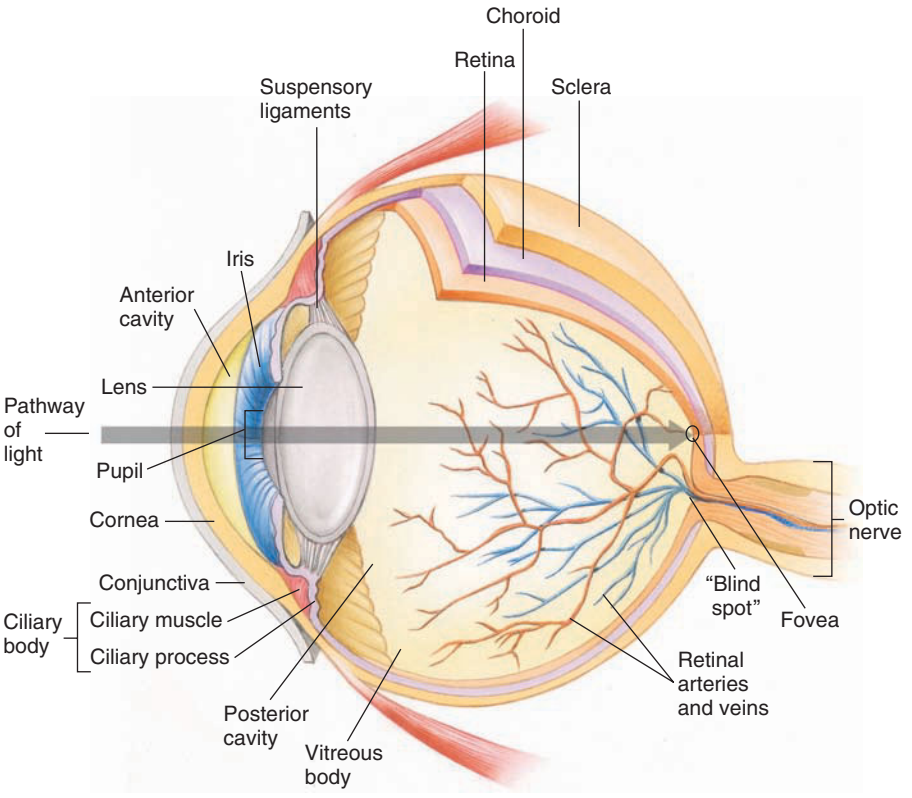

Figure 42-18 ***Animated*** Structure of the human eye

Light passes through the human eye to photoreceptor cells in the retina. In this lateral view, the eye is shown partly sectioned along the sagittal plane to expose its internal structures.

overlap in information they receive results in the same visual information striking the two retinas (light-sensitive areas) at the same time. This **binocular vision** is important in judging distance and in depth perception.

The vertebrate eye can be compared to an old-fashioned camera. An adjustable lens can be focused for different distances, and a diaphragm, called the **iris,** regulates the size of the light opening, called the **pupil** (▮ Fig. 42-18). The **retina** corresponds to the light-sensitive film used in a camera. Outside the retina is the **choroid layer,** a sheet of cells filled with black pigment that absorbs extra light. This mechanism prevents light from being reflected back into the photoreceptors, which would cause blurring of images. (Cameras are also black on the inside.) The choroid is rich in blood vessels that supply the retina.

The outer coat of the eyeball, called the **sclera,** is a tough, opaque, curved sheet of connective tissue that protects the inner structures and helps maintain the rigidity of the eyeball. On the front surface of the eye, this sheet becomes the thinner, transparent **cornea,** through which light enters. The cornea serves as a fixed lens that focuses light.

The lens of the eye is a transparent, elastic ball just behind the iris. It bends the light rays coming in and brings them to a focus on the retina. The lens is aided by the curved surface of the cornea and by the refractive properties (ability to bend light rays) of the liquids inside the eyeball. The **anterior cavity** between the cornea and the lens is filled with a watery substance, the **aqueous fluid.** The larger **posterior cavity** between the lens and the retina is filled with a more viscous fluid, the **vitreous body.** Both fluids are important in maintaining the shape of the eyeball by providing an internal fluid pressure.

At its anterior margin, the choroid is thick and projects medially into the eyeball, forming the **ciliary body,** which consists of ciliary processes and the ciliary muscle. The ciliary processes are glandlike folds that project toward the lens and secrete the aqueous fluid.

We focus a camera by changing the distance between the lens and the film. The eye has the power of **accommodation,** the ability to change focus for near or far vision by changing the shape of the lens (▮ Fig. 42-19). This accommodation is accom-

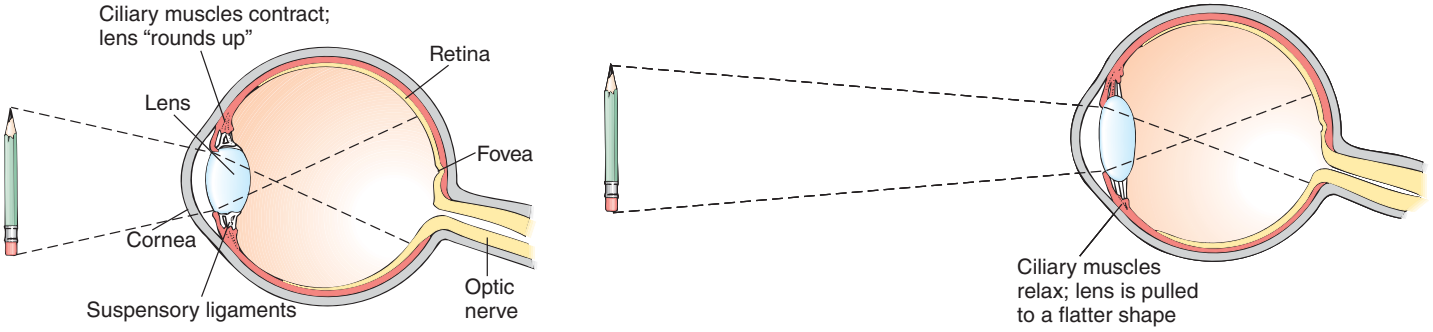

Figure 42-19 ***Animated*** Accommodation

How the eye changes focus for **(a)** near and **(b)** distant vision.

plished by the **ciliary muscle,** a part of the ciliary body. To focus on close objects, the ciliary muscle contracts, making the elastic lens rounder. To focus on more distant objects, the ciliary muscle relaxes and the lens assumes a flattened (ovoid) shape.

The amount of light entering the eye is regulated by the iris, a ring of smooth muscle that appears as blue, green, gray, or brown depending on the amount and nature of pigment present. The iris consists of two mutually antagonistic sets of muscle fibers. One set is arranged circularly and contracts to *decrease* the size of the pupil. The other is arranged radially and contracts to *increase* the size of the pupil.

Each eye also has six muscles that extend from the surface of the eyeball to various points in the bony socket. These muscles enable the eye as a whole to move and be oriented in a given direction. Cranial nerves innervate the muscles in such a way that the eyes normally move together and focus on the same area.

The retina contains light-sensitive rods and cones

The light-sensitive structure in the vertebrate eye is the retina, which lines the posterior two thirds of the eyeball and covers the choroid. The retina, which is composed of 10 layers, contains the photoreceptor cells called, according to shape, **rods** and **cones.** In both rod and cone cells, infoldings of the plasma membrane form stacks of membranous discs that contain the photopigments. The discs greatly increase the light-absorbing surface.

The human eye has about 125 million rods and 6.5 million cones. Rods function in dim light so that we can detect shape and movement. They are not sensitive to colors. Because the rods are more numerous in the periphery of the retina, you can see an object better in dim light if you look slightly to one side of it (allowing the image to fall on the rods).

Cones respond to light at higher levels of intensity, such as daylight, and they allow us to perceive fine detail. Cones are responsible for color vision; they are differentially sensitive to different wavelengths (colors) of light. In primates and certain hunting birds (such as eagles), the cones are most concentrated in the **fovea,** a small, depressed area in the center of the retina. The fovea is the region of sharpest vision because it has the greatest density of receptor cells and because the retina is thinner there.

Light must pass through several layers of connecting neurons in the retina to reach the rods and cones (Fig. 42-20). This arrangement lets the rods and cones contact a layer of pigmented epithelium that provides retinal, a component of rhodopsin. The retina has five main types of neurons: (1) Photoreceptors (rods and cones) synapse on (2) **bipolar cells,** which make synaptic contact with (3) **ganglion cells.** Two types of lateral interneurons are the (4) **horizontal cells,** which receive information from the photoreceptor cells and send it to bipolar cells, and (5) **amacrine cells,** which receive messages from the bipolar cells and send signals back to the bipolar cells or to ganglion cells (Fig. 42-21). Interestingly, one group of ganglion cells project to the suprachiasmatic nucleus, the body's main biological clock. These gan-

Key Point

(b) Rods (*red elongated structures*) and two cones (*shorter, thicker, yellow structures*) are seen in this SEM. The elongated rods permit you to see shape and movement, whereas the shorter cones allow you to view the world in color.

Figure 42-20 ***Animated*** Organization of the retina

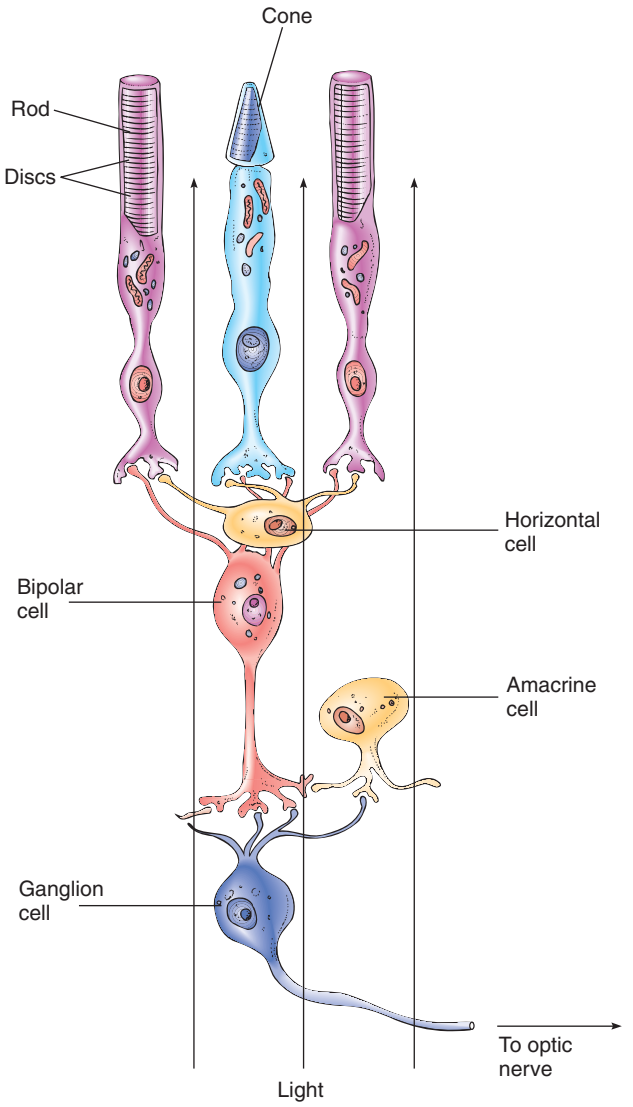

Figure 42-21 Neural pathway in the retina

The photoreceptor cells (rods and cones) are located in the back of the retina. They synapse with bipolar and horizontal cells. The bipolar cells synapse with ganglion cells and amacrine cells. Axons of ganglion cells make up the optic nerve.

glion cells contain a light-sensitive pigment (melanopsin) that is important in nonvisual responses to light.

The axons of the ganglion cells extend across the surface of the retina and unite to form the **optic nerve.** The area where the optic nerve passes out of the eyeball, the **optic disk,** is known as the *blind spot;* because it lacks rods and cones, images falling on it cannot be perceived.

Here is a simplified summary of the visual pathway:

Light passes through cornea ⟶ through aqueous fluid ⟶ through lens ⟶ through vitreous body ⟶ image forms on photoreceptor cells in retina ⟶ signal bipolar cells ⟶ signal ganglion cells ⟶ optic nerve transmits signals to thalamus ⟶ integration by visual areas of cerebral cortex

A chemical change in rhodopsin leads to the response of a rod to light

How is light converted into the neural signals that transmit information about environmental stimuli into pictures in the brain? Rod cells are so sensitive to light that they can respond to a single photon. Rhodopsin in the rod cells and some very closely related photopigments in the cone cells are responsible for the ability to see. Rhodopsin consists of *opsin,* a large protein that is chemically joined with *retinal,* an aldehyde of vitamin A (see Fig. 3-14). Two isomers of retinal exist: the *cis* form, which is folded, and the *trans* form, which is straight.

In the dark, opsin binds to retinal in the *cis* form. Cyclic GMP (cyclic guanosine monophosphate, a molecule similar to cyclic AMP) opens nonspecific channels that permit passage of Na^+ and other cations into the rod cell (Fig. 42-22). This process depolarizes the rod cell, which releases the neurotransmitter glutamate. The glutamate hyperpolarizes the membrane of the bipolar cell so it does not transmit messages.

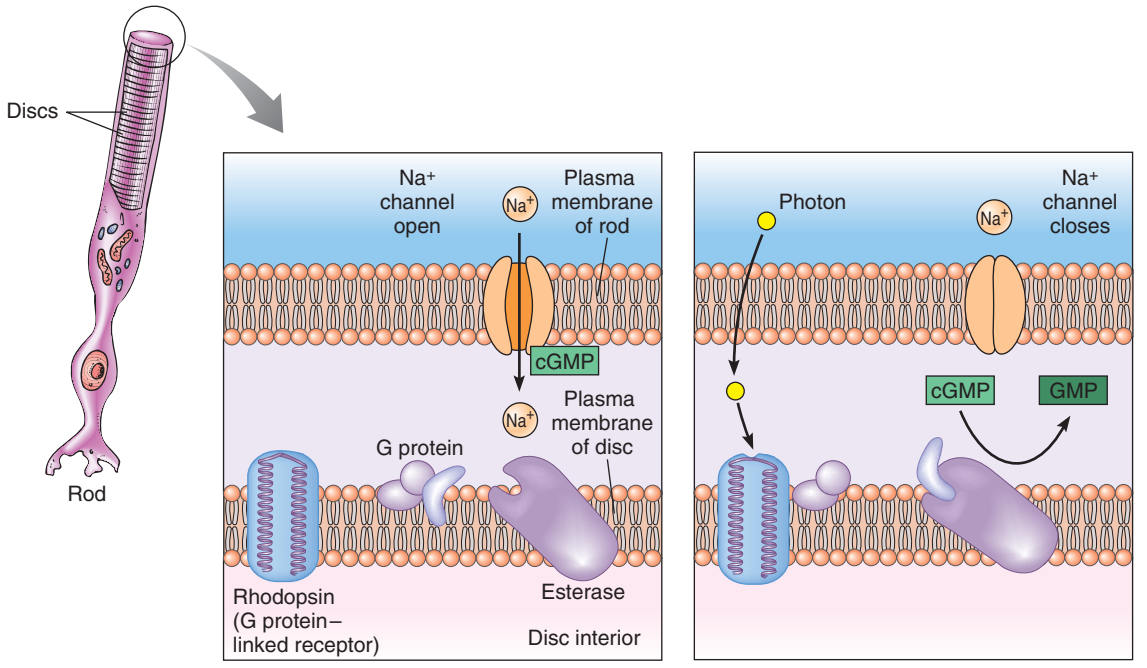
Note that the photoreceptor differs from other neurons in that the ion channels in its membrane are normally open; it is depolarized and continuously releases neurotransmitter. The steady flow of ions into the cell when the environment is dark is called the *dark current.* Another unusual characteristic of photoreceptors, and of bipolar cells, is that they do not produce action potentials. Their release of neurotransmitter is graded, regulated by the extent of depolarization.

When light strikes rhodopsin, light energy is transduced. This process can be considered in three stages:

1. Light activates rhodopsin. Light transforms *cis*-retinal to *trans*-retinal. Rhodopsin changes shape and breaks down into its components, opsin and retinal. This is the light-dependent process in vision.
2. Rhodopsin is part of a signal transduction pathway. When it changes shape, it binds with **transducin,** a G protein. Transducin activates an esterase that hydrolyzes cyclic GMP (cGMP) to GMP, reducing the concentration of cGMP.
3. When the concentration of cGMP in the rod decreases, its Na^+ channels begin to close. Fewer cations pass into the rod cell, and it becomes more negative (hyperpolarized). The rod cell then releases less glutamate. Thus, light decreases the number of neural signals from the rod cells.

The release of glutamate normally hyperpolarizes the membrane of the bipolar cell, so a decrease in glutamate release results in its depolarization. The depolarized bipolar cell increases its release of a neurotransmitter, which typically stimulates the ganglion cell.

When you move from bright daylight to a dark room, you experience "blindness" for a few moments while your eyes adapt. During exposure to bright light, rhodopsin breaks down, decreasing the sensitivity of your eyes. **Dark adaptation** occurs as enzymes restore rhodopsin to a form in which it can respond to light. In dim light, vision depends on the rods. Conversely, when you move from the dark to bright light, your eyes are very sensitive and you may feel "blinded" by the light. **Light adapta-**



(a) In the dark, sodium channels are open. The rod cell is depolarized and releases the inhibitory neurotransmitter glutamate (not shown).

(b) Light makes rhodopsin change shape, activating a signal transduction pathway. The activation of a G protein leads to hyperpolarization and a decrease in inhibitory signals from the rod cell.

Figure 42-22 The biochemistry of vision

The discs of the rod are infoldings of the plasma membrane. In the dark the rod cell is depolarized; in the light it becomes hyperpolarized.

tion occurs as some of the photopigments break down and the sensitivity of your eyes decreases.

Color vision depends on three types of cones

Many invertebrates and at least some animals in each vertebrate class have color vision. Color perception depends on cones. Most mammals have two types of cones, but humans and other primates have three types: blue, green, and red. Each contains a slightly different photopigment. Although the retinal portion of the pigment molecule is the same as in rhodopsin, the opsin protein differs slightly in each type of photoreceptor.

Each type of cone responds to light within a considerable range of wavelengths but is named for the ability of its pigment to absorb a particular wavelength more strongly than other cones do. For example, red light can be absorbed by all three types of cones, but those cones most sensitive to red act as red receptors. By comparing the relative responses of the three types of cones, the brain can detect colors of intermediate wavelengths. Color blindness occurs when there is a deficiency of one or more of the three types of cones. This is usually an inherited X-linked condition (see Fig. 11-16).

Integration of visual information begins in the retina

The size, intensity, and location of light stimuli determine initial processing in the retina. Rods and cones send signals directly to bipolar cells, and bipolar cells send signals directly to ganglion cells. However, as illustrated in Figure 42-21, photoreceptor cells can also transmit signals to horizontal cells, and bipolar cells can transmit signals to amacrine cells. Ganglion cells are inhibited by amacrine cells and can be inhibited indirectly by horizontal cells as a result of their action on bipolar cells. Thus, the horizontal and amacrine cells integrate signals laterally.

Bipolar, horizontal, and amacrine cells combine signals from several photoreceptors. Each ganglion cell has a **receptive field,** a specific group of photoreceptors that light must strike for the ganglion cell to be stimulated. Ganglion cells are activated or inhibited depending on which photoreceptor cells have been stimulated.

The pattern of neuron firing in the retina is very important. The signals sent to ganglion cells depend on spatial patterns and timing of the light striking the retina. Ganglion cells receive signals about specific types of visual stimuli, such as color, brightness, and motion, and transmit this information about the character-

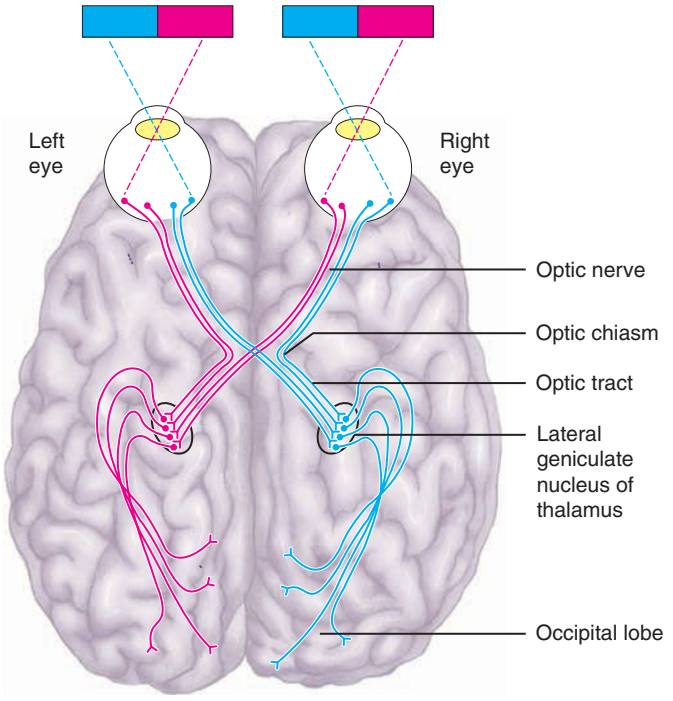


Figure 42-23 ***Animated*** Neural pathway for transmission of visual information

Axons of ganglion cells form the optic nerves. The optic nerves cross, forming the optic chiasm. Many optic nerve fibers end in the lateral geniculate nuclei of the thalamus. From there, signals are sent to the visual cortex in the occipital lobe. Brain is viewed from above with overlying structures removed.

istics of a visual image. Ganglion cells produce action potentials, in contrast with rods and cones and most other neurons of the retina, which produce only graded potentials.

The retina begins the construction of visual images, but those images are interpreted in the brain. Axons of more than a million ganglion cells form the optic nerves that transmit information to the brain by complex, encoded signals. The optic nerves cross in the floor of the hypothalamus, forming an X-shaped structure, the **optic chiasm** (Fig. 42-23). Some of the axons of the optic nerves cross over and then extend to the opposite side of the brain.

Axons of the optic nerves end in the **lateral geniculate nuclei** of the thalamus. From there, neurons send signals to the **primary visual cortex** in the occipital lobe of the cerebrum. The lateral geniculate nucleus controls which information is sent to the visual cortex. Neurons in the reticular activating system are involved in this integration. Information is transmitted from the primary visual cortex to other cortical areas for further processing.

Different types of ganglion cells receive information about different aspects of a visual stimulus. As a result, information from each point in the retina is transmitted in parallel by several types of ganglion cells. These cells project to different kinds of neurons in the lateral geniculate nucleus and primary visual cortex.

Neurobiologists have not yet discovered all the mechanisms by which the brain makes sense out of the visual information it receives. We know that a large part of the association areas of the cerebrum are involved in integrating visual input. The neurons of the visual cortex are organized as a map of the external visual field. They are also organized into columns. Each column of neurons receives signals originating from light entering either the right or left eye. Columns are also organized by orientation of light. Neurons in a column receive signals originally triggered by light with the same orientation. However, these signals originate from different locations in the retina.

Review

- How does the insect's compound eye compare with the vertebrate eye?
- What happens when light strikes rhodopsin? (Include a description of the signal transduction pathway in your answer.)
- What is the sequence of neural signaling in the retina?
- What is meant by the statement "Vision happens mainly in the brain?"

SUMMARY WITH KEY TERMS

Learning Objectives

1 Describe sensory system function, including sensory reception, energy transduction, receptor potential, sensory adaptation, and perception (page 894).

- **Sensory receptors** are neuron endings or specialized receptor cells in close contact with neurons. **Sense organs** consist of sensory receptors and accessory cells.
- Sensory receptors absorb energy, transduce that energy—**energy transduction**—into electrical energy, and produce **receptor potentials,** which are depolarizations or hyperpolarizations of the membrane. Receptor potentials are **graded responses.**
- Sensory receptors transmit coded signals to the CNS through **sensory neurons. Sensory adaptation,** the decrease in frequency of action potentials in a sensory neuron even when the stimulus is maintained, decreases response to that stimulus.
- The brain interprets sensations by converting them to perceptions of stimuli. Sensory **perception** is the process of selecting, interpreting, and organizing sensory information.

ThomsonNOW™ Learn more about sensory reception in human skin by clicking on the figure in ThomsonNOW.

2 Classify sensory receptors according to the location of stimuli to which they respond and according to the types of energy they transduce (page 896).

- Sensory receptors can be classified according to the location of the stimuli to which they respond. **Exteroceptors**

receive stimuli from the outside environment. **Interoceptors** detect changes within the body, such as changes in pH, osmotic pressure, body temperature, and the chemical composition of the blood.

- Sensory receptors can be classified according to the types of energy they transduce. Thermoreceptors respond to heat and cold. Electroreceptors sense differences in electrical potential. Some electromagnetic receptors can detect Earth's magnetic field. Nociceptors (pain receptors) respond to mechanical, temperature, and other stimuli that could be damaging. Mechanoreceptors transduce mechanical energy—touch, pressure, gravity, stretching, and movement. Chemoreceptors transduce certain chemical compounds, and photoreceptors transduce light energy.

3 Identify three functions of thermoreceptors (page 897).

- **Thermoreceptors** transduce thermal energy; they respond to heat and cold. Some parasites use thermoreceptors to find an endothermic host. Some animals use thermoreceptors to locate endothermic prey. In endothermic animals, thermoreceptors provide cues about body temperature.

4 Describe the functions of electroreceptors and electromagnetic receptors (page 898).

- **Electroreceptors,** used by predatory fishes to detect prey, respond to electrical stimuli.
- Some electroreceptors, called **electromagnetic receptors,** are sensitive enough to detect Earth's magnetic field. Some animals use information about magnetic fields to orient themselves. Many migratory animals use magnetic fields to navigate.

5 Describe the functions of nociceptors, and identify the roles of glutamate and substance P (page 898).

- **Nociceptors** are pain receptors; they are free nerve endings of certain sensory neurons that respond to strong tactile stimuli, temperature extremes, and certain chemicals.
- Sensory neurons that transmit pain signals release the neurotransmitters **glutamate** and **substance P.** Substance P enhances and prolongs the actions of glutamate.

6 Compare the functions and mechanisms of action of the following mechanoreceptors: tactile receptors, proprioceptors, statocysts, hair cells, and lateral line organs (page 898).

- **Mechanoreceptors** transduce mechanical energy, permitting animals to feel, hear, and maintain balance. Mechanoreceptors respond to touch, pressure, gravity, stretch, or movement. They are activated when they change shape as a result of being mechanically pushed or pulled.
- **Tactile receptors** in the skin respond to mechanical displacement of hairs or to displacement of the receptor cells themselves. The **Pacinian corpuscle** is a tactile receptor that responds to touch and pressure.
- **Proprioceptors** allow an animal to perceive orientation of its body and the positions of its parts. **Muscle spindles, Golgi tendon organs,** and **joint receptors** are proprioceptors that continuously respond to tension and movement.
- **Statocysts,** gravity receptors found in many invertebrates, are simple organs of equilibrium. A statocyst consists of a chamber lined with ciliated mechanoreceptors; the chamber contains **statoliths,** granules of sand grains or calcium carbonate that change position as the animal moves. As statoliths move, sensory hairs bend and different sensory cells are stimulated. This mechanical displacement results in receptor potentials and action potentials that inform the CNS of the change in position.
- Vertebrate **hair cells** detect movement; they are found in the lateral line of fishes, the vestibular apparatus, semicircular canals, and cochlea. Each hair cell has a single **kinocilium,** which is a true cilium, and **stereocilia,** which are microvilli that contain actin filaments.
- **Lateral line organs** supplement vision in fishes and some amphibians by informing the animal of moving objects or objects in its path.

7 Compare the structure and function of the saccule and utricle with that of the semicircular canals in maintaining equilibrium (page 898).

- The vertebrate **inner ear** consists of a **labyrinth** of fluid-filled chambers and canals that help maintain equilibrium. The **vestibular apparatus** in the upper part of the labyrinth consists of the **saccule, utricle,** and **semicircular canals.**
- The saccule and utricle contain **otoliths** that change position when the head is tilted or when the body is moving in a straight line. The otoliths stimulate hair cells that send signals to the brain, enabling the animal to perceive the direction of gravity.
- The semicircular canals inform the brain about turning movements. Clumps of hair cells, called **cristae,** are located within each bulblike enlargement, called an **ampulla.** Cristae are stimulated by movements of the **endolymph,** a fluid that fills each canal.

8 Trace the path taken by sound waves through the structures of the ear, and explain how the organ of Corti functions as an auditory receptor (page 898).

- In terrestrial vertebrates, the **organ of Corti** within the **cochlea** contains auditory receptors.
- Sound waves pass through the **external auditory canal** and cause the **tympanic membrane** (eardrum) to vibrate. The ear bones—**malleus, incus,** and **stapes**—transmit and amplify the vibrations through the middle ear.
- Vibrations pass through the **oval window** to fluid within the vestibular canal. Pressure waves press on the membranes that separate the three ducts of the cochlea.
- The bulging of the **round window** serves as an escape valve for the pressure. The pressure waves cause movements of the **basilar membrane.** These movements stimulate the hair cells of the organ of Corti by rubbing them against the overlying **tectorial membrane.**
- Neural impulses are initiated in the dendrites of neurons that lie at the base of each hair cell and are transmitted by the **cochlear nerve** to the brain.

ThomsonNOW™ Watch the human ear in action by clicking on the figures in ThomsonNOW.

9 Compare the structure and function of the receptors of taste and smell, and describe the function of the vomeronasal organ (page 906).

- **Chemoreceptors** transduce certain kinds of chemical compounds, allowing **gustation,** or taste, and **olfaction,** or smell.
- In vertebrates, taste receptor cells are specialized epithelial cells in **taste buds.** The **olfactory epithelium** contains specialized olfactory cells with axons that extend to the brain as fibers of the **olfactory nerves.**
- When a molecule binds with a receptor on a taste receptor cell or an olfactory receptor cell, a signal transduction process involving a G protein is initiated.

- Receptors that make up the **vomeronasal organ,** located in the nasal epithelium of mammals, detect **pheromones,** small, volatile signaling molecules released by animals.

ThomsonNOW™ Learn more about taste buds and olfactory epithelium by clicking on the figures in ThomsonNOW.

10 Contrast simple eyes, compound eyes, and vertebrate eyes (page 909).
- **Photoreceptors** transduce light energy and serve as the sensory receptors in eyespots and eyes.
- **Eyespots,** or **ocelli,** found in cnidarians and flatworms, detect light but do not form images.
- The **compound eye** of insects and crustaceans consists of visual units called **ommatidia,** which collectively produce a **mosaic** image. Each ommatidium has a transparent **lens** and a **crystalline cone** that focus light onto receptor cells called **retinular cells.**
- We can compare the vertebrate eye to an old-fashioned camera.

11 Describe the functions of each structure of the vertebrate eye (page 909).
- In the human eye, light enters through the **cornea,** is focused by the lens, and produces an image on the **retina.** The **iris** regulates the amount of light that can enter.

ThomsonNOW™ Learn more about the human eye and the organization of the retina by clicking on the figures in ThomsonNOW.

12 Describe the events that take place in human vision; compare the two types of photoreceptors, and describe the signal transduction pathway as part of your explanation (page 909).
- The retina contains the photoreceptor cells: **rods,** which function in dim light and form images in black and white; and **cones,** which function in bright light and permit color vision.
- The retina also contains **bipolar cells** that send signals to **ganglion cells.** Two types of lateral interneurons integrate information: **Horizontal cells** receive signals from the rods and cones and send signals to bipolar cells, and **amacrine cells** receive signals from bipolar cells and send signals back to bipolar cells and to ganglion cells.
- When the environment is dark, ion channels in the plasma membranes of rod cells are open and the cells are depolarized; they release glutamate, which hyperpolarizes the membranes of bipolar cells so they do not send signals.
- When light strikes the photopigment **rhodopsin** in the rod cells, its retinal portion changes shape and initiates a signal transduction process that involves **transducin.** This G protein activates an esterase that hydrolyzes cGMP, reducing its concentration. As a result, ion channels close and the membrane becomes hyperpolarized. The rod cells release less glutamate, and fewer signals are transmitted. As a result, bipolar cells become depolarized and release neurotransmitter that stimulates ganglion cells.
- Axons of the ganglion cells make up the **optic nerves.** The optic nerves transmit information to the **lateral geniculate nuclei** in the thalamus. From there, neurons project to the **primary visual cortex** and then to integration centers in the cerebral cortex.

ThomsonNOW™ See how vision disorders change the eye by clicking on the figure in ThomsonNOW.

TEST YOUR UNDERSTANDING

1. Which of the following is *not* true of a sensory receptor? (a) detects a stimulus in the environment (b) converts energy of the stimulus into electrical energy (c) produces a receptor potential (d) produces a graded response (e) interprets sensory stimuli
2. A sensory receptor absorbs energy from some stimulus. The next step is (a) release of neurotransmitter (b) transmission of an action potential (c) energy transduction (d) transmission of a receptor potential (e) sensory adaptation
3. Interoceptors (a) help maintain homeostasis (b) are located in the skin (c) are photoreceptors (d) adapt rapidly (e) convert absorbed energy directly into action potentials
4. Which of the following are *not* correctly matched? (a) mechanoreceptors—touch, pressure (b) electroreceptors—voltage (c) photoreceptors—light (d) chemoreceptors—gravity (e) nociceptors—extreme temperature
5. A Pacinian corpuscle (a) is a mechanoreceptor (b) responds to heat (c) responds to pressure (d) a, b, and c (e) a and c
6. Which of the following is *not* located in the vertebrate inner ear? (a) vestibular apparatus (b) cochlea (c) malleus (d) organ of Corti (e) utricle
7. The auditory receptors are located in the (a) utricle (b) organ of Corti (c) vestibular apparatus (d) saccule (e) semicircular canals
8. Which of the following is/are associated with informing the brain about turning movements? (a) semicircular canals (b) saccule (c) lymph (d) otoliths (e) utricle
9. Which of the following receptors do *not* have hair cells? (a) lateral line organ (b) saccule (c) utricle (d) semicircular canals (e) rods
10. In the process of hearing, the basilar membrane vibrates. Which event occurs next? (a) tympanic membrane vibrates (b) bones in middle ear amplify and conduct vibrations (c) cochlear nerve transmits impulses to organ of Corti (d) hair cells in organ of Corti are stimulated (e) vibrations conducted to chemoreceptors
11. In olfaction, (a) pheromones stimulate the taste buds (b) the number of odorous molecules determines the magnitude of the receptor potential (c) chemical signals are converted directly into electrical signals (d) a G protein is activated and leads to the closing of gated channels (e) the concentration

of cyclic AMP increases, leading to hyperpolarization of the receptor

12. The vomeronasal organ (a) detects pheromones (b) is located at the back of the tongue (c) sends signals directly to the thalamus (d) releases pheromones (e) detects signals from predators
13. Mechanical stimulation of stereocilia (a) decreases the number of action potentials (b) inhibits glutamate secretion (c) causes voltage changes (d) degrades opiates (e) causes rhodopsin release
14. In the human visual pathway, after light passes through the cornea, it (a) stimulates ganglion cells (b) passes through the lens (c) sends signals through the optic nerve (d) depolarizes horizontal cells (e) hyperpolarizes rod cells
15. Cones (a) are most concentrated in the ganglion area (b) are more numerous than rods (c) are responsible for vision in bright light (d) are found in all animals with photoreceptors (e) are a type of bipolar cell
16. Rhodopsin (a) is concentrated in bipolar cells (b) binds with a G protein (c) changes shape when the membrane of the cone is depolarized (d) sends signals to the lateral geniculate nuclei (e) activates substance P

CRITICAL THINKING

1. If all neurons transmit the same type of message, how do you know the difference between sound and light? How are you able to distinguish between an intense pain and a mild one? How are these discriminations adaptive?
2. Connoisseurs can recognize many varieties of cheese or wine by "tasting." How can this be, when there are only a few types of taste receptors? How might it be adaptive for organisms to have only four or five basic tastes?
3. Design a synaptic mechanism by which the same neurotransmitter has an excitatory effect on one bipolar cell and an inhibitory effect on another.
4. **Evolution Link.** Proteins known as opsins are present in the photoreceptors of all light-sensitive receptors that have been studied. What does this suggest about the relationships of organisms as diverse as amoebas, flatworms, crayfish, and elephants?
5. **Evolution Link.** Once the ability to produce images evolved, eyes evolved relatively rapidly. Hypothesize why eyes evolved quickly and are now present in the majority of animal groups.

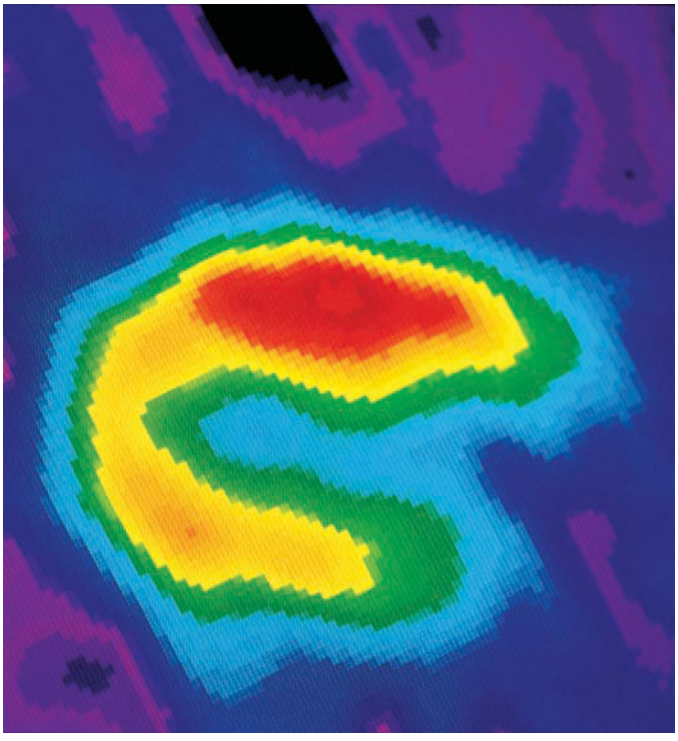
Internal Transport



Ted Horowitz /Corbis

PET scan visualizing the left ventricle of the human heart. The scan measures metabolic activity based on glucose levels in the cardiac muscle tissue, providing information about the condition of the heart. (The color progression from least to most active is blue, green, yellow, red.)

KEY CONCEPTS

A circulatory system typically consists of blood, a heart, and a system of blood vessels or spaces through which blood circulates.

Arthropods and most mollusks have an open circulatory system in which blood bathes the tissues directly; some invertebrates and all vertebrates have a closed circulatory system in which blood flows through a continuous circuit of blood vessels.

The vertebrate circulatory system transports nutrients, oxygen, wastes, and hormones; helps maintain fluid balance, appropriate pH, and body temperature; and defends the body against disease.

During the evolution of terrestrial vertebrates, adaptations in circulatory system structures separated oxygen-rich from oxygen-poor blood. The four-chambered hearts and double circuits of endothermic birds and mammals completely separate oxygen-rich blood from oxygen-poor blood.

The lymphatic system helps maintain fluid homeostasis by returning interstitial fluid to the blood.

Most cells need a continuous supply of nutrients and oxygen and the removal of waste products. In very small animals, these metabolic needs are met by simple **diffusion,** the net movement of particles from a region of higher concentration to a region of lower concentration as a result of random motion. A molecule can diffuse 1 micrometer (μm) in less than 1 millisecond (msec), so diffusion is adequate over microscopic distances. In invertebrates that are only a few cells thick, diffusion is an effective mechanism for distributing materials to and from their cells. Consequently, many small, aquatic invertebrates have no circulatory system. Fluid between the cells, called **interstitial fluid,** or tissue fluid, bathes the cells and provides a medium for diffusion of oxygen, nutrients, and wastes.

How much time diffusion requires increases with the square of the distance over which diffusion occurs. A cell that is 10 μm away from its oxygen (or nutrient) supply can receive oxygen by diffusion in about 50 msec, but a cell that is 1000 μm (1 mm) away from its oxygen supply would have to wait several minutes and could not survive if it had to depend on diffusion alone. In animals that are many cells thick, specialized **circulatory systems** transport oxygen, nutrients, hormones, and other materials to the interstitial fluid surrounding all the cells and remove metabolic wastes. A circulatory system reduces the diffusion distance that needed materials must travel. In most animals, a circulatory system interacts with every other organ system in the body.

The positron-emission tomography (PET) scan shown here visualizes the left ventricle of the human heart. The human circulatory system, known as the **cardiovascular system,** is the focus of extensive research because cardiovascular disease is the leading

cause of death in the United States and most other industrial societies. A major risk factor for cardiovascular disease is elevated levels of cholesterol and low-density lipoprotein (LDL) in the blood. In contrast, high-density lipoprotein (HDL) seems to play a protective role, removing excess cholesterol from the blood and tissues. Cells in the liver and certain other organs bind with the HDL, remove the cholesterol, and use it in synthesizing needed compounds.

Researchers have identified a gene in mice that codes for an HDL receptor. When investigators knock out this gene, cholesterol levels more than double. As new receptors and mechanisms involved in lipid transport and metabolism are discovered, they serve as targets for new drugs and other treatments for cardiovascular disease. ■

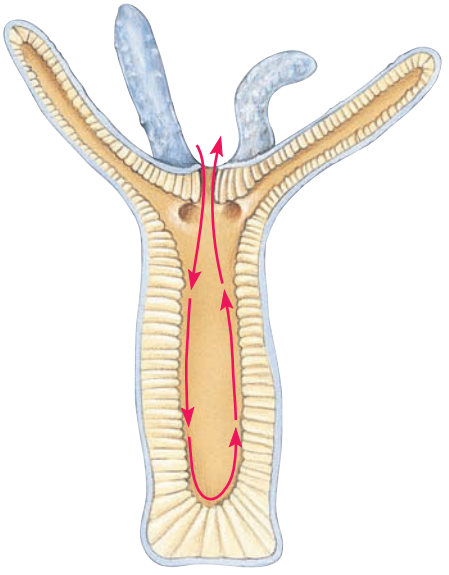
TYPES OF CIRCULATORY SYSTEMS

Learning Objective

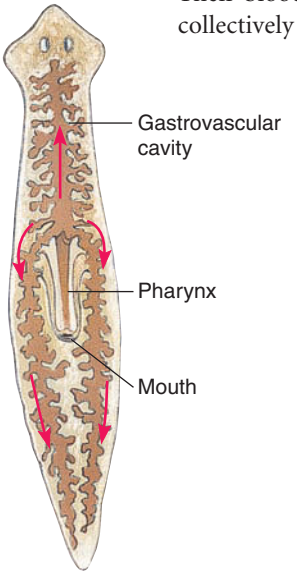
1 Compare and contrast internal transport in animals with no circulatory system, those with an open circulatory system, and those with a closed circulatory system.

No specialized circulatory structures are present in sponges, cnidarians (such as jellyfish), ctenophores (comb jellies), flatworms, or nematodes (roundworms). In cnidarians, the central gastrovascular cavity serves as a circulatory organ as well as a digestive organ (Fig. 43-1a). As the animal stretches and contracts, body movements stir up the contents of the gastrovascular cavity and help distribute nutrients.

The flattened body of the flatworm permits effective gas exchange by diffusion (Fig. 43-1b). Its branched gastrovascular cavity brings nutrients close to all the cells. As in cnidarians, circulation is aided by contractions of the body wall muscles, which agitate the fluid in the gastrovascular cavity. The branching excretory system of planarians provides for internal transport of metabolic wastes that are then expelled from the body.



(a) In *Hydra* and other cnidarians, nutrients circulate through the gastrovascular cavity and come in contact with the inner layer of body cells. Nutrients diffuse the short distance to the outer layer of cells.



(b) In planarian flatworms, the branched gastrovascular cavity allows nutrients to come within close proximity of most body cells.

Figure 43-1 Invertebrates with no circulatory system

Fluid in the body cavity of nematodes and other pseudocoelomate animals helps circulate materials. Nutrients, oxygen, and wastes dissolve in this fluid and diffuse through it to and from the cells. Body movements of the animal move the fluid and thus distribute these materials.

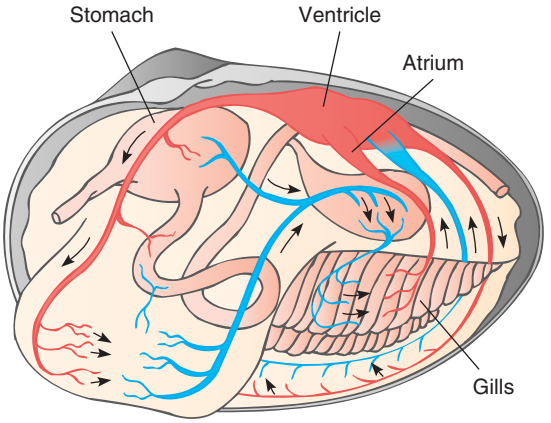
Larger animals require a circulatory system to efficiently distribute materials. A circulatory system typically has the following components: (1) **blood,** a connective tissue consisting of cells and cell fragments dispersed in fluid known as *plasma;* (2) a pumping organ, generally a **heart;** and (3) a system of **blood vessels** or spaces through which blood circulates. Two main types of circulatory systems are open and closed systems.

Many invertebrates have an open circulatory system

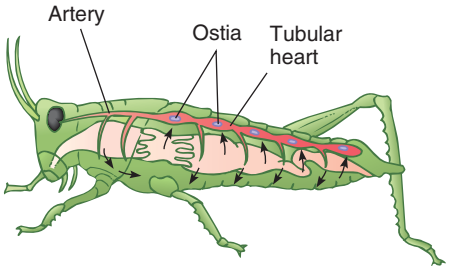
Arthropods and most mollusks have an **open circulatory system,** in which the heart pumps blood into vessels that have open ends. Their blood and interstitial fluid are indistinguishable and are collectively referred to as **hemolymph.** This fluid spills out of the open ends of the blood vessels, filling large spaces, called *sinuses.* The sinuses make up the **hemocoel** (blood cavity), which is not part of the coelom. (In arthropods and mollusks, the coelom is reduced.) The hemolymph bathes the cells of the body directly. Hemolymph re-enters the circulatory system through openings in the heart (in arthropods) or through open-ended vessels that lead to the gills (in mollusks).

In the open circulatory system of most mollusks, the heart typically has three chambers (Fig. 43-2a). The two *atria* receive hemolymph from the gills. Then the single *ventricle* pumps oxygen-rich hemolymph into blood vessels that conduct it into the large sinuses of the hemocoel. After bathing the body cells, the hemolymph passes into vessels that lead to the gills, where it is recharged with oxygen. The hemolymph then returns to the heart.

Some mollusks, as well as arthropods, have a hemolymph pigment, **hemocyanin,** containing copper that transports oxygen. When oxygenated, hemocyanin is blue and imparts a bluish color to the hemolymph of these animals (the original blue bloods!).



(a) In most mollusks, hemolymph enters vessels that conduct it to the gills, where it is recharged with oxygen. Hemolymph then returns to the heart.



(b) In arthropods, a tubular heart pumps hemolymph into arteries that deliver it to the sinuses of the hemocoel. After circulating, hemolymph re-enters the heart through ostia in the heart wall.

Figure 43-2 ***Animated*** Open circulatory systems

In mollusks and arthropods, a heart pumps the blood into arteries that end in sinuses of the hemocoel. Hemolymph circulates through the hemocoel.

In arthropods, a tubular heart pumps hemolymph into arteries, blood vessels that deliver it to the sinuses of the hemocoel (Fig. 43-2b). Hemolymph then circulates through the hemocoel, eventually returning to the pericardial cavity surrounding the heart. Hemolymph enters the heart through ostia, tiny openings equipped with valves that prevent backflow. The rate of hemolymph circulation increases when the animal moves. Thus, when an animal is active and most needs nutrients for fuel, its own movement ensures effective circulation.

In crayfish and other crustaceans, gas exchange takes place as hemolymph circulates through the gills. However, an open circulatory system cannot provide enough oxygen to maintain the active lifestyle of insects. Hemolymph mainly distributes nutrients and hormones in insects. Oxygen diffuses directly to the cells through a system of air tubes (tracheae) that make up the respiratory system (see Figure 45-2).

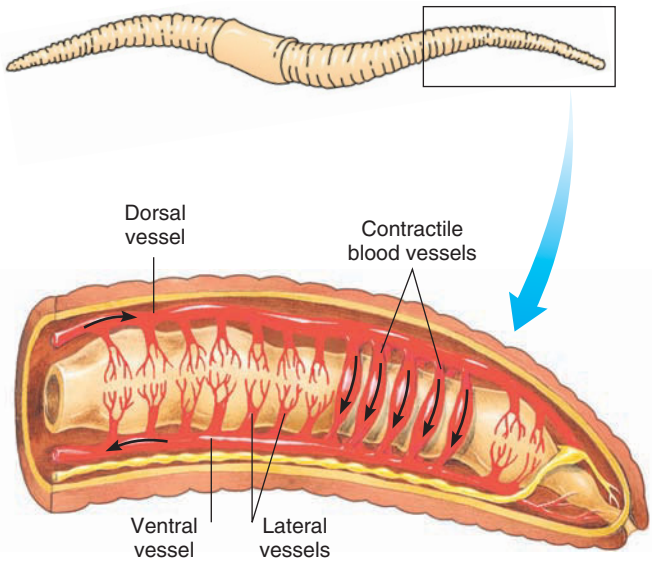


Figure 43-3 ***Animated*** Closed circulatory system of the earthworm

Blood circulates through a continuous system of blood vessels. Five pairs of contractile blood vessels deliver blood from the dorsal vessel to the ventral vessel.

Some invertebrates have a closed circulatory system

Annelids, some mollusks (cephalopods), and echinoderms have a **closed circulatory system.** In them, blood flows through a continuous circuit of blood vessels. The walls of the smallest blood vessels, the *capillaries,* are thin enough to permit diffusion of gases, nutrients, and wastes between blood in the vessels and the interstitial fluid that bathes the cells.

A rudimentary closed circulatory system characterizes proboscis worms (phylum Nemertea). This system consists of a complete network of blood vessels but no heart. Blood flow depends on movements of the animal and on contractions in the walls of large blood vessels.

Earthworms and other annelids have a closed circulatory system (Fig. 43-3). Two main blood vessels extend lengthwise in the body. The ventral vessel conducts blood posteriorly, and the dorsal vessel conducts blood anteriorly. Dorsal and ventral vessels are connected by lateral vessels in every segment. Branches of the lateral vessels deliver blood to the surface, where it is oxygenated. In the anterior part of the worm, five pairs of contractile blood vessels (sometimes called "hearts") connect dorsal and ventral vessels. Contractions of these paired vessels and of the dorsal vessel, as well as contraction of the body wall muscles, circulate the blood. Earthworms have **hemoglobin,** the same red pigment that transports oxygen in vertebrate blood. However, their hemoglobin is not contained within red blood cells but is dissolved in the blood plasma.

Although other mollusks have an open circulatory system, the fast-moving cephalopods, such as the squid and octopus, require a more efficient means of internal transport. They have a

closed system made even more effective by accessory "hearts" at the base of the gills, which speed passage of blood through the gills.

Vertebrates have a closed circulatory system

All vertebrates have a ventral, muscular heart that pumps blood into a closed system of blood vessels. **Capillaries,** the tiniest blood vessels, have very thin walls that permit exchange of materials between blood and interstitial fluid. The vertebrate circulatory system consists of heart, blood vessels, blood, lymph, lymph vessels, and associated organs such as the thymus, spleen, and liver. The system performs several functions:

1. Transports nutrients from the digestive system and from storage depots to each cell
2. Transports oxygen from respiratory structures (gills or lungs) to the cells
3. Transports metabolic wastes from each cell to organs that excrete them
4. Transports hormones from endocrine glands to target tissues
5. Helps maintain fluid balance
6. Helps distribute metabolic heat within the body, which helps maintain a constant body temperature in endothermic animals
7. Helps maintain appropriate pH
8. Defends the body against invading microorganisms

Review

- How are nutrients and oxygen transported to the body cells in a hydra, flatworm, earthworm, insect, and frog?
- How does an open circulatory system differ from a closed circulatory system?
- What are five functions of the vertebrate circulatory system?

VERTEBRATE BLOOD

Learning Objectives

2 Compare the structure and function of plasma, red blood cells, white blood cells, and platelets.

3 Summarize the sequence of events involved in blood clotting.

In vertebrates, blood consists of a pale yellowish fluid called **plasma,** in which red blood cells, white blood cells, and platelets are suspended (Fig. 43-4 and Table 43-1). In humans the total circulating blood volume is 5 L (5.3 qt) in an adult female and about 5.5 L (5.8 qt) in an adult male. About 55% of the blood volume is plasma. The remaining 45% is made up of blood cells and platelets. Because cells and platelets are heavier than plasma, they can be separated from it by centrifugation. Plasma does not separate from blood cells in the body, because the blood is constantly mixed as it circulates in the blood vessels.

Plasma is the fluid component of blood

Plasma consists of water (about 92%), proteins (about 7%), salts, and a variety of materials being transported, such as dissolved gases, nutrients, wastes, and hormones. Plasma is in dynamic equilibrium with the interstitial fluid bathing the cells and with the intracellular fluid. As blood passes through the capillaries, substances continuously move into and out of the plasma. Any deviation from its normal composition signals one or more organs to restore homeostasis.

Plasma contains several kinds of **plasma proteins,** each with specific properties and functions: **fibrinogen;** alpha, beta, and gamma **globulins;** and **albumin.** Fibrinogen is one of the proteins involved in the clotting process. When the proteins involved in blood clotting have been removed from the plasma, the remaining liquid is called **serum.** Alpha globulins include certain

TABLE 43-1

Cell Components of Blood

	Normal Range	Function	Pathology
Red Blood Cells (RBCs)	Male: 4.2–5.4 million/μL Female: 3.6–5.0 million/μL	Oxygen transport; carbon dioxide transport	Too few: anemia Too many: polycythemia
Platelets	150,000–400,000/μL	Essential for clotting	Clotting malfunctions; bleeding; easy bruising
White Blood Cells (WBCs)	5000–10,000/μL		
Neutrophils	About 60% of WBCs	Phagocytosis	Too many: may be due to bacterial infection, inflammation, myelogenous leukemia
Eosinophils	1%–3% of WBCs	Play some role in allergic response	Too many: may result from allergic reaction, parasitic infestation
Basophils	1% of WBCs	May play role in prevention of inappropriate clotting	
Lymphocytes	25%–35% of WBCs	Produce antibodies; destroy foreign cells	Atypical lymphocytes present in infectious mononucleosis; too many may be due to lymphocytic leukemia, certain viral infections
Monocytes	6% of WBCs	Differentiate to form macrophages	May increase in monocytic leukemia and fungal infections

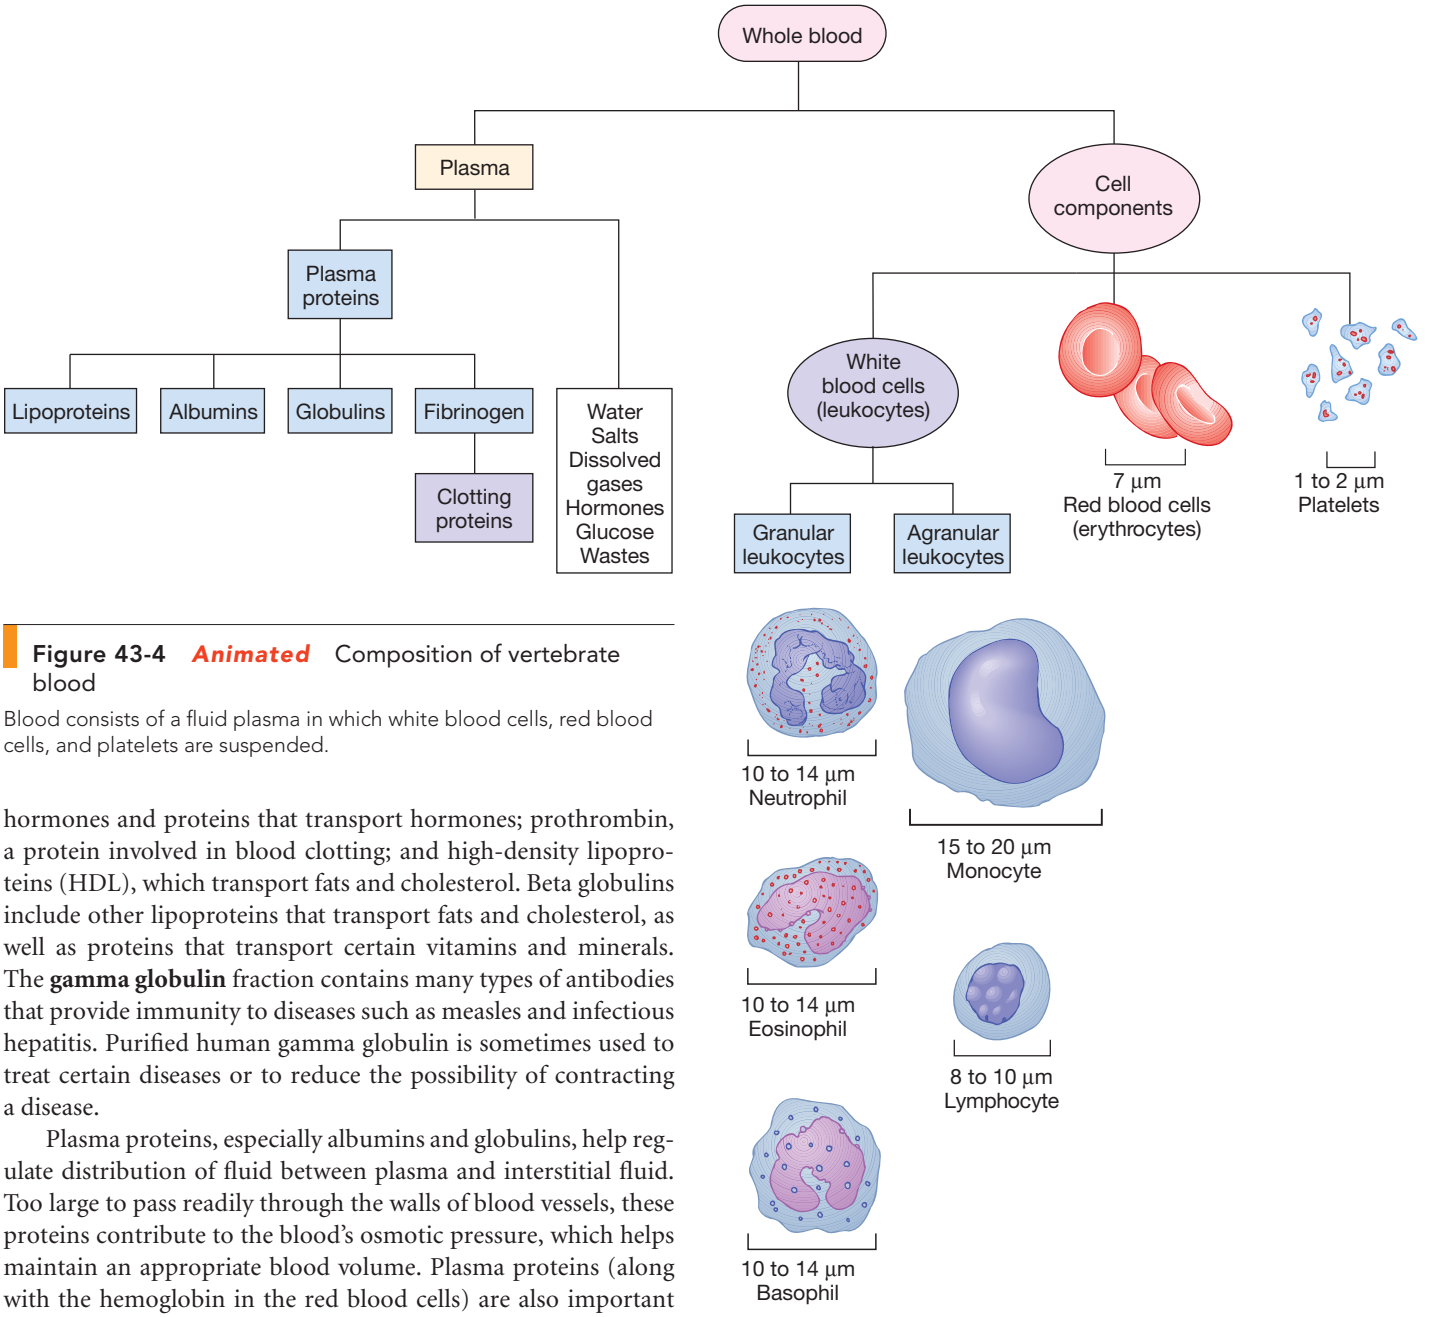

Figure 43-4 ***Animated*** Composition of vertebrate blood

Blood consists of a fluid plasma in which white blood cells, red blood cells, and platelets are suspended.

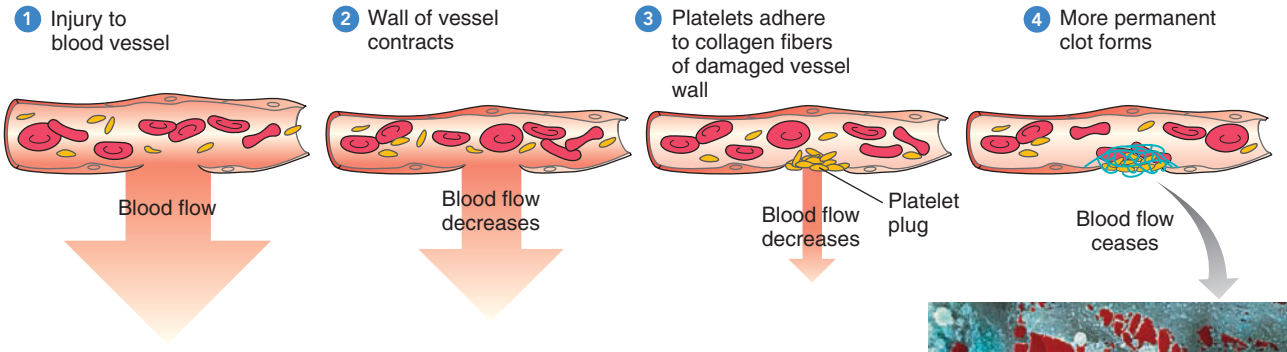
hormones and proteins that transport hormones; prothrombin, a protein involved in blood clotting; and high-density lipoproteins (HDL), which transport fats and cholesterol. Beta globulins include other lipoproteins that transport fats and cholesterol, as well as proteins that transport certain vitamins and minerals. The **gamma globulin** fraction contains many types of antibodies that provide immunity to diseases such as measles and infectious hepatitis. Purified human gamma globulin is sometimes used to treat certain diseases or to reduce the possibility of contracting a disease.

Plasma proteins, especially albumins and globulins, help regulate distribution of fluid between plasma and interstitial fluid. Too large to pass readily through the walls of blood vessels, these proteins contribute to the blood's osmotic pressure, which helps maintain an appropriate blood volume. Plasma proteins (along with the hemoglobin in the red blood cells) are also important acid–base buffers. They help maintain the pH of the blood within a narrow range—near its normal, slightly alkaline pH of 7.4.

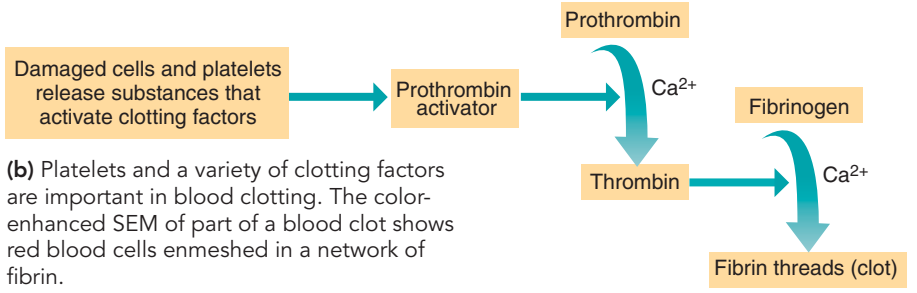
Red blood cells transport oxygen

Erythrocytes, informally called **red blood cells (RBCs),** are highly specialized for transporting oxygen. In most vertebrates except mammals, circulating RBCs have nuclei. For example, birds have large, oval, nucleated RBCs. In mammals, the nucleus is ejected from the RBC as the cell develops. Each mammalian RBC is a flexible, biconcave disc 7 to 8 µm in diameter and 1 to 2 µm thick. An internal elastic framework maintains the disc shape and permits the cell to bend and twist as it passes through blood vessels even smaller than its own diameter. Its biconcave shape provides a high ratio of surface area to volume, allowing efficient diffusion of oxygen and carbon dioxide into and out of the cell. In an adult human, about 30 trillion RBCs circulate in the blood, approximately 5 million per µL.

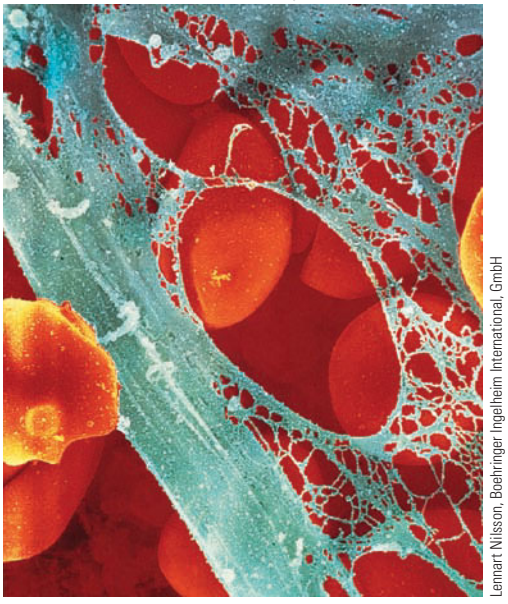
Erythrocytes are produced within the red bone marrow of certain bones: vertebrae, ribs, breastbone, skull bones, and long bones. As an RBC develops, it produces great quantities of hemoglobin, the oxygen-transporting pigment that gives vertebrate blood its red color. (Oxygen transport is discussed in Chapter 45.) The life span of a human RBC is about 120 days. As blood circulates through the liver and spleen, phagocytic cells remove worn-out RBCs from the circulation. These RBCs are then disassembled, and some of their components are recycled. In the human body, more than 2.4 million RBCs are destroyed every second, so an equal number must be produced in the bone marrow to replace them. Red blood cell production is regulated by the



(a) How a blood clot forms when a blood vessel is injured.



(b) Platelets and a variety of clotting factors are important in blood clotting. The color-enhanced SEM of part of a blood clot shows red blood cells enmeshed in a network of fibrin.



Lennart Nilsson, Boehringer Ingelheim International, GmbH

Figure 43-5 Blood clotting

hormone **erythropoietin,** which the kidneys release in response to a decrease in oxygen.

Anemia is a deficiency in hemoglobin (often accompanied by a decrease in the number of RBCs).When hemoglobin is insufficient, the amount of oxygen transported is inadequate to supply the body's needs. An anemic person may complain of feeling weak and may become easily fatigued. Three general causes of anemia are (1) loss of blood from hemorrhage or internal bleeding; (2) decreased production of hemoglobin or red blood cells, as in iron-deficiency anemia or pernicious anemia (which can be caused by vitamin B_{12} deficiency); and (3) increased rate of RBC destruction—the **hemolytic anemias,** such as sickle cell anemia (see Chapter 16).

White blood cells defend the body against disease organisms

The **leukocytes,** or **white blood cells (WBCs),** are specialized to defend the body against harmful bacteria and other microorganisms. Leukocytes are amoeba-like cells capable of independent movement. Some types routinely slip through the walls of blood vessels and enter the tissues. Human blood contains five kinds of leukocytes, classified as either granular or agranular (see Fig. 43-4). Both types are manufactured in the red bone marrow.

The **granular leukocytes** are characterized by large, lobed nuclei and distinctive granules in their cytoplasm. The three varieties of granular leukocytes are the neutrophils, eosinophils, and basophils. **Neutrophils,** the principal phagocytic cells in the blood, are especially adept at seeking out and ingesting bacteria. They also phagocytose dead cells, a cleanup task especially demanding after injury or infection. Most granules in neutrophils contain enzymes that digest ingested material.

Eosinophils have large granules that stain bright red with eosin, an acidic dye. The lysosomes of these WBCs contain enzymes such as oxidases and peroxidases, which suggests that they function in detoxifying foreign proteins and other substances. Eosinophils increase in number during allergic reactions and during parasitic (for example, tapeworm) infestations.

Basophils exhibit deep blue granules when stained with basic dyes. Like eosinophils, these cells play a role in allergic reactions. Basophils do not contain lysosomes. Granules in their cytoplasm contain **histamine,** a substance that dilates blood vessels and makes capillaries more permeable. Basophils release histamine in injured tissues and in allergic responses. Other basophil granules contain **heparin,** an anticoagulant that helps prevent blood from clotting inappropriately within the blood vessels.

Agranular leukocytes lack large, distinctive granules, and their nuclei are rounded or kidney shaped. Two types of agranular leukocytes are lymphocytes and monocytes. Some **lymphocytes** are specialized to produce antibodies, whereas others directly attack foreign invaders such as bacteria or viruses (discussed in Chapter 44).

Monocytes are the largest WBCs, reaching 20 μm in diameter. After circulating in the blood for about 24 hours, a monocyte leaves the circulation and completes its development in the tissues. The monocyte greatly enlarges and becomes a **macrophage,** a giant scavenger cell. All macrophages found in the tissues develop this way. Macrophages voraciously engulf bacteria, dead cells, and debris.

Human blood normally has about 7000 WBCs per μL of blood (only 1 for every 700 RBCs). During bacterial infections the number may rise sharply, so a WBC count is useful in diagnosis. The proportion of each kind of WBC is determined by a differential WBC count. The normal distribution of WBCs is indicated in Table 43-1.

Leukemia is a form of cancer in which any one of the various kinds of WBCs multiplies rapidly within the bone marrow. Many of these cells do not mature, and their large numbers crowd out developing RBCs and platelets, leading to anemia and impaired clotting. A common cause of death from leukemia is internal hemorrhaging, especially in the brain. Another frequent cause of death is infection; although the WBC count may rise dramatically, the cells are immature and abnormal and cannot defend the body against disease organisms.

Platelets function in blood clotting

In most vertebrates other than mammals, the blood contains small, oval, nucleated cells called **thrombocytes** that function in blood clotting. Mammals have **platelets,** tiny spherical or disc-shaped bits of cytoplasm that lack nuclei. About 300,000 platelets per μL are present in human blood. Platelets are pinched off from very large cells in the bone marrow. Thus, a platelet is not a whole cell but a fragment of cytoplasm enclosed by a membrane.

Platelets function in blood clotting and may also stimulate the immune system. When a blood vessel is cut, it constricts to reduce blood loss. Platelets physically patch the break by sticking to the rough, cut edges of the vessel. As platelets begin to gather, they release substances that attract other platelets. The platelets become sticky and adhere to collagen fibers in the blood vessel wall. Within about 5 minutes after injury, they form a platelet plug, or temporary clot.

At the same time that the temporary clot forms, a stronger, more permanent clot begins to develop. More than 30 chemical substances interact in this complex process. The series of reactions that leads to clotting is triggered when one of the clotting factors in the blood is activated by contact with the injured tissue. In **hemophilia,** one clotting factor is absent, as a result of an inherited genetic mutation (see Chapter 16).

Prothrombin, a plasma protein manufactured in the liver, requires vitamin K for its production. In the presence of clotting factors, calcium ions, and compounds released from platelets, prothrombin is converted to **thrombin.** Then thrombin catalyzes the conversion of the soluble plasma protein *fibrinogen* to an insoluble protein, **fibrin.** Once formed, fibrin polymerizes, producing long threads that stick to the damaged surface of the blood vessel and form the webbing of the clot. These threads trap blood cells and platelets, which help strengthen the clot. The clotting process is summarized in Figure 43-5.

VERTEBRATE BLOOD VESSELS

Learning Objective

4 Compare the structure and function of different types of blood vessels, including arteries, arterioles, capillaries, and veins.

The vertebrate circulatory system includes three main types of blood vessels: arteries, capillaries, and veins (Fig. 43-6). An **artery** carries blood away from a heart chamber, toward other tissues. When an artery enters an organ, it divides into many smaller branches called **arterioles.** The arterioles deliver blood into the microscopic capillaries. After blood circulates through an organ, capillaries merge to form **veins** that channel the blood back toward the heart.

The wall of an artery or vein has three layers (see Fig. 43-6b). The innermost layer, which lines the blood vessel, consists mainly of **endothelium,** a tissue that resembles squamous epithelium (see Chapter 38). The middle layer is connective tissue and smooth muscle cells, and the outer coat is connective tissue rich in elastic and collagen fibers.

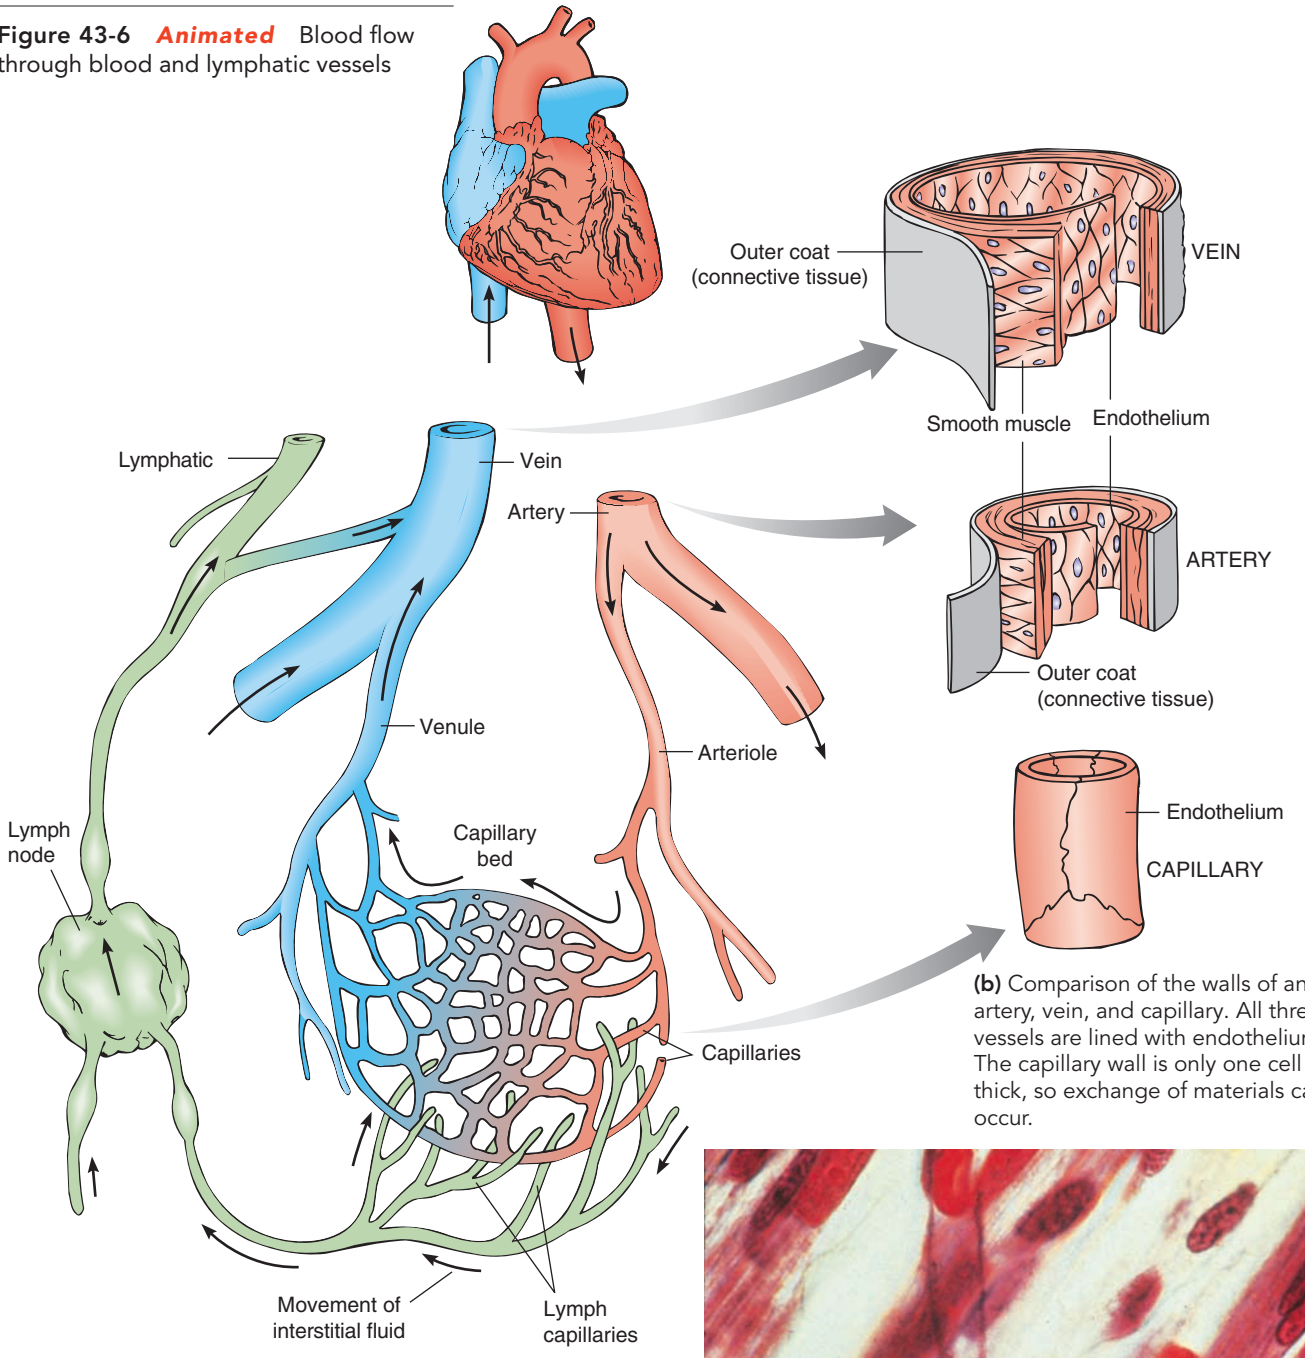
Gases and nutrients cannot pass through the thick walls of arteries and veins. Materials are exchanged between the blood and interstitial fluid bathing the cells through the capillary walls, which are only one cell thick. Capillary networks in the body are so extensive that at least one of these tiny vessels is located close to every cell in the body. The total length of all capillaries in the body has been estimated to be more than 96,000 km!

Smooth muscle in the arteriole wall can constrict (**vasoconstriction**) or relax (**vasodilation**), changing the radius of the arteriole. Such changes help maintain appropriate blood pressure and help control the volume of blood passing to a particular tissue. Changes in blood flow are regulated by the nervous system in response to the metabolic needs of the tissue, as well as by the demands of the body as a whole. For example, when a tissue is metabolizing rapidly, it needs more nutrients and oxygen. During exercise, arterioles within skeletal muscles dilate, increasing by more than 10-fold the amount of blood flowing to these muscle tissues.

If all your blood vessels dilated at the same time, you would not have enough blood to fill them completely. Normally your liver, kidneys, and brain receive the lion's share of blood. However, if an emergency suddenly occurred requiring rapid action, your blood would be rerouted quickly in favor of heart and muscles. At such a time the digestive system and kidneys can do with less blood, because they are not crucial in responding to the crisis.

The small vessels that directly link arterioles with venules (small veins) are **metarterioles.** The true capillaries branch off from the metarterioles and then rejoin them (Fig. 43-7). True

Figure 43-6 ***Animated*** Blood flow through blood and lymphatic vessels



(a) The heart pumps blood into arteries. Blood then flows through arterioles, capillaries, and veins, which return it to the heart. Some plasma leaves the capillaries and becomes interstitial fluid. Lymphatic vessels return excess interstitial fluid to the blood through ducts that lead into large veins in the shoulder region. Blood vessels with oxygen-rich blood are shown in red. Those with oxygen-poor blood are shown in blue.

(b) Comparison of the walls of an artery, vein, and capillary. All three vessels are lined with endothelium. The capillary wall is only one cell thick, so exchange of materials can occur.

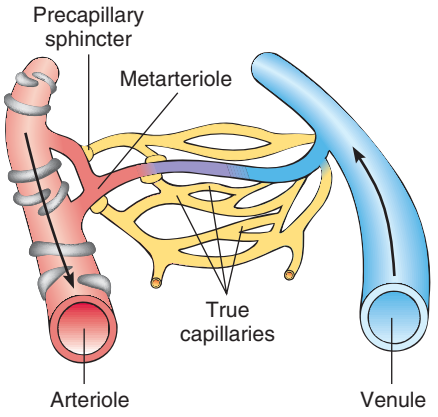
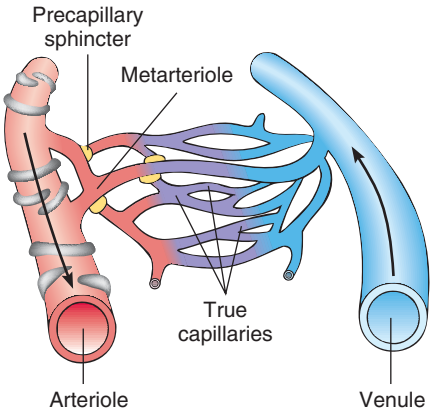
(c) LM of red blood cells passing through capillaries almost in single file.

capillaries also interconnect with one another. Wherever a capillary branches from a metarteriole, a smooth muscle cell serves as a *precapillary sphincter* that opens and closes continuously, directing blood first to one and then to another section of tissue. These precapillary sphincters (along with the smooth muscle in the walls of arteries and arterioles) regulate the blood supply to each organ and its subdivisions.



(a) Sphincters closed. When a tissue is inactive, only its metarterioles are open.



(b) Sphincters open. When the tissue becomes active, decreased oxygen tension in the tissue relaxes the precapillary sphincters, and the capillaries open. This process increases the blood supply and thus the delivery of nutrients and oxygen to the active tissue.

Figure 43-7 Blood flow through a capillary network

As a tissue becomes active, the pattern of blood flow through its capillary networks changes.

EVOLUTION OF THE VERTEBRATE CARDIOVASCULAR SYSTEM

Learning Objective

5 Trace the evolution of the vertebrate cardiovascular system from fish to mammal.

The vertebrate cardiovascular system became modified in the course of evolution, as the site of gas exchange shifted from gills to lungs and as certain vertebrates became active, endothermic animals with higher metabolic rates. The vertebrate heart has one or two **atria** (sing., *atrium*), chambers that receive blood returning from the tissues, and one or two **ventricles** that pump blood into the arteries (Fig. 43-8). Vertebrates in some groups have additional chambers.

The fish heart has one atrium and one ventricle. The atrium pumps blood into the ventricle, which pumps blood into a single circuit of blood vessels. Blood is oxygenated as it passes through capillaries in the gills. After blood circulates through the gill capillaries, its pressure is low, so blood passes very slowly to the other organs. The fish's swimming movements facilitate circulation. Blood returning to the heart has a low oxygen content. A thin-walled sinus venosus receives blood returning from the tissues and pumps it into the atrium.

In amphibians, blood flows through a double circuit: the **pulmonary circulation** and the **systemic circulation.** Oxygen-rich and oxygen-poor blood are kept somewhat separate. The amphibian heart has two atria and one ventricle. A *sinus venosus* collects oxygen-poor blood returning from the veins and pumps it into the right atrium. Blood returning from the lungs passes directly into the left atrium.

Both atria pump into the single ventricle, but oxygen-poor blood is pumped out of the ventricle before oxygen-rich blood enters it. Blood passes into an artery, the *conus arteriosus,* equipped with a fold that helps keep the blood separate. Much of the oxygen-poor blood is directed into the pulmonary circulation, which delivers it to the lungs and skin, where it is recharged with oxygen. The systemic circulation delivers oxygen-rich blood into arteries that conduct it to the various tissues of the body.

Most reptiles also have a double circuit of blood flow, made more efficient by a wall that partly divides the ventricle. Mixing of oxygen-rich and oxygen-poor blood is minimized by the timing of contractions of the left and right sides of the heart and by pressure differences. In crocodilians (crocodiles and alligators), the wall between the ventricles is complete, so the heart consists of two atria and two ventricles. Thus, a four-chambered heart first evolved among the reptiles.

Unlike birds and mammals, amphibians and reptiles do not ventilate their lungs continuously. Therefore, it would be inefficient to pump blood through the pulmonary circulation continuously. The shunts between the two sides of the heart allow blood to be distributed to the lungs as needed.

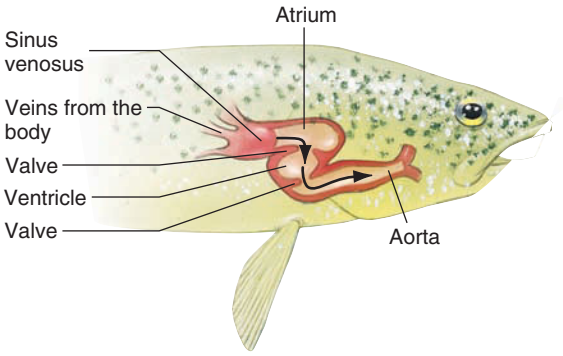
In all birds and mammals (and in crocodilians), the septum (wall) between the ventricles is complete. Biologists hypothesize that the completely divided heart evolved twice during the course of vertebrate evolution; first in the crocodilian–bird clade and then independently in mammals. The septum (wall) between the ventricles prevents oxygen-rich blood in the left chamber from mixing with oxygen-poor blood in the right chamber. The conus arteriosus has split and become the base of the **aorta** (the largest artery) and the pulmonary artery. No sinus venosus is present as a separate chamber, but a vestige remains as the *sinoatrial node* (the pacemaker).

Complete separation of the right and left sides of the heart requires blood to pass through the heart twice each time it tours the body. The complete double circuit allows birds and mammals to maintain relatively high blood pressures in the systemic circulation and modest pressures in the pulmonary circulation. The higher pressure is necessary for efficient circulation of blood through the body. However, the delicate air sacs and capillaries of the lungs would be damaged by this pressure.

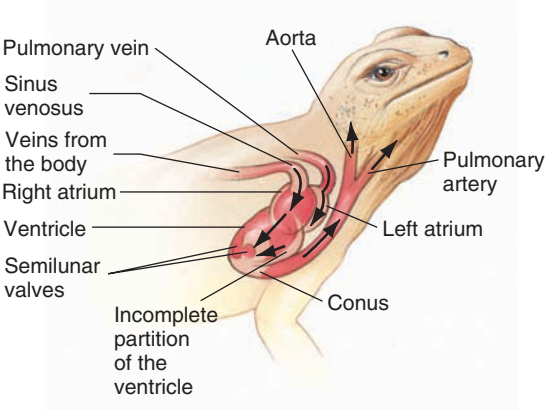
The double circulatory circuit delivers materials to the tissues rapidly and efficiently. Because their blood contains more oxygen

Key Point

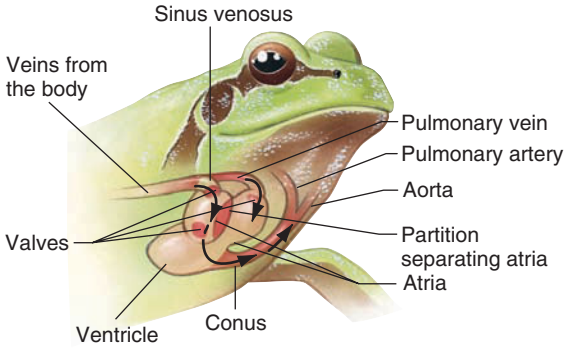
The four-chambered heart and double circuit that separates oxygen-rich from oxygen-poor blood are important adaptations that evolved as vertebrates diversified and some became active, terrestrial, endothermic animals.



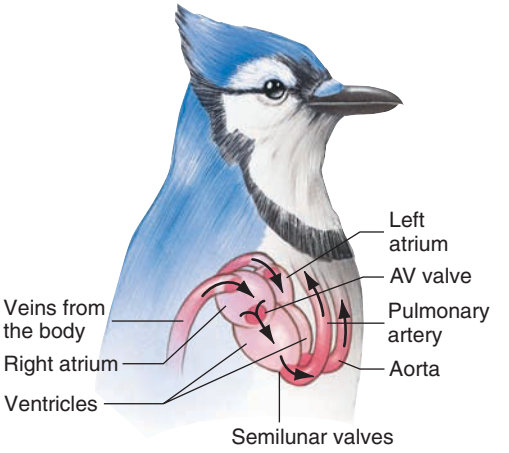
(a) Fishes. The single atrium and ventricle of the fish heart are part of a single circuit of blood flow.



(c) Reptiles. The reptilian heart has two atria and two ventricles. In most reptiles, the wall separating the ventricles is incomplete, so blood from the right and left chambers mixes to some extent. In crocodiles and alligators, the septum is complete and the heart consists of four separate chambers.



(b) Amphibians. In amphibians, the heart consists of two atria and one ventricle, and blood flows through a double circuit.



(d) Birds and mammals. In birds and mammals, the two atria and two ventricles separate oxygen-rich blood from oxygen-poor blood.

Figure 43-8 Evolution of the vertebrate cardiovascular system

per unit volume and circulates more rapidly than in other vertebrates, the tissues of birds and mammals receive more oxygen. As a result, these animals can maintain a higher metabolic rate and a constant, high body temperature even in cold surroundings.

The pattern of blood circulation in birds and mammals can be summarized as follows:

Veins (conduct blood from organs) ⟶ right atrium ⟶ right ventricle ⟶ pulmonary arteries ⟶ capillaries in the lungs ⟶ pulmonary veins ⟶ left atrium ⟶ left ventricle ⟶ aorta ⟶ arteries (conduct blood to organs) ⟶ arterioles ⟶ capillaries

Review

THE HUMAN HEART

Learning Objectives

6 Describe the structure and function of the human heart. (Include the heart's conduction system in your answer.)

7 Trace the events of the cardiac cycle, and relate normal heart sounds to these events.

8 Define *cardiac output,* describe how it is regulated, and identify factors that affect it.

Not much bigger than a fist and weighing less than a pound, the human heart is a remarkable organ that beats about 2.5 billion times in an average lifetime, pumping about 300 million L (80 million gal) of blood. To meet the body's changing needs, the heart can vary its output from 5 L to more than 20 L of blood per minute.

Your heart is a hollow, muscular organ located in the chest cavity directly under the breastbone. Its wall consists mainly of cardiac muscle attached to a framework of collagen fibers. The **pericardium,** a tough connective tissue sac, encloses the heart. A smooth layer of endothelium covers the inner surface of the pericardium and the outer surface of the heart. Between these two surfaces is a small **pericardial cavity** filled with fluid, which reduces friction to a minimum as the heart beats.

A wall, or **septum,** separates the right atrium and ventricle from the left atrium and ventricle. Between the atria, the wall is known as the **interatrial septum;** between the ventricles, the **interventricular septum.** A shallow depression, the **fossa ovalis,** on the interatrial septum marks the place where an opening, the **foramen ovale,** was located in the fetal heart. In the fetus, the foramen ovale lets the blood flow directly from right to left atrium, so very little passes to the nonfunctional lungs. A small muscular pouch, called an **auricle,** lies at the upper surface of each atrium.

To keep blood from flowing backward, the heart has valves that close automatically (Fig. 43-9). The valve between the right atrium and right ventricle is called the **right atrioventricular (AV) valve,** or **tricuspid valve.** The **left AV valve** (between the left atrium and left ventricle) is the **mitral valve,** or **bicuspid valve.** The AV valves are held in place by stout cords, or "heartstrings," the **chordae tendineae.** These cords attach the valves to the papillary muscles that project from the walls of the ventricles.

When blood returning from the tissues fills the atria, blood pressure on the AV valves forces them to open into the ventricles, filling the ventricles with blood. As the ventricles contract, blood is forced back against the AV valves, pushing them closed. Contraction of the papillary muscles and tensing of the chordae tendineae prevent the valves from opening backward into the atria. These valves are like swinging doors that open in only one direction.

Semilunar valves (named for their flaps, which are shaped like half-moons) guard the exits from the heart. The semilunar valve between the left ventricle and the aorta is the **aortic valve,** and the one between the right ventricle and the pulmonary artery is the **pulmonary valve.** When blood passes out of the ventricles, the flaps of the semilunar valves are pushed aside and offer no resistance to blood flow. But when the ventricles are relaxing and filling with blood from the atria, blood pressure in the arteries is higher than in the ventricles. Blood then fills the pouches of the valves, stretching them across the artery so blood cannot flow back into the ventricle.

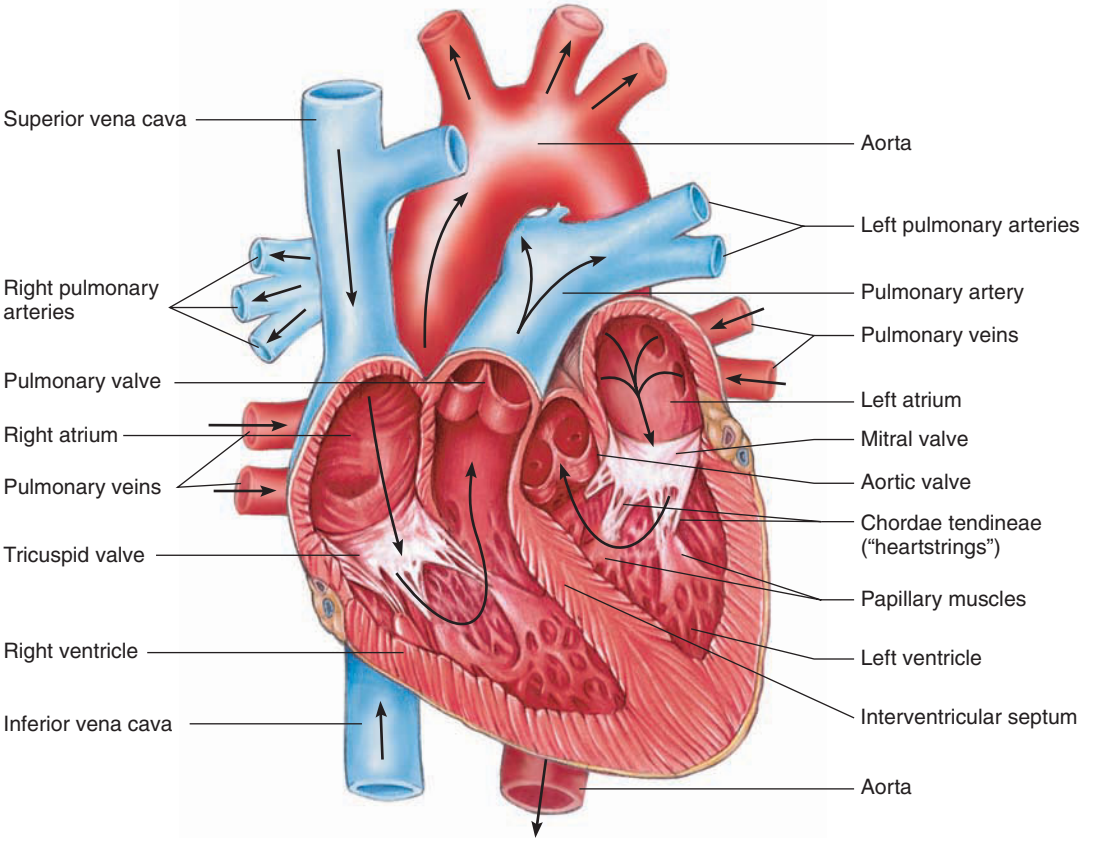

Figure 43-9 ***Animated*** Section through the human heart showing the valves

Note the right and left atria, which receive blood, and the right and left ventricles, which pump blood into the arteries. Arrows indicate the pattern of blood flow.

Each heartbeat is initiated by a pacemaker

Horror films sometimes feature a scene in which a heart cut out of a human body continues to beat. Scriptwriters of these tales actually have some factual basis for their gruesome fantasies, because a heart carefully removed from the body does continue to beat for many hours if kept in a nutritive, oxygenated fluid. This is possible because the contractions of cardiac muscle begin within the muscle itself and can occur independently of any nerve supply (Fig. 43-10a).

At their ends cardiac muscle cells are joined by dense bands called **intercalated discs** (Fig. 43-10b and c). Each disc is a type of *gap junction* (see Chapter 5) in which two cells connect through pores. This type of junction is of great physiological importance, because it offers very little resistance to the passage of an action potential. Ions move easily through the gap junctions, allowing the entire atrial (or ventricular) muscle mass to contract as one giant cell.

Compared with skeletal muscle that has action potentials typically lasting 1 to 2 msec, the action potentials of cardiac muscle are much longer, several hundred milliseconds. Voltage-activated Ca^{2+} channels open during depolarization of cardiac muscle fibers. Entry of Ca^{2+} contributes to the longer depolarization time. Another factor is a type of K^+ channel that stays open when the cell is at its resting potential but closes during depolarization, lengthening depolarization time by decreasing the permeability of the membrane to K^+. From experiments on isolated cardiac muscle fibers, investigators determined that spontaneous contraction results from the combination of a slow decrease in K^+ permeability and a slow increase in Na^+ and Ca^{2+} permeability.

A specialized conduction system ensures that the heart beats in a regular and effective rhythm. Each beat is initiated by the **pacemaker,** also called the **sinoatrial (SA) node.** The SA node is a small mass of specialized cardiac muscle in the posterior wall of the right atrium near the opening of a large vein, the superior vena cava. The action potential in the SA node is triggered mainly by the opening of Ca^{2+} channels. Ends of the SA node fibers fuse with ordinary atrial muscle fibers, so each action potential spreads through both atria, producing atrial contraction.

One group of atrial muscle fibers conducts the action potential directly to the **atrioventricular (AV) node,** located in the right atrium along the lower part of the septum. Here transmission is delayed briefly so that the atria finish contracting before the ventricles begin to contract. From the AV node the action potential spreads into specialized muscle fibers that make up the **AV bundle.** The AV bundle divides, sending branches into each ventricle. Fibers of the bundle branches divide further, eventually forming small *Purkinje fibers.* When an impulse reaches the ends of the Purkinje fibers, it spreads through the ordinary cardiac muscle fibers of the ventricles.

SA node ⟶ atrial muscle fibers (atria contract) ⟶ AV node ⟶ AV bundle ⟶ right and left bundle branches ⟶ Purkinje fibers ⟶ ventricular muscle fibers (ventricles contract)

As each wave of contraction spreads through the heart, electric currents flow into the tissues surrounding the heart and onto

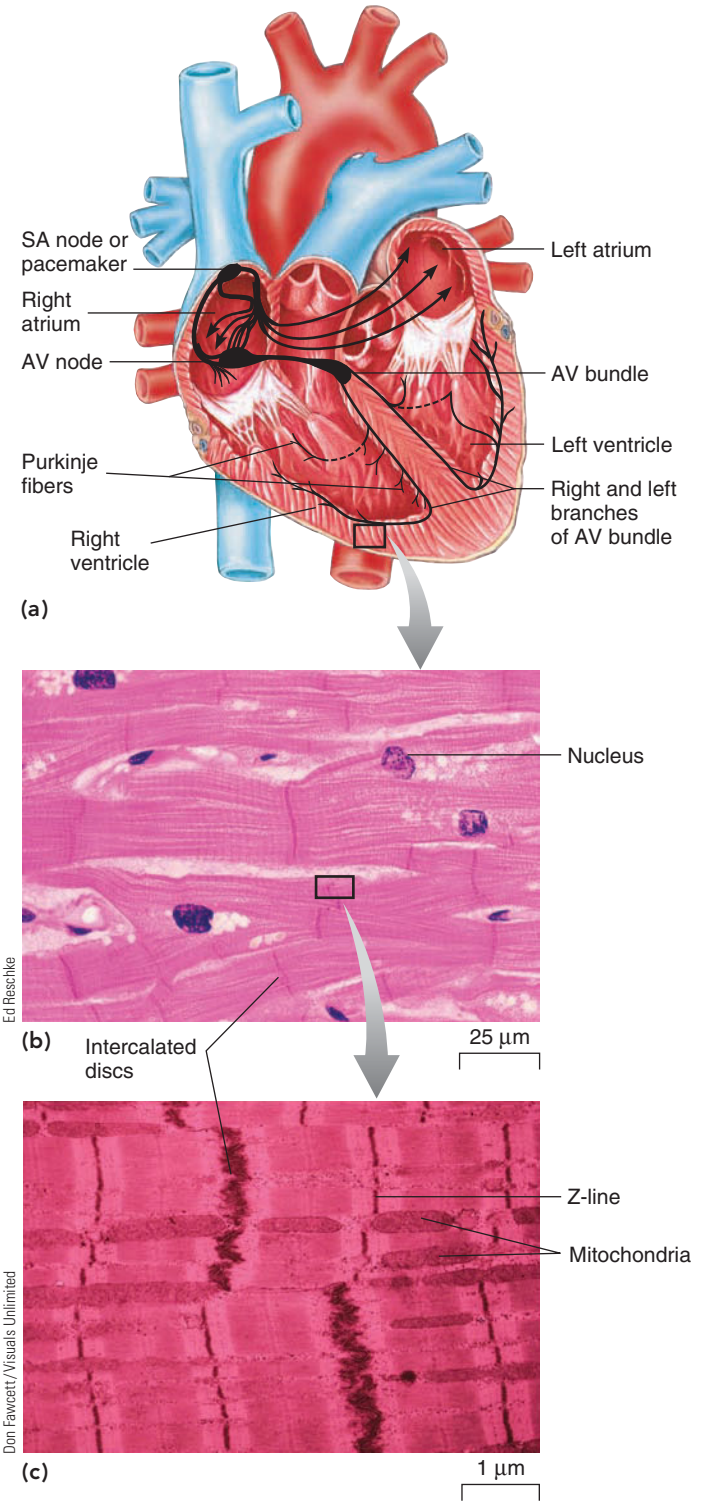

Figure 43-10 ***Animated*** Conduction system of the heart

(a) The sinoatrial (SA) node initiates each heartbeat. The action potential spreads through the muscle fibers of the atria, producing atrial contraction. Transmission is briefly delayed at the atrioventricular (AV) node before the action potential spreads through specialized muscle fibers into the ventricles. **(b)** LM of cardiac muscle. **(c)** TEM of cardiac muscle.

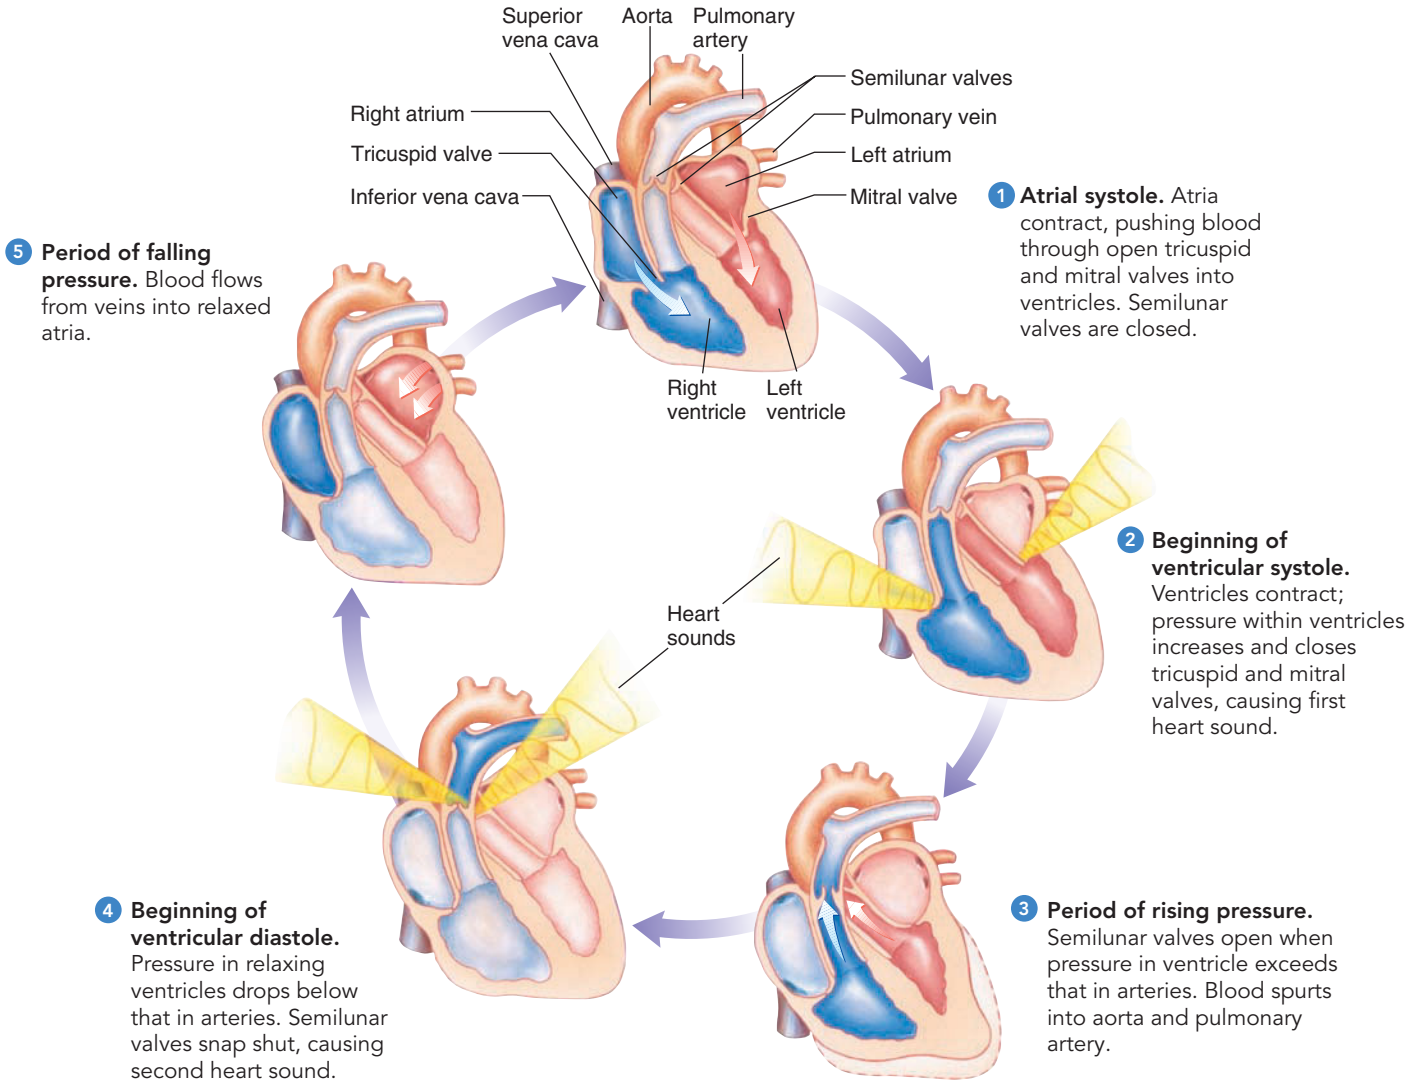

Figure 43-11 ***Animated*** The cardiac cycle

The cycle comprises contraction of both atria followed by both ventricles. White arrows indicate the direction of blood flow; dotted lines indicate the change in size as contraction occurs.

the body surface. By placing electrodes on the body surface on opposite sides of the heart, a physician can amplify and record the electrical activity. The graph produced is called an **electrocardiogram** (**EKG** or **ECG**). Abnormalities in the EKG indicate disorders in the heart or its rhythm. For example, in **heart block,** impulse transmission is delayed or blocked at some point in the conduction system. **Artificial pacemakers** can help patients with severe heart block. The pacemaker is implanted beneath the skin and its electrodes connected to the heart. This device provides continuous rhythmic impulses that avoid the block and drive the heartbeat.

Each minute the heart beats about 70 times. One complete heartbeat takes about 0.8 second and is referred to as a **cardiac cycle.** That portion of the cycle in which contraction occurs is known as **systole;** the period of relaxation is **diastole.** Figure 43-11 shows the sequence of events that occur during one cardiac cycle.

You can measure your heart rate by placing a finger over the radial artery in your wrist or the carotid artery in your neck and counting the pulsations for 1 minute. **Arterial pulse** is the alternate expansion and recoil of an artery. Each time the left ventricle pumps blood into the aorta, the elastic wall of the aorta expands to accommodate the blood. This expansion moves in a wave down the aorta and the arteries that branch from it. When this pressure wave passes, the elastic arterial wall snaps back to its normal size.

When you listen to the heartbeat with a stethoscope, you can hear two main heart sounds, "lub-dup," which repeat rhythmically. These sounds result from the heart valves closing. When the valves close, they cause turbulence in blood flow that sets up vibrations in the walls of the heart chambers. The first heart sound, "lub," is low-pitched, not very loud, and fairly long-lasting. It is caused mainly by the closing of the AV (mitral and tricuspid) valves and marks the beginning of ventricular systole. The "lub"

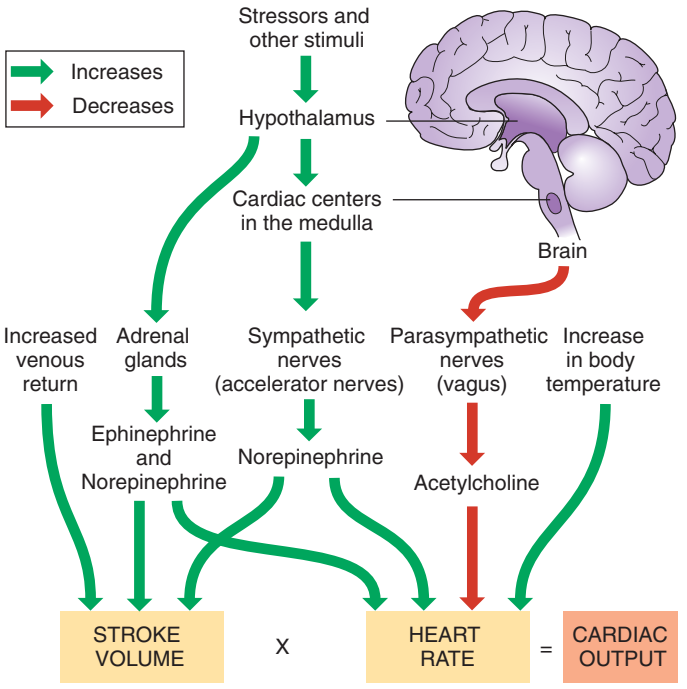

Figure 43-12 Some factors that influence cardiac output

sound is quickly followed by the higher-pitched, louder, sharper, and shorter "dup" sound. Heard almost as a quick snap, the "dup" marks the closing of the semilunar valves and the beginning of ventricular diastole.

The quality of these sounds tells a discerning physician much about the state of the valves. For example, when a valve does not close tightly, blood may flow backward. When the semilunar valves are injured, a soft, hissing noise ("lub-shhh") known as a **heart murmur** is heard in place of the normal sound. Valve deformities are sometimes present at birth, or they may result from certain diseases, such as rheumatic fever or syphilis. Diseased or deformed valves can be surgically repaired or replaced with artificial valves.

The nervous system regulates heart rate

Although the heart can beat independently, its rate is, in fact, carefully regulated by the nervous and endocrine systems (Fig. 43-12). Sensory receptors in the walls of certain blood vessels and heart chambers are sensitive to changes in blood pressure. When stimulated, the receptors send messages to **cardiac centers** in the medulla of the brain. These cardiac centers govern two sets of autonomic nerves that pass to the SA node: parasympathetic and sympathetic nerves.

Parasympathetic and sympathetic nerves have opposite effects on heart rate (see Fig. 41-17). Parasympathetic nerves release the neurotransmitter *acetylcholine,* which slows the heart. Acetylcholine slows the rate of depolarization by increasing the membrane's permeability to K^+ (Fig. 43-13a). Sympathetic nerves release norepinephrine, which speeds the heart rate and increases the strength of contraction. Norepinephrine stimulates Ca^{2+} channel opening during depolarization (Fig. 43-13b).

Both norepinephrine and acetylcholine act indirectly on ion channels. They activate a *signal transduction* process involving a G protein. Norepinephrine binds to *beta-adrenergic receptors,* one of the two main types of adrenergic receptors. These receptors are targeted by *beta blockers,* drugs that block the actions of norepinephrine on the heart and are used clinically in treating hypertension and other types of heart disease.

In response to physical and emotional stressors, the adrenal glands release epinephrine and norepinephrine, which speed the heart. An elevated body temperature also increases heart rate. During fever, the heart may beat more than 100 times per minute. As you might expect, heart rate decreases when body temperature is lowered. This is the reason that physicians may deliberately lower a patient's temperature during heart surgery.

Stroke volume depends on venous return

The volume of blood one ventricle pumps during one beat is the **stroke volume.** Stroke volume depends mainly on **venous return,** the amount of blood the veins deliver to the heart. According to **Starling's law of the heart,** if the veins deliver more blood to the heart, the heart pumps more blood (within physiological limits). When extra amounts of blood fill the heart chambers, the cardiac muscle fibers stretch more and contract with greater force, pumping a larger volume of blood into the arteries. Norepinephrine released by sympathetic nerves and epinephrine released by the adrenal glands during stress also increase the force of contraction of cardiac muscle fibers.

Cardiac output varies with the body's need

By multiplying the stroke volume by the number of times the left ventricle beats per minute, we can compute the **cardiac output (CO).** The CO is the volume of blood pumped by the left ventricle into the aorta in 1 minute. For example, in a resting adult the heart may beat about 72 times per minute and pump about 70 mL of blood with each contraction.

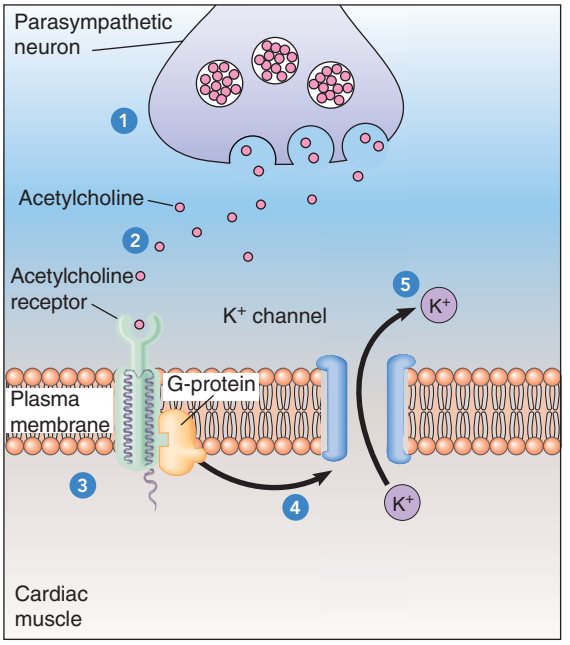
$$\text{CO} = \text{stroke volume} \times \text{heart rate (number of ventricular contractions per minute)}$$

$$= 70\ \text{mL/stroke} \times 72\ \text{strokes/min}$$

$$= 5040\ \text{mL/min (about 5 L/min)}$$

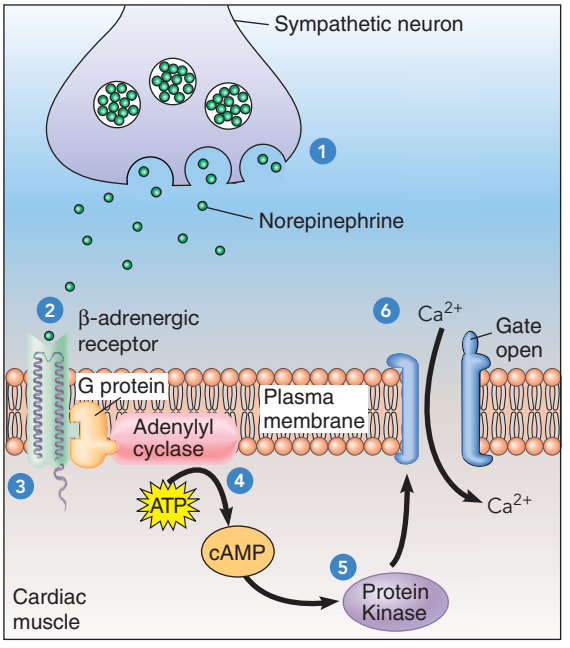
Cardiac output varies with changes in either stroke volume or heart rate (see Fig. 43-12).When stroke volume increases, CO increases. The CO varies dramatically with the changing needs of the body. During stress or heavy exercise, the normal heart can increase its CO fivefold so that it pumps 20 to 30 L of blood per minute.

1. Parasympathetic neuron releases acetylcholine.
2. Acetylcholine binds with receptors on plasma membrane of cardiac muscle.
3. Receptor activates G protein.
4. G protein binds with K^+ channel, opening it.
5. K^+ leaves the cell, hyperpolarizing the membrane. Action potentials occur more slowly.



(a) Parasympathetic action on cardiac muscle

1. Sympathetic neuron releases norepinephrine.
2. Norepinephrine binds with receptors on the plasma membrane of cardiac muscle.
3. Receptor activates G protein.
4. G protein activates adenylyl cyclase, which converts ATP to cyclic AMP.
5. Cyclic AMP activates protein kinase.
6. Protein kinase phosphorylates Ca^{2+} channels so that they open more easily when neuron is depolarized. Action potentials occur more rapidly.



(b) Sympathetic action on cardiac muscle

Figure 43-13 Actions of sympathetic and parasympathetic neurons on cardiac muscle cells

Neurotransmitters released by sympathetic and parasympathetic neurons initiate a signal transduction process.

BLOOD PRESSURE

Learning Objective

9 Identify factors that determine and regulate blood pressure, and compare blood pressure in different types of blood vessels.

Blood pressure is the force exerted by the blood against the inner walls of the blood vessels. It is determined by CO, blood volume, and the resistance to blood flow (Fig. 43-14a).When CO increases, the increased blood flow causes a rise in blood pressure. When CO decreases, the decreased blood flow causes a fall in blood pressure. If the volume of blood is reduced by hemorrhage or by chronic bleeding, the blood pressure drops. In contrast, an increase in blood volume results in an increase in blood pressure. For example, a high dietary intake of salt causes water retention. This increases blood volume and raises blood pressure.

Blood flow is impeded by resistance; when the resistance to flow increases, blood pressure rises. **Peripheral resistance** is the resistance to blood flow caused by blood viscosity and by friction between blood and the blood vessel wall. In the blood of a healthy person, viscosity remains fairly constant and is only a minor influence on changes in blood pressure. More important is the friction between blood and the blood vessel wall. The length and diameter of a blood vessel determine the amount of surface area in contact with the blood. Blood vessel length does not change, but the diameter, especially of an arteriole, does. A small change in blood vessel diameter causes a big change in blood pressure. Constriction of blood vessels raises blood pressure; dilation lowers blood pressure.

Blood pressure in arteries rises during systole and falls during diastole. The National Institutes of Health defines normal blood pressure as a systolic pressure of less than 120 and a diastolic pressure of less than 80. An example of a normal blood pressure, measured in the upper arm with a sphygmomanometer, is 110/73 mm of mercury, abbreviated mm Hg. Systolic pressure is indicated by the first number, diastolic by the second.

If you have a blood pressure of 120 to 139 systolic over 80 to 89 diastolic, you are considered *prehypertensive,* and you need to modify your lifestyle to prevent cardiovascular disease and

CARDIOVASCULAR DISEASE

Cardiovascular disease is the leading cause of death in the United States and in most other industrialized countries. Death often results from some complication of **atherosclerosis,**[1] a progressive disease in which the walls of certain arteries are damaged, inflamed, and narrowed as a result of lipid deposits in their walls. Although it can affect almost any artery, the disease most often develops in the aorta and in the coronary and cerebral arteries. When it occurs in the cerebral arteries, less blood is delivered to the brain. This condition can lead to a **cerebrovascular accident (CVA),** commonly referred to as a stroke.

The mechanisms leading to atherosclerosis are not completely understood. A widely accepted hypothesis is that the disease process is a "response to injury." Studies indicate that the injury commonly occurs when excess low-density lipoprotein (LDL), known as "bad" cholesterol, in the blood triggers inflammation in the inner layer of the arterial wall. (Inflammation, discussed in Chapter 44, is one of the body's most important responses to infection or injury.) Other suspected causes are infectious agents and toxins, including those from cigarette smoke.

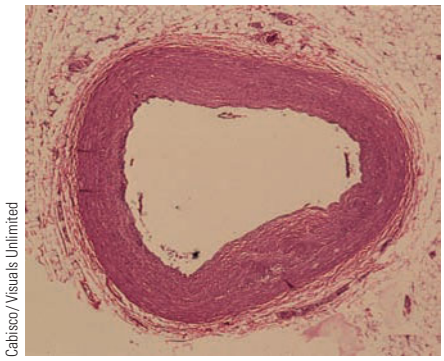
When excess LDLs are present, they become oxidized and adhere to the wall of the blood vessel. Macrophages take up LDL cholesterol and stimulate a series of events that promotes inflammation. Underlying smooth muscle fibers then migrate to the inner lining of the artery and multiply there. Collagen and other connective tissue fibers also proliferate, reducing the elasticity of the artery wall. The muscle fibers and collagen form a fibrous cap of tissue over the injured area of the artery. The buildup of fatty substances, smooth muscle fibers, collagen, and sometimes, calcium is called **atherosclerotic plaque.**

As atherosclerotic plaque develops, arteries lose their ability to stretch when filled with blood. As the walls thicken, the diameter of the artery decreases, and it gradually becomes occluded (blocked), as shown in the figure. The occluded vessels deliver less blood to the tissues, which then become **ischemic,** or lacking in blood. Now the tissue is deprived of an adequate oxygen and nutrient supply.

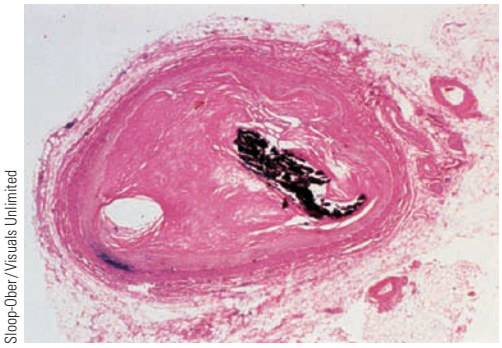
In **ischemic heart disease,** the increased need for oxygen during exercise or emotional stress results in the pain characteristic of **angina pectoris.** Nitroglycerin pills or a nitroglycerin patch dilates veins, decreasing venous return. Cardiac output is lowered so the heart is not working as hard and requires less oxygen. Nitroglycerin also dilates the coronary arteries slightly, allowing more blood to reach the heart muscle. *Calcium ion channel blockers* are drugs that slow the heart by inhibiting the passage of Ca^{2+} into cardiac muscle fibers. They also dilate the coronary arteries.

Myocardial infarction (MI), or heart attack, is a very serious, often fatal, consequence of cardiovascular disease. MI is the leading cause of death and disability

[1] Atherosclerosis is a type of arteriosclerosis that affects large and medium-sized arteries. *Arteriosclerosis* is a general term for thickening of the walls of arteries.



(a) Normal coronary artery.



(b) This artery is almost completely blocked with atherosclerotic plaque.

Progression of atherosclerosis. LMs of cross sections through two arteries showing changes that take place in atherosclerosis.

stroke. Lifestyle changes that will reduce your risk include exercising, losing excess weight, following a heart-healthy diet, reducing salt intake, limiting alcohol, and not smoking.

If your systolic pressure consistently measures 140 mm Hg or higher or your diastolic pressure measures 90 mm Hg or higher, you have **hypertension,** or high blood pressure. Hypertension is a risk factor for atherosclerosis and other cardiovascular disease (see *Focus On: Cardiovascular Disease*). In hypertension, there is usually increased vascular resistance, especially in the arterioles and small arteries. The heart's workload increases because it must pump against this greater resistance. If this condition persists, the left ventricle enlarges and may deteriorate in function. Heredity, aging, and ethnicity contribute to the development of hypertension.

Blood pressure varies in different blood vessels

As you might guess, blood pressure is greatest in the large arteries, decreasing as blood flows away from the heart and through the smaller arteries and capillaries (Fig. 43-14b). By the time blood enters the veins, its pressure is very low, even approaching zero. Flow rate can be maintained in veins at low pressure, because they are low-resistance vessels. Their diameter is larger than that of corresponding arteries, and their walls have little smooth muscle. Flow of blood through veins depends on several factors, including skeletal muscle movement, which compresses veins. Most veins larger than 2 mm (0.08 in) in diameter that conduct blood

in the United States. In fact, for about 65% of men and almost 50% of women, the first symptom of atherosclerotic cardiovascular disease is MI or sudden cardiac death, death within one hour of onset of the symptoms. MI often results from a sudden decrease in coronary blood supply. The part of cardiac muscle deprived of oxygen dies within a few minutes and is then referred to as an **infarct.** The sudden decrease in blood supply often occurs when inflammation causes the fibrous cap over the atherosclerotic plaque to break open. Platelets adhere to the roughened arterial wall and initiate clotting.

A **thrombus,** a clot that forms within a blood vessel or within the heart, can block a sizable branch of a coronary artery. Blood flow to a portion of heart muscle is impeded or completely halted. When such blockage, referred to as a *coronary occlusion,* prevents blood flow to a large region of cardiac muscle, the heart may stop beating; that is, **cardiac arrest** occurs, and death can follow within moments. If only a small part of the heart is affected, however, the heart may continue to function. Cells in the region deprived of oxygen die and are replaced by scar tissue.

An episode of ischemia may trigger a fatal arrhythmia such as **ventricular fibrillation,** a condition in which the ventricles contract very rapidly without actually pumping blood. The pulse may stop, and blood pressure may fall precipitously. Ventricular fibrillation has been linked with about 65% of cardiac arrests. The only effective treatment for fibrillation is **defibrillation** with electric shock. The shock appears to depolarize every muscle fiber in the heart so that its timing mechanism can reset.

Patients with progressive cardiovascular disease can be treated with *coronary bypass surgery* in which veins from another location in the patient's body are grafted around occluded coronary arteries. The newly positioned blood vessels restore adequate blood flow to the affected area. Another procedure, *coronary angioplasty,* involves inserting a small balloon into an occluded coronary artery. Inflating the balloon breaks up the plaque in the arterial wall and thus widens the vessel.

Approaches to preventing and treating cardiovascular disease include use of anti-inflammatory agents and statins, medications that lower cholesterol level. A molecular marker of inflammation called C-reactive protein (CRP) is used to assess the risk of heart disease. Several major *modifiable* risk factors for cardiovascular disease have been identified:

1. *Elevated LDL–cholesterol levels in the blood:* Elevation of LDL–cholesterol levels is associated with diets rich in total calories, total fats, saturated fats, and cholesterol.
2. *Hypertension:* The higher the blood pressure is, the greater the risk. The hormone angiotensin II, which at abnormally high levels is thought to contribute to hypertension, also stimulates inflammation.
3. *Cigarette smoking:* The risk of developing atherosclerosis is 2 to 6 times as great in smokers as in nonsmokers and is directly proportional to the number of cigarettes smoked daily. Components of cigarette smoke cause oxidants to form, which may contribute to the inflammation by increasing oxidation of the altered LDL in the arterial wall.
4. *Diabetes mellitus:* In this endocrine disorder, glucose is not metabolized normally. The body shifts to fat metabolism, and there is a marked increase in circulating lipids, leading to atherosclerosis. Impaired glucose tolerance is also a risk factor.
5. *Physical inactivity:* One in four adults in the United States has a sedentary lifestyle and does not engage in regular exercise. Physical inactivity contributes to more than one third of the approximately 500,000 deaths related to heart disease in the United States each year. Exercise reduces the concentrations of triacylglycerols (triglycerides) and cholesterol in the blood (these lipids have been associated with heart disease). At the same time, exercise increases the concentration of high-density lipoproteins (HDLs), which protect against heart disease.
6. *Obesity:* Obesity can affect cholesterol levels and increase the risk of hypertension and diabetes.

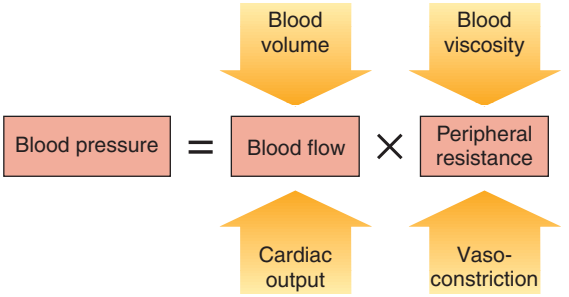
The risk of developing cardiovascular disease also increases with age. Other probable risk factors currently being studied are hereditary predisposition, hormone levels, stress and behavior patterns, and dietary factors.

against the force of gravity are equipped with *valves* to prevent backflow (Fig. 43-15). Such valves usually consist of two cusps formed by inward extensions of the vein wall.

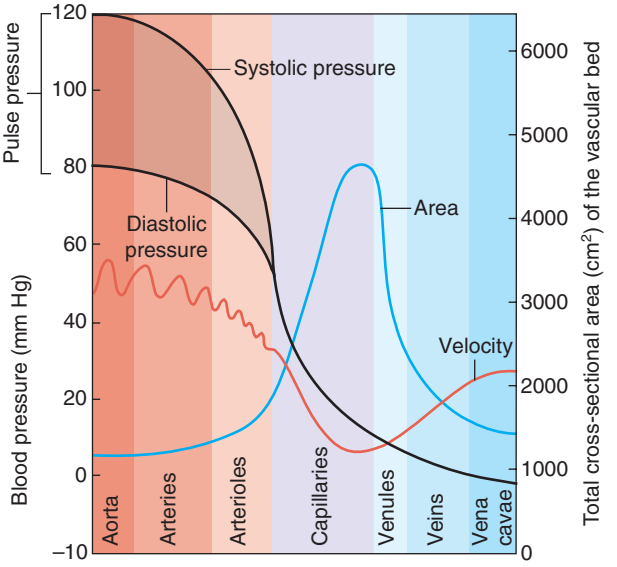
When a person stands perfectly still for a long time, as when a soldier stands at attention or a store clerk stands at a cash register, blood tends to pool in the veins. When fully distended, veins can accept no more blood from the capillaries. Pressure in the capillaries increases, and large amounts of plasma are forced out of the circulation through the thin capillary walls. Within just a few minutes, as much as 20% of the blood volume is lost from the circulation—with drastic effect. Arterial blood pressure falls dramatically, reducing blood flow to the brain. Sometimes the resulting lack of oxygen in the brain causes fainting, a protective response. Lying in a prone position increases blood supply to the brain. In fact, lifting a person who has fainted to an upright position can result in circulatory shock and even death.

Blood pressure is carefully regulated

Each time you get up from a horizontal position, your blood pressure changes. Several mechanisms interact to maintain normal blood pressure so that you do not faint when you get out of bed each morning or change position during the day. When blood pressure decreases, sympathetic nerves to the blood vessels stimulate vasoconstriction, causing the pressure to rise again.



(a) Blood pressure depends on blood flow and resistance to that flow. A variety of factors affect blood flow and resistance.



(b) Blood pressure varies in different types of blood vessels. Systolic and diastolic variations in arterial blood pressures are shown. Note that the venous pressure drops below zero (below atmospheric pressure) near the heart.

Figure 43-14 ***Animated*** Blood pressure

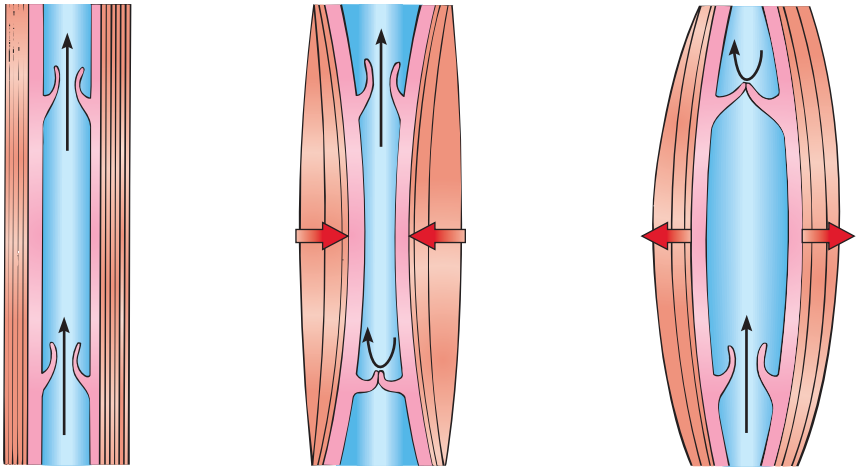
Area in graph refers to the surface area of blood vessels in contact with blood.

Baroreceptors, specialized receptors in the walls of certain arteries and in the heart wall, are sensitive to changes in blood pressure. When an increase in blood pressure stretches the baroreceptors, messages are sent to the cardiac and vasomotor centers in the medulla of the brain. The cardiac center stimulates parasympathetic nerves that slow the heart, lowering blood pressure. The vasomotor center inhibits sympathetic nerves that constrict arterioles; this action causes vasodilation, which also lowers blood pressure. These neural reflexes continuously work in a complementary way to maintain blood pressure within normal limits.

Several hormones are also involved in regulating blood pressure (discussed in more detail in Chapters 47 and 48). In response to low blood pressure, the kidneys release **renin,** which activates the **renin–angiotensin–aldosterone pathway.** Renin acts on a plasma protein (angiotensinogen), triggering a cascade of reactions that produces the hormone **angiotensin II,** a powerful vasoconstrictor. Vasoconstriction *increases* blood pressure, restoring homeostasis. Angiotensin II also acts indirectly to maintain blood pressure by increasing the synthesis and release of the hormone **aldosterone** by the adrenal glands. Aldosterone increases retention of Na^+ by the kidneys, resulting in greater fluid retention and increased blood volume.

When the body becomes dehydrated, the osmotic concentration of the blood increases. In response, the posterior lobe of the pituitary gland releases **antidiuretic hormone (ADH).** ADH increases reabsorption of water in the kidneys (and only a small volume of concentrated urine is produced). Blood volume increases, increasing blood pressure and restoring homeostasis.

When blood volume increases, the atria of the heart release a hormone called **atrial natriuretic peptide (ANP),** which increases sodium excretion. As a result, blood pressure *decreases.* Nitric oxide also helps regulate blood pressure by causing vasodilation and thus decreased blood pressure.



(a) Resting condition.

(b) Muscles contract. Muscles bulge, compressing veins and forcing blood toward the heart. The lower valve prevents backflow.

(c) Muscles relax. The vein expands and fills with blood from below. The upper valve prevents backflow.

Figure 43-15 ***Animated*** Venous blood flow

Contraction of skeletal muscles helps move blood through the veins.

Review

- What is peripheral resistance? How does it affect blood pressure?
- Blood pressure is low in capillaries. How does this help retain fluid in the circulation?

THE PATTERN OF CIRCULATION

Learning Objective

10 Trace a drop of blood through the pulmonary and systemic circulations, naming in sequence each structure through which it passes.

Most vertebrates other than fishes have a double circuit of blood vessels: (1) the pulmonary circulation connects the heart and lungs; and (2) the systemic circulation connects the heart with all the body tissues. You can trace this general pattern of circulation in Figure 43-16.

The pulmonary circulation oxygenates the blood

Blood from the tissues returns to the right atrium of the heart. This oxygen-poor blood, loaded with carbon dioxide, is pumped by the right ventricle into the pulmonary circulation. As it emerges from the heart, the large pulmonary trunk branches to form the **pulmonary arteries** that deliver blood to the lungs. These are the only arteries that carry oxygen-poor blood.

In the lungs the pulmonary arteries branch into smaller and smaller vessels, which finally give rise to extensive networks of pulmonary capillaries that surround the air sacs of the lungs. As blood circulates through the pulmonary capillaries, carbon dioxide diffuses out of the blood and into the air sacs. Oxygen from the air sacs diffuses into the blood so that by the time it enters the **pulmonary veins** leading back to the left atrium of the heart, the blood is charged with oxygen. Pulmonary veins are the only veins in the body that carry blood rich in oxygen.

In summary, blood flows through the pulmonary circulation in the following sequence:

Right atrium ⟶ right ventricle ⟶ pulmonary arteries ⟶ pulmonary capillaries (in lungs) ⟶ pulmonary veins ⟶ left atrium

The systemic circulation delivers blood to the tissues

Blood entering the systemic circulation is pumped by the left ventricle into the *aorta,* the largest artery. Arteries that branch off from the aorta conduct blood to all regions of the body. Some of the principal branches include the **coronary arteries** to the heart wall itself, the **carotid arteries** to the brain, the **subclavian arteries** to the shoulder region, the **mesenteric artery** to the intestine, the **renal arteries** to the kidneys, and the **iliac arteries** to the legs (Fig. 43-17). Each of these arteries gives rise to smaller and smaller vessels, somewhat like branches of a tree that divide until they form tiny twigs. Eventually blood flows into capillary networks within each tissue or organ.

Blood returning from the capillary networks within the brain passes through the **jugular veins.** Blood from the shoulders and arms drains into the **subclavian veins.** These veins and others returning blood from the upper portion of the body merge to form a very large vein that empties blood into the right atrium. In humans this vein is called the **superior vena cava.** The **renal veins** from the kidneys, **iliac veins** from the lower limbs, **hepatic veins** from the liver, and other veins from the lower portion of the body return blood to the **inferior vena cava,** which delivers blood to the right atrium.

Key Point

The right side of the heart receives oxygen-poor blood and pumps it into the pulmonary circulation. The left side of the heart receives oxygen-rich blood from the lungs and pumps it into the systemic circulation.

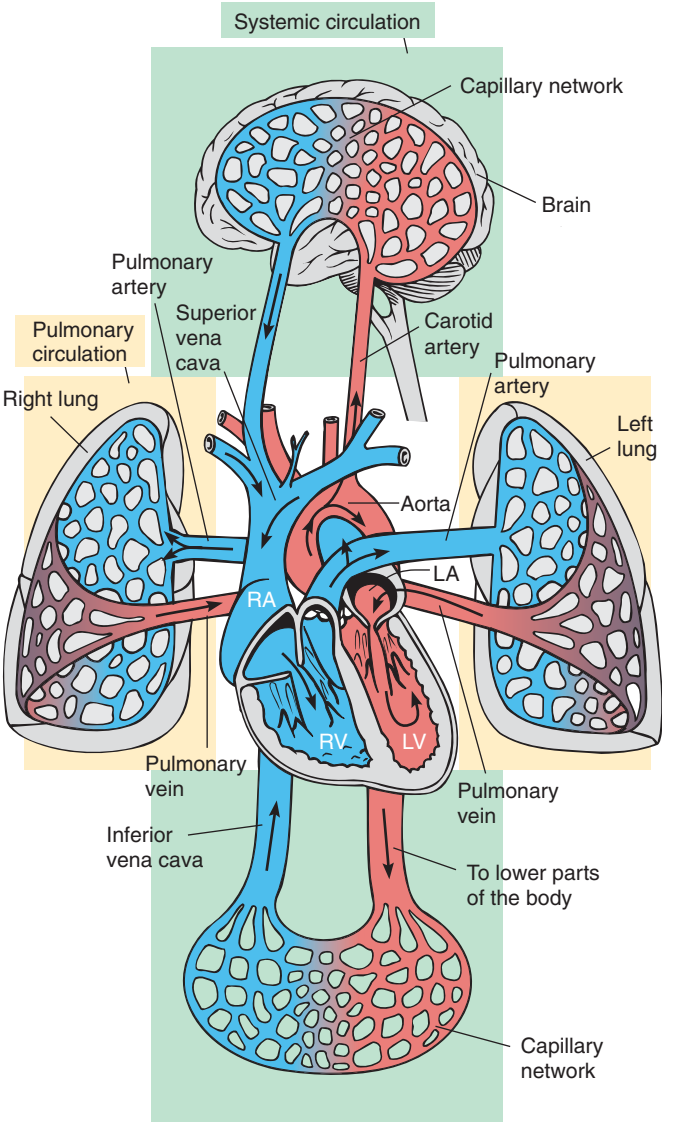


Figure 43-16 ***Animated*** Systemic and pulmonary circulation

In this highly simplified diagram, red represents oxygen-rich blood and blue represents oxygen-poor blood. Green screen highlights systemic circulation. Yellow screen highlights pulmonary circulation.

As an example of blood circulation through the systemic circuit, let us trace a drop of blood from the heart to the right leg and back to the heart:

> Left atrium ⟶ left ventricle ⟶ aorta ⟶ right common iliac artery ⟶ smaller arteries in leg ⟶ capillaries in leg ⟶ small veins in leg ⟶ common iliac vein ⟶ inferior vena cava ⟶ right atrium

In most fishes, amphibians, and reptiles, the heart muscle is spongy and receives oxygen directly from the blood as it passes through the heart chambers. However, in birds and mammals the walls of the heart are too thick for nutrients and oxygen to reach all the muscle fibers by diffusion. Instead, the cardiac muscle has its own system of blood vessels. In humans, **coronary arteries** give rise to a network of capillaries within the heart wall. The **coronary veins** join to form a large vein, the **coronary sinus,** which empties directly into the right atrium.

Blood almost always travels from artery to capillary to vein to the heart. An exception occurs in the **hepatic portal system.** Instead of leading directly back to the heart (as most veins do), the hepatic portal vein delivers nutrients from the intestine to the liver. Within the liver, the hepatic portal vein gives rise to an extensive network of tiny blood sinuses. As blood courses through the hepatic sinuses, liver cells remove nutrients and store them. Eventually liver sinuses merge to form hepatic veins, which deliver blood to the inferior vena cava.

Review

- What sequence of blood vessels and heart chambers would a red blood cell pass through on its way (1) from the inferior vena cava to the aorta and (2) from the renal vein to the renal artery?
- What is the function of the hepatic portal system? How does its sequence of blood vessels differ from that in most other circulatory routes?

THE LYMPHATIC SYSTEM

Learning Objective

11 Describe the structure and functions of the lymphatic system.

Vertebrates have in addition to the blood circulatory system an accessory circulatory system, the **lymphatic system** (Fig. 43-18). The lymphatic system (1) collects and returns interstitial fluid to the blood, (2) launches immune responses that defend the body against disease organisms, and (3) absorbs lipids from the

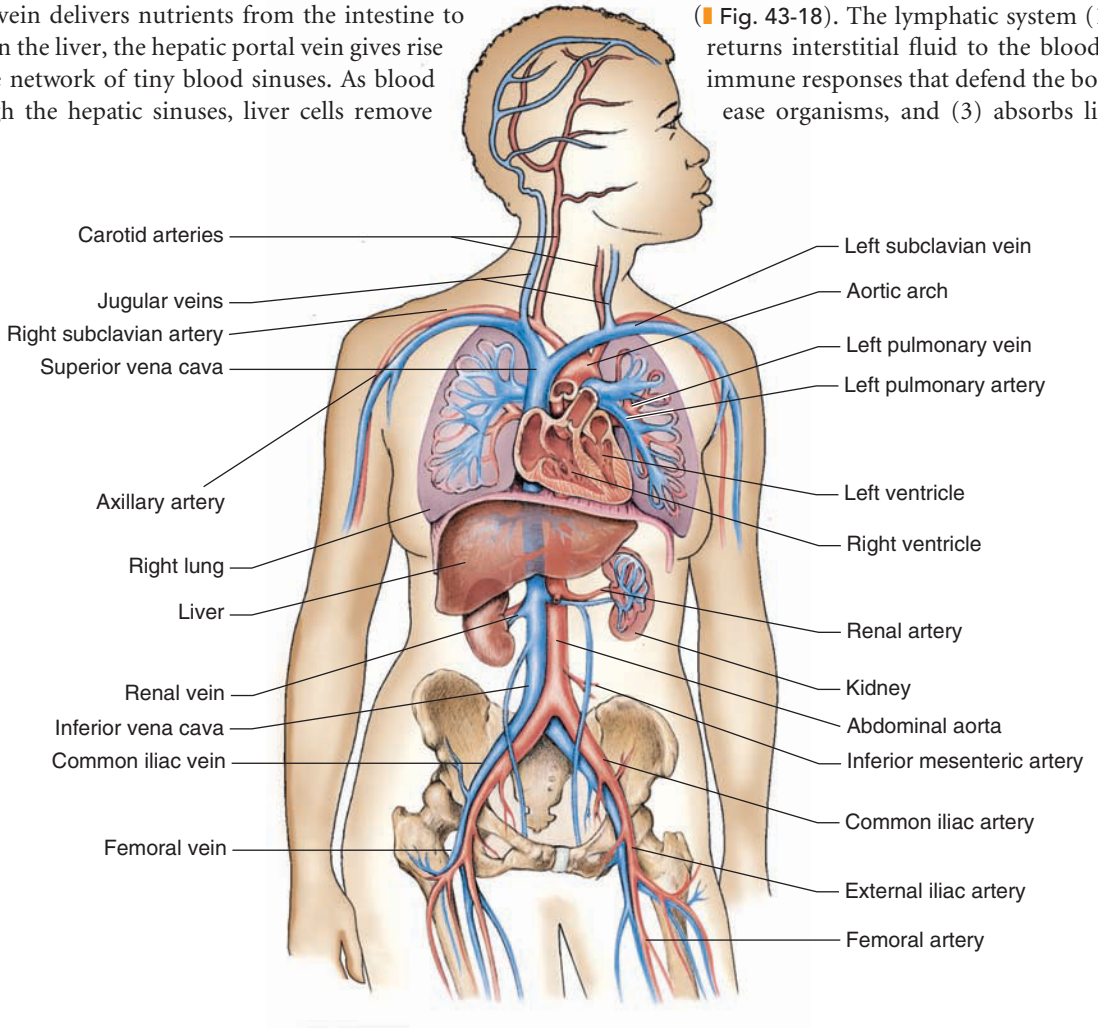

Figure 43-17 ***Animated*** Blood circulation through some of the principal arteries and veins of the human body

Blood vessels carrying oxygen-rich blood are red; those carrying oxygen-poor blood are blue.

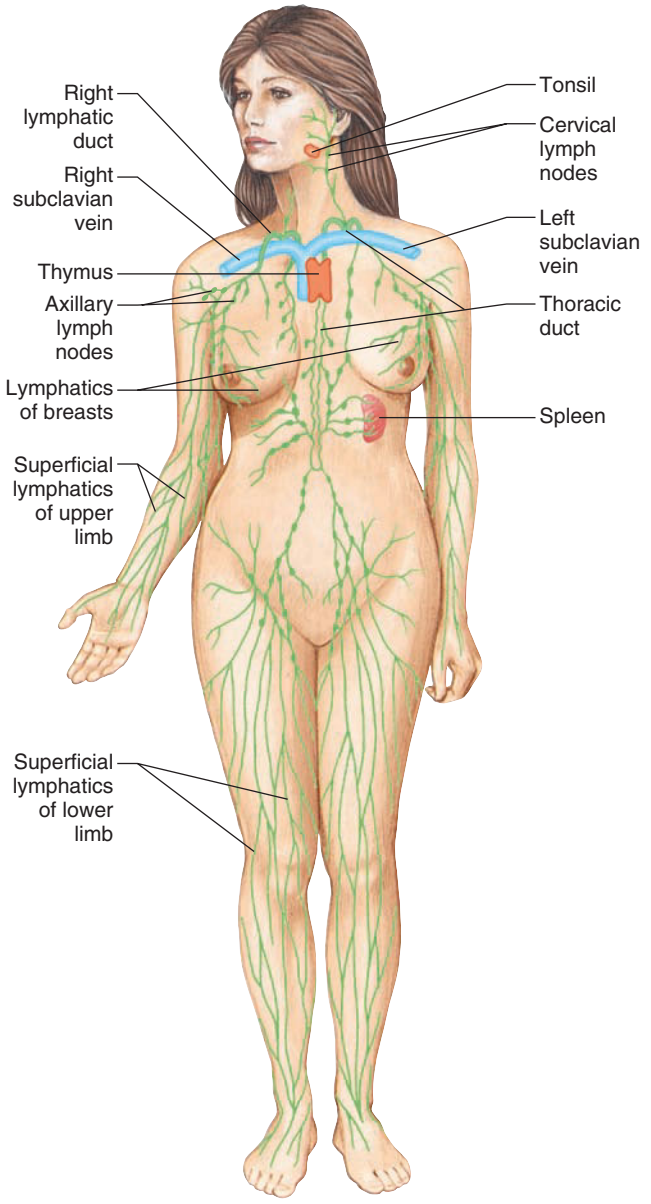

Figure 43-18 ***Animated*** Human lymphatic system

Note that the lymphatic vessels extend into most tissues of the body but the lymph nodes are clustered in certain regions. The right lymphatic duct drains lymph from the upper right quadrant of the body. The thoracic duct drains lymph from other regions of the body.

digestive tract. In this section we focus on the first function. We discuss immunity in Chapter 44 and lipid absorption in Chapter 46.

The lymphatic system consists of lymphatic vessels and lymph tissue

The lymphatic system consists of (1) an extensive network of **lymphatic vessels,** or simply **lymphatics,** that conduct **lymph,** the clear, watery fluid formed from interstitial fluid; and (2) **lymph**

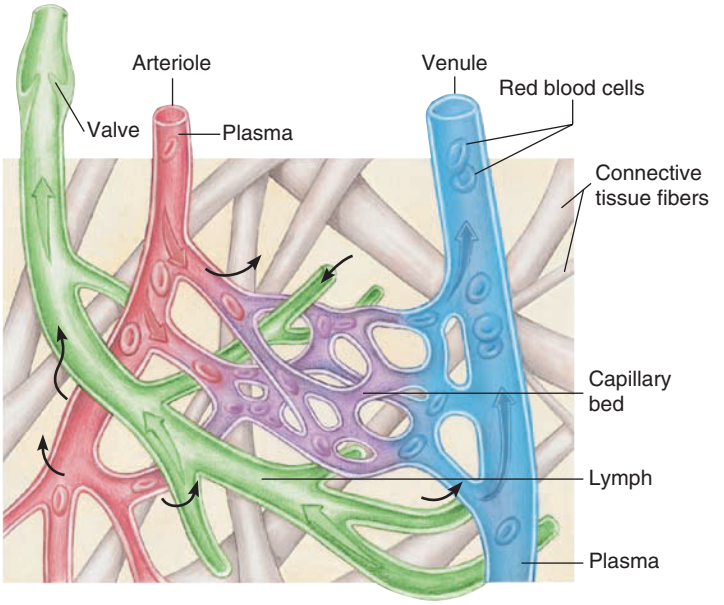

Figure 43-19 Lymph capillaries

Lymph capillaries drain excess interstitial fluid from the tissues. Note that blood capillaries are connected to vessels at both ends, whereas lymph capillaries (*shown in green*) are "dead-end streets." The arrows indicate direction of flow.

tissue, a type of connective tissue with large numbers of lymphocytes. Lymph tissue is organized into small masses of tissue called **lymph nodes** and **lymph nodules.** The tonsils, thymus gland, and spleen, which consist mainly of lymph tissue, are also part of the lymphatic system.

Tiny "dead-end" capillaries of the lymphatic system extend into almost all body tissues (Fig. 43-19). Lymph capillaries join to form larger lymphatics (which you can think of as lymph veins). There are no lymph arteries.

Interstitial fluid enters lymph capillaries, where it becomes lymph. The lymph is conveyed into lymphatics, which at certain locations empty into lymph nodes. As lymph circulates through the lymph nodes, phagocytes filter out bacteria and other harmful materials. The lymph then flows into lymphatics that conduct it away from the lymph node. Lymphatics from all over the body conduct lymph toward the shoulder region. These vessels join the circulatory system at the base of the subclavian veins by way of ducts: the **thoracic duct** on the left side and the **right lymphatic duct** on the right.

Tonsils are masses of lymph tissue under the lining of the oral cavity and throat. (When enlarged, the pharyngeal tonsils in back of the nose are called **adenoids.**) Tonsils help protect the respiratory system from infection by destroying bacteria and other foreign matter that enter the body through the mouth or nose. Unfortunately, tonsils are sometimes overcome by invading bacteria and become the site of frequent infection themselves.

Some vertebrates, such as frogs, have lymph "hearts," which pulsate and squeeze lymph along. However, in mammals the walls of lymphatic vessels themselves pulsate. Valves within the lymphatics prevent the lymph from flowing backward. When

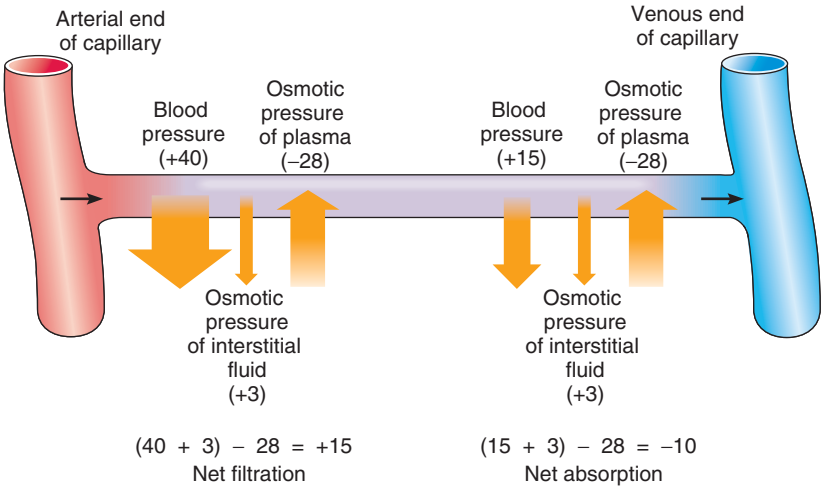

Figure 43-20 Fluid movement between blood and interstitial fluid

Blood hydrostatic pressure and osmotic pressures are responsible for fluid movement, and thus exchange of dissolved materials, between blood and interstitial fluid. At the arterial end of a capillary, blood pressure forces plasma out of the capillary. The osmotic pressure of the blood is an opposing force acting to draw fluid into the blood. Osmotic pressure of the interstitial fluid contributes to the net filtration pressure but does not change much between arterial and venous ends of the capillary. At the venous end of the capillary, fluid enters the blood because blood pressure is much lower. However, more fluid leaves the blood than returns, and the lymphatic system collects the excess interstitial fluid. The numbers given are hypothetical and represent millimeters of mercury. Net filtration is the total pressure moving fluid out of the capillary. Net absorption is the total pressure drawing fluid into the capillary.

muscles contract or when arteries pulsate, pressure on the lymphatic vessels increases lymph flow. The rate at which lymph flows is slow and variable, and the total lymph flow is about 100 mL per hour—far slower than the 5 L per min of blood flowing in the vascular system.

The lymphatic system plays an important role in fluid homeostasis

When blood enters a capillary network, it is under rather high pressure, so some plasma is forced out of the capillaries into the tissues. Once it leaves the blood vessels, this fluid is called *interstitial fluid*, or tissue fluid. It contains no red blood cells or platelets and only a few white blood cells. Its protein content is about one fourth that found in plasma, because proteins are too large to pass easily through capillary walls. However, smaller molecules dissolved in the plasma do pass out with the fluid leaving the blood vessels. Thus, interstitial fluid contains glucose, amino acids, other nutrients, and oxygen, as well as a variety of salts. This nourishing fluid bathes all the cells.

The main force (*filtration pressure*) pushing plasma out of the blood is hydrostatic pressure, that is, the blood pressure against the capillary wall (Fig. 43-20). The osmotic pressure of the interstitial fluid adds to the filtration pressure. The principal opposing force is the osmotic pressure of the blood, which is greater than the osmotic pressure of the interstitial fluid and restrains fluid loss from the capillary.

At the venous ends of the capillaries the blood hydrostatic pressure is much lower, and the osmotic pressure of the blood draws fluid back into the capillary. However, not as much fluid is absorbed back into the circulation as is filtered out. Furthermore, protein does not return effectively into the venous capillaries and instead tends to accumulate in the interstitial fluid. These potential problems are so serious that without the lymphatic system, fluid balance in the body would be significantly disturbed within a few hours, and death would occur within about 24 hours. The lymphatic system preserves fluid balance by collecting some of the interstitial fluid (about 10%), including the protein that accumulates in it, and returning it to the circulation.

The walls of the lymph capillaries consist of endothelial cells that overlap slightly. When interstitial fluid accumulates, it presses against these cells, pushing them inward like tiny swinging doors that swing in only one direction. As fluid accumulates within the lymph capillary, these cell doors are pushed closed.

Obstruction of the lymphatic vessels causes **edema,** swelling from excessive accumulation of interstitial fluid. Lymphatic vessels can be blocked as a result of injury, inflammation, surgery, or parasitic infection. For example, when a breast is removed (mastectomy) because of cancer, lymph nodes in the underarm region may also be removed to prevent the spread of cancer cells. The disrupted lymph circulation makes the patient's arm swell. New lymphatic vessels develop within a few months, and the swelling slowly subsides.

Review

- What are the relationships among plasma, interstitial fluid, and lymph?
- How does the lymphatic system help maintain fluid balance?

SUMMARY WITH KEY TERMS

Learning Objectives

1 Compare and contrast internal transport in animals with no circulatory system, those with an open circulatory system, and those with a closed circulatory system (page 920).

- Small, simple invertebrates, such as sponges, cnidarians, and flatworms, depend on **diffusion** for internal transport.

Larger animals require a specialized **circulatory system,** which typically consists of **blood,** a **heart,** and a system of **blood vessels** or spaces through which blood circulates. In all animals, **interstitial fluid,** the tissue fluid between cells, brings oxygen and nutrients into contact with cells.

- Arthropods and most mollusks have an **open circulatory system** in which blood flows into a **hemocoel,** bathing the tissues directly.
- Some invertebrates and all vertebrates have a **closed circulatory system** in which blood flows through a continuous circuit of blood vessels.
- The vertebrate circulatory system consists of a muscular heart that pumps blood into a system of **arteries, capillaries,** and **veins.** This system transports nutrients, oxygen, wastes, and hormones; helps maintain fluid balance, appropriate pH, and body temperature; and defends the body against disease.

ThomsonNOW™ Learn more about open and closed circulatory systems by clicking on the figures in ThomsonNOW.

2 Compare the structure and function of plasma, red blood cells, white blood cells, and platelets (page 922).
- **Plasma** consists of water, salts, substances in transport, and **plasma proteins,** including albumins, globulins, and fibrinogen.
- **Red blood cells,** also called **erythrocytes,** transport oxygen and carbon dioxide. Red blood cells produce large quantities of **hemoglobin,** a red pigment that binds with oxygen.
- **White blood cells,** also called **leukocytes,** defend the body against disease organisms. **Lymphocytes** and **monocytes** are agranular white blood cells; **neutrophils, eosinophils,** and **basophils** are granular white blood cells.
- **Platelets** patch damaged blood vessels and release substances essential for blood clotting.

ThomsonNOW™ Learn more about the composition of vertebrate blood by clicking on the figures in ThomsonNOW.

3 Summarize the sequence of events involved in blood clotting (page 922).
- Damaged cells and platelets release substances that activate clotting factors. Prothrombin is converted to **thrombin,** which catalyzes the conversion of **fibrinogen** to an insoluble protein, **fibrin.** Fibrin forms long threads that make up the webbing of the clot.

4 Compare the structure and function of different types of blood vessels, including arteries, arterioles, capillaries, and veins (page 925).
- Arteries carry blood away from the heart; veins return blood to the heart.
- **Arterioles** constrict (**vasoconstriction**) and dilate (**vasodilation**) to regulate blood pressure and distribution of blood to the tissues.
- Capillaries are the thin-walled exchange vessels through which blood and tissues transfer materials.

5 Trace the evolution of the vertebrate cardiovascular system from fish to mammal (page 927).
- The vertebrate heart has one or two **atria,** which receive blood, and one or two **ventricles,** which pump blood into the arteries.
- The fish heart consists of a single atrium and ventricle that are part of a single circuit of blood flow.
- In terrestrial vertebrates, circulatory systems separate oxygen-rich from oxygen-poor blood; this allows the higher metabolic rate needed to support an active terrestrial lifestyle.
- Amphibians have two atria and a ventricle, and blood flows through a double circuit so that oxygen-rich blood is partly separated from oxygen-poor blood. Most reptiles have a wall that partly divides the ventricles, minimizing the mixing of oxygen-rich and oxygen-poor blood.
- The four-chambered hearts of birds and mammals separate oxygen-rich blood from oxygen-poor blood.

6 Describe the structure and function of the human heart. (Include the heart's conduction system in your answer.) (page 928).
- The heart is enclosed by a **pericardium** and has valves that prevent backflow of blood. The valve between the right atrium and ventricle is the **right atrioventricular (AV) valve,** or **tricuspid valve.** The valve between the left atrium and ventricle is the **mitral valve. Semilunar valves** guard the exits from the heart. Cardiac muscle fibers are joined by **intercalated discs.**
- The **sinoatrial (SA) node,** or **pacemaker,** initiates each heartbeat. A specialized electrical conduction system coordinates heartbeats.

ThomsonNOW™ Learn more about heart anatomy by clicking on the figure in ThomsonNOW.

ThomsonNOW™ See cardiac conduction by clicking on the figure in ThomsonNOW.

7 Trace the events of the cardiac cycle, and relate normal heart sounds to these events (page 928).
- One complete heartbeat makes up a **cardiac cycle.** Contraction occurs during **systole.** The period of relaxation is **diastole.** At the beginning of ventricular systole, the closing of the AV valves makes a low-pitched "lub" sound. The closing of the semilunar valves, the beginning of ventricular diastole, makes a short, loud "dup" sound.

ThomsonNOW™ Watch the cardiac cycle by clicking on the figure in ThomsonNOW.

8 Define *cardiac output,* describe how it is regulated, and identify factors that affect it (page 929).
- **Cardiac output (CO)** equals **stroke volume** times heart rate. Stroke volume depends on **venous return** and on neural messages and hormones, especially epinephrine and norepinephrine. According to **Starling's law of the heart,** the more blood delivered to the heart by the veins, the more blood the heart pumps.
- Heart rate is regulated mainly by the nervous system and is influenced by hormones and body temperature.

9 Identify factors that determine and regulate blood pressure, and compare blood pressure in different types of blood vessels (page 933).
- **Blood pressure** is the force blood exerts against the inner walls of the blood vessel. Blood pressure is greatest in the arteries and decreases as blood flows through the capillaries.
- Blood pressure depends on cardiac output, blood volume, and resistance to blood flow. **Peripheral resistance** is the resistance to blood flow caused by blood viscosity and by friction between blood and the blood vessel wall.
- **Baroreceptors** sensitive to blood pressure changes send messages to the cardiac and vasomotor centers in the medulla of the brain. When informed of an increase in blood pressure, the cardiac center stimulates parasympathetic nerves that slow heart rate, and the vasomotor center inhibits sympathetic nerves that constrict blood vessels. These actions reduce blood pressure.
- **Angiotensin II** is a hormone that raises blood pressure. **Aldosterone** helps regulate salt excretion, which affects blood volume and blood pressure.

ThomsonNOW™ Learn more about determining blood pressure by clicking on the figure in ThomsonNOW.

10 Trace a drop of blood through the pulmonary and systemic circulations, naming in sequence each structure through which it passes (page 937).

- The **pulmonary circulation** connects the heart and the lungs; the **systemic circulation** connects the heart and the tissues.
- In the pulmonary circulation, the right ventricle pumps blood into the **pulmonary arteries,** which go to the lungs. Blood circulates through pulmonary capillaries in the lung and then is conducted to the left atrium by a **pulmonary vein.**
- In the systemic circulation, the left ventricle pumps blood into the **aorta,** which branches into arteries leading to the body organs. After flowing through capillary networks within various organs, blood flows into veins that conduct it to the **superior vena cava** or **inferior vena cava,** which returns blood to the right atrium.
- The **coronary arteries** supply the heart muscle with blood. The **hepatic portal system** circulates nutrient-rich blood through the liver.

ThomsonNOW™ Learn more about systemic and pulmonary circulation by clicking on the figures in ThomsonNOW.

11 Describe the structure and functions of the lymphatic system (page 938).

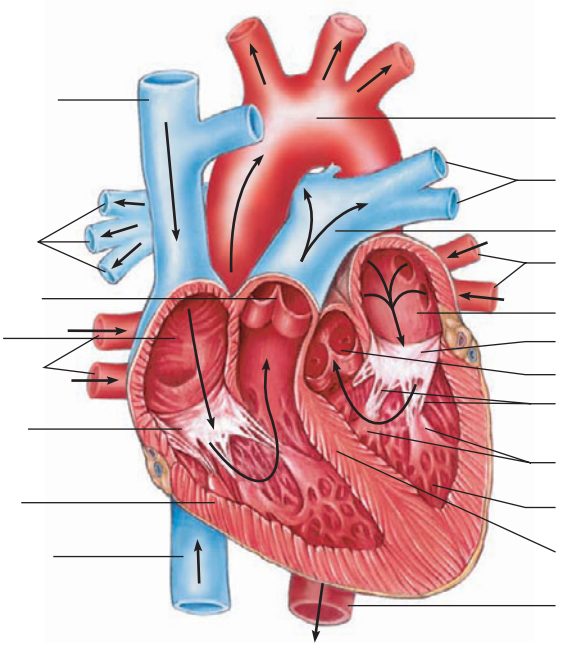
- The **lymphatic system** collects interstitial fluid and returns it to the blood, so it plays an important role in homeostasis of fluids. The lymph system also defends the body against disease and absorbs lipids from the digestive tract.
- **Lymphatic vessels** conduct **lymph,** a clear fluid formed from interstitial fluid, to the **thoracic duct** and **right lymphatic duct** in the shoulder region; these ducts return lymph to the blood circulatory system. **Lymph nodes** are small masses of tissue that filter bacteria and harmful materials out of lymph.

ThomsonNOW™ Learn more about the human lymphatic system by clicking on the figure in ThomsonNOW.

TEST YOUR UNDERSTANDING

1. An open circulatory system (a) is found in flatworms (b) typically includes a hemocoel (c) has a continuous circuit of vessels with openings in the capillaries (d) is characteristic of vertebrates (e) is typically found in animals with a two-chambered heart
2. Which of the following is *not* a function of the vertebrate circulatory system? (a) helps maintain appropriate pH (b) transports nutrients, oxygen, and metabolic wastes (c) helps maintain fluid balance (d) produces hemocyanin (e) provides internal defense
3. Lipoproteins (a) are mainly transported in granular leukocytes (b) transport cholesterol (c) have been linked to clotting disorders (d) are associated with platelets (e) are stored in red blood cells
4. Which of the following are most closely associated with oxygen transport? (a) red blood cells (b) platelets (c) neutrophils (d) basophils (e) lymphocytes
5. Which of the following are most closely associated with blood clotting? (a) red blood cells (b) platelets (c) neutrophils (d) basophils (e) lymphocytes
6. In blood clotting, (a) thrombin ⟶ prothrombin; fibrinogen ⟶ fibrin (b) prothrombin ⟶ thrombin; fibrin⟶ fibrinogen (c) prothrombin ⟶ thrombin; fibrinogen ⟶ fibrin (d) clotting factors ⟶ platelets; thrombin ⟶ fibrinogen (e) prothrombin ⟶ thrombin; fibrinogen ⟶ platelets
7. Blood vessels that carry blood away from the heart are (a) arteries (b) sinuses (c) veins (d) capillaries (e) arterioles and venules
8. Arterioles (a) help regulate blood pressure (b) help regulate distribution of blood to the tissues (c) deliver blood to arteries (d) a, b, and c (e) a and b
9. Which choice most accurately describes one sequence of blood flow? (a) right atrium ⟶ right ventricle ⟶ pulmonary artery (b) right atrium ⟶ left atrium ⟶ left ventricle ⟶ aorta (c) left atrium ⟶ left ventricle ⟶ pulmonary artery (d) left ventricle ⟶ left atrium ⟶ aorta (e) right atrium ⟶ right ventricle ⟶ aorta
10. Which choice most accurately describes one sequence of blood flow? (a) pulmonary vein ⟶ pulmonary artery ⟶ right atrium (b) pulmonary artery ⟶ left atrium ⟶ left ventricle (c) pulmonary artery ⟶ pulmonary capillaries ⟶ pulmonary vein ⟶ left atrium (d) left ventricle ⟶ aorta ⟶ pulmonary artery (e) pulmonary artery ⟶ pulmonary capillaries ⟶ pulmonary vein ⟶ right atrium
11. A cardiac cycle (a) consists of one ventricular heartbeat (b) includes a systole (c) equals stroke volume times heart rate (d) includes a diastole (e) includes a systole and a diastole
12. Blood pressure is determined by (a) cardiac output (b) peripheral resistance (c) blood volume (d) a, b, and c (e) b and c
13. Lymph forms from (a) interstitial fluid (b) blood serum (c) plasma combined with protein (d) fluid released by lymph nodes (e) angiotensins
14. The valve between the right atrium and right ventricle is the (a) mitral valve (b) semilunar valve (c) tricuspid valve (d) pulmonary valve (e) aortic valve
15. Norepinephrine (a) slows heart rate (b) is released in cardiac muscle by parasympathetic nerves (c) causes K^+ channels in cardiac muscle to open (d) decreases stroke volume (e) causes Ca^{2+} channels in cardiac muscle to open
16. Baroreceptors (a) stimulate renin release (b) activate the renin–angiotensin–aldosterone pathway (c) stimulate sympathetic nerves (d) are stimulated by increased blood pressure (e) send messages to cardiac centers that increase blood pressure
17. Atherosclerosis (a) is associated with thickening of the walls of arteries (b) is associated with high concentrations of low-density lipoprotein (c) can lead to ischemic heart disease (d) a, b, and c (e) b and c

18. Label the diagram. See Figure 43-9 to check your answers.



CRITICAL THINKING

1. How is the heart of the fish specifically adapted to its lifestyle?
2. When the nerves to the heart are cut, the heart rate increases to about 100 contractions per minute. What does this indicate about the regulation of the heart rate?
3. List five modifiable risk factors associated with the development of cardiovascular disease. Describe the disease process in atherosclerosis, and explain the association between atherosclerosis and ischemic heart disease. What happens in myocardial infarction?
4. **Evolution Link.** A heart divided into four chambers independently evolved in birds and mammals. What are the advantages of this adaptation?

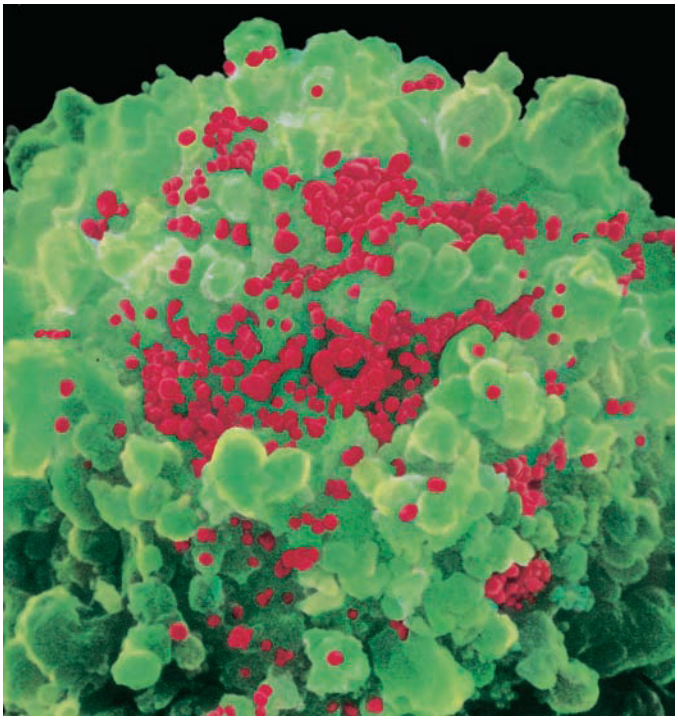
The Immune System: Internal Defense



NIBSC /Science Photo Library/Photo Researchers, Inc.

A T cell infected with HIV. In this colorized SEM, an immune system T cell (*green*) is infected by human immunodeficiency virus (HIV; *red*).

KEY CONCEPTS

Nonspecific immune responses provide general and immediate protection against pathogens, some toxins, and cancer cells.

Specific immune responses include cell-mediated immunity and antibody-mediated immunity.

In cell-mediated immunity, specific lymphocytes known as T cells are activated and then release proteins that destroy cells infected with viruses or other intracellular pathogens.

In antibody-mediated immunity, specific lymphocytes known as B cells are activated; they multiply and differentiate into plasma cells, which produce antibodies.

Sometimes the immune system is hypersensitive, such as in allergic responses; immune responses directed at self tissue can cause autoimmune disease.

The **immune system,** our internal defense system, protects the body against disease-causing organisms and certain toxins. Derived from the Latin for "safe," the word *immune* refers to the early observation that when people recovered from smallpox and other serious infections, they were safe from contracting the same illnesses again.

Disease-causing organisms, or **pathogens,** include certain viruses, bacteria, fungi, and protozoa. Pathogens enter the body with air, food, and water; during copulation; and through wounds in the skin. The immune system recognizes pathogens and toxins and responds to eliminate them.

Sometimes pathogens overcome the body's internal defenses, and disease results. Some diseases, as well as certain genetic mutations, prevent or compromise immune function. HIV, the retrovirus that causes AIDS, infects T cells, an important component of the immune system (see photograph).

The immune system responds in ways that are clinically important. This system may overfunction, as in allergic reactions, may endanger the life of a fetus that is Rh incompatible, or may destroy the cells of organ transplants. In about 5% of adults in highly developed countries, certain immune responses are directed against self tissues, resulting in *autoimmune disease.*

Immunology, the study of internal defense systems of humans and other animals, is one of the most rapidly changing, challenging, and exciting fields of biomedical research. The immune system is a collection of many types of cells and tissues scattered throughout the body. Immune responses require communication among cells, or **cell signaling.** Cells of the immune system communicate

directly by means of their surface molecules and indirectly by release of messenger molecules. Understanding the complex signaling systems of the immune system is a major focus of research.

One of the greatest accomplishments of immunologists has been the development of vaccines that prevent disease. Another has been developing techniques for successful tissue and organ transplantation. Sophisticated research tools, such as gene transfer, have enabled immunologists to expand their knowledge of the cells and molecules that interact to generate immune responses. These techniques have led to development of new approaches to the prevention and treatment of disease. Much has been learned, and many challenges lie ahead. ■

NONSPECIFIC AND SPECIFIC IMMUNITY: AN OVERVIEW

Learning Objectives

1 Distinguish between nonspecific and specific immune responses.
2 Compare, in general terms, the immune responses of invertebrates and vertebrates.

An **immune response** is the process of recognizing foreign or dangerous macromolecules and responding to eliminate them. Two main types of immune responses protect the body: nonspecific and specific (Fig. 44-1). **Nonspecific immune responses,** or *innate immunity,* provide immediate, general protection against pathogens, parasites, some toxins and drugs, and cancer cells. Nonspecific immune responses prevent most pathogens from entering the body and rapidly destroy those that do penetrate the outer defenses. For example, the cuticle or skin provides a physical barrier to pathogens that come in contact with an animal's body. Phagocytosis, another nonspecific defense, destroys bacteria that invade the body.

Specific immune responses, also referred to as *adaptive* or *acquired immunity,* are highly specific for distinct macromolecules. Any molecule that cells of the immune system specifically recognize as foreign is called an **antigen.** Proteins are the most powerful antigens, but some polysaccharides and lipids are also antigenic. Specific immune responses are directed toward particular antigens and typically include the production of **antibodies,** highly specific proteins that recognize and bind to specific antigens. An important characteristic of specific immune responses is **immunological memory,** which means that the system "remembers" foreign or dangerous molecules and responds more effectively to repeated encounters with the same molecules.

The immune system responds to danger signals

For more than 50 years, immunologists based their work on the hypothesis that internal defense depends on the animal's ability to distinguish between *self* and *nonself.* Such recognition is possible because each individual is biochemically unique. Cells have surface proteins different from those on the cells of other species or even other individuals of the same species. An animal's immune system recognizes its own cells and can identify those of

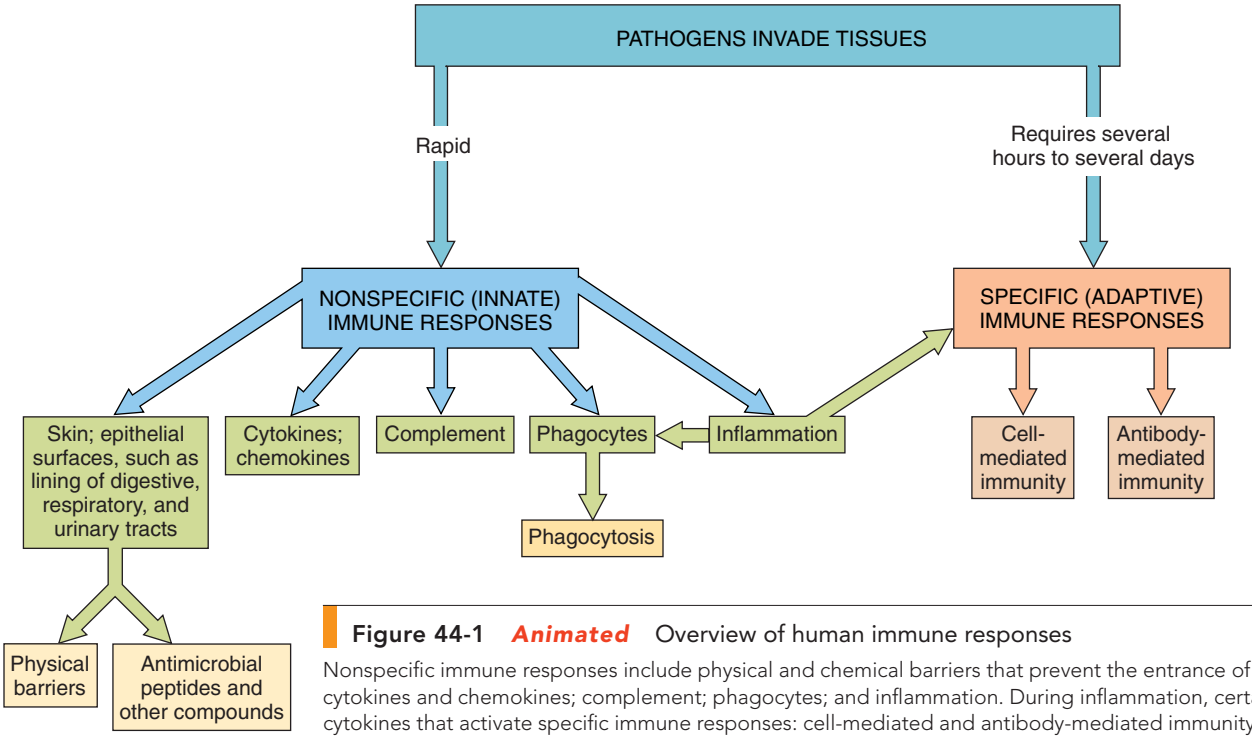


Figure 44-1 ***Animated*** Overview of human immune responses

Nonspecific immune responses include physical and chemical barriers that prevent the entrance of pathogens; cytokines and chemokines; complement; phagocytes; and inflammation. During inflammation, certain cells release cytokines that activate specific immune responses: cell-mediated and antibody-mediated immunity.

other organisms as foreign. Thus, the distinctive macromolecules of a pathogen that invades an animal stimulate the animal's defensive responses. A single bacterium may have from 10 to more than 1000 distinctive macromolecules on its surface.

Immunologists are aware of several limitations of the self–nonself hypothesis. For example, the immune system does not typically respond to foreign molecules that are harmless. The **danger model,** proposed by Polly Matzinger of the U.S. National Institutes of Health, hypothesizes that the immune system does more than distinguish between self and nonself. It responds to danger signals from injured tissues, such as proteins released when cell membranes are damaged. Most immunologists now agree that internal defense relies on a combination of factors, including the ability to identify foreign molecules *and* to respond to chemical clues from injured tissues.

Invertebrates launch nonspecific immune responses

Many invertebrates (cnidarians, annelids, and mollusks) are covered by mucus that traps and kills pathogens. Tough external skeletons, such as cuticles, shells, or chitinous exoskeletons, shield the bodies of nematodes, most mollusks, arthropods, and many other invertebrates.

All animal species studied have **phagocytes** that move through the body and engulf and destroy bacteria and other foreign matter. In mollusks, substances in the hemolymph (blood) enhance phagocytosis. Annelids are the only invertebrates known to have *natural killer cells,* a type of lymphocyte that kills cells infected by pathogens.

Researchers have described more than 800 **antimicrobial peptides,** chemicals that inactivate or kill pathogens. Investigators have identified antimicrobial peptides in all eukaryotes (including plants) that have been studied, suggesting an early common origin of these molecules. When researchers inject an antigen into an insect, as many as 15 different antimicrobial peptides are produced within a few hours. These chemicals are very effective in part because of their small size (a dozen or fewer amino acids), which facilitates their rapid production and diffusion.

What stimulates an animal to produce antimicrobial peptides and other immune defenses? Animal cells have receptors that recognize certain types of pathogen molecules and then signal the cell to produce antimicrobial peptides.

Like vertebrates, invertebrates distinguish between their own cells and those of other species. For example, sponge cells have specific glycoproteins on their surfaces that enable them to recognize their own species. When cells of two different species are mixed, they reassort according to species. When two different species of sponges are forced to grow in contact with each other, tissue is destroyed along the region of contact. Cnidarians (such as corals), annelids (such as earthworms), arthropods (such as insects), and echinoderms (such as sea stars) reject tissue grafted from other animals, even from the same species.

Certain cnidarians, arthropods, some echinoderms, and simple chordates (such as tunicates) appear to remember antigens for a short period. As mentioned earlier, immunological memory enables the body to respond more effectively when it encounters the same pathogens again. Although certain invertebrates demonstrate some specificity and memory, their immune responses are primarily nonspecific. Echinoderms and tunicates are the simplest animals known to have differentiated white blood cells that perform limited immune functions.

Vertebrates launch nonspecific and specific immune responses

Vertebrates carry out a variety of nonspecific immune responses (discussed in the next section). However, the sophisticated specific immune responses are a distinctive feature of these animals. The specialized lymphatic system that has evolved in vertebrates includes cells such as **lymphocytes,** white blood cells specialized to carry out immune responses, and organs such as lymph nodes (see Chapter 43). Specific immune responses, including lymphocytes and antibodies, first evolved in jawed vertebrates. In the discussion that follows, we focus on the human immune system, with references to immune mechanisms of other animals.

Review

- What are two key ways in which specific immune responses differ from nonspecific immune responses?
- In general, how do vertebrate immune responses differ from invertebrate responses?

NONSPECIFIC IMMUNE RESPONSES

Learning Objective

3 Describe nonspecific immune responses, including physical and chemical barriers; recognition by Toll-like receptors; the actions of cells, such as phagocytes and natural killer cells; cytokines and the proteins that make up the complement system; and the inflammatory response.

Physical and chemical barriers prevent most pathogens from entering the body. An animal's first line of defense is its outer covering—cuticle, shell, chitin, or skin—which blocks the entry of pathogens. Microorganisms that enter with food are usually destroyed by the acid secretions and enzymes of the stomach, which are effective chemical barriers. In addition, peptides, known as **defensins,** are produced by epithelium in the skin of many animals, including mammals. Also found in saliva, defensins kill a variety of bacteria and fungi.

Mucous membranes of the respiratory and reproductive tracts protect these passageways that open to the outside of the body. For example, pathogens that enter the body with inhaled air may be filtered out by hairs in the nose or trapped in the sticky mucous lining of the respiratory tract. Once trapped, they are destroyed by phagocytes. Mucus contains a substance called *mucin,* which chemically destroys invaders. **Lysozyme,** an enzyme found in many tissues, as well as in tears and other body fluids, attacks the cell walls of many gram-positive bacteria.

When pathogens breach the body's outer barriers, their chemical properties activate other nonspecific defense responses,

(c) A macrophage takes in trapped bacteria along with its own plasma membrane. The macrophage plasma membrane will seal over the bacteria, and powerful lysosomal enzymes will destroy them.

and most invaders are quickly eliminated. Nonspecific immune responses are activated by **Toll-like receptors,** cell-surface receptors on phagocytes and certain other types of cells. Toll-like receptors (homologous to a protein known as the Toll protein in *Drosophila*) recognize certain common molecular features of classes of pathogens called **pathogen-associated molecular patterns,** or **PAMPs.** PAMPs are shared by whole groups of viruses, bacteria, or fungi. Examples of PAMPs include the double-stranded RNA of certain viruses and peptidoglycan in gram-positive bacteria. When activated by PAMPs, Toll-like receptors activate phagocytes.

Nonspecific immune responses depend on the action of several types of cells, including phagocytes and natural killer cells. These responses also involve numerous molecules, including *cytokines,* which are important signaling molecules, and proteins of the *complement system* that destroy pathogens. The activation and concentration of these cells and molecules produce inflammation, a major nonspecific immune response.

Phagocytes and natural killer cells destroy pathogens

Neutrophils, the most common type of white blood cell (see Chapter 43), and macrophages are the main phagocytes in the body. Recall that **phagocytosis** is a type of endocytosis in which cells engulf microorganisms, foreign matter, or other cells (see Fig. 5-21). A neutrophil can phagocytose about 20 bacteria before it becomes inactivated (perhaps by leaking lysosomal enzymes) and dies.

Macrophages are large phagocytes that develop from nongranular white blood cells called *monocytes.* A macrophage can phagocytose about 100 bacteria during its life span (Fig. 44-2). Some macrophages patrol the body's tissues, phagocytosing damaged cells or foreign matter (including bacteria); they also release antiviral agents. Other macrophages stay in one place and destroy bacteria that pass by. For example, air sacs in the lungs contain large numbers of macrophages that destroy foreign matter entering with inhaled air.

Vertebrate macrophages have Toll-like receptors that recognize certain PAMPs and respond by producing cytokines. For ex-

ample, when stimulated by a lipopolysaccharide found on gram-negative bacteria, macrophages release cytokines that enhance the inflammatory response.

Can bacteria counteract the phagocyte's attack? Many strategies have evolved in bacteria that protect them from their hosts. *Streptococcus pneumoniae,* for example, has cell walls or capsules that resist the action of the phagocyte's lysosomal enzymes. Other bacteria release enzymes that destroy lysosomal membranes. The powerful lysosomal enzymes then spill out into the cytoplasm and may destroy the phagocyte.

Natural killer (NK) cells are large, granular lymphocytes that originate in the bone marrow. They account for about 10% of circulating lymphocytes. NK cells are active against tumor cells and cells infected with some types of viruses. They destroy target cells by both nonspecific and specific (antibody-mediated) processes.

NK cells release cytokines, as well as perforins and granzymes, enzymes that destroy target cells. **Perforins** cause pores to form in the plasma membrane of the target cell, allowing granzymes to enter the cell. **Granzymes** then activate a cascade of reactions that cause the cell to self-destruct by **apoptosis,** programmed cell death. Several cytokines stimulate NK cell activity. When NK cell levels are high, resistance to certain cancers may be strengthened. Psychological stressors are thought to decrease NK cell activity and thus enhance tumor growth.

Cytokines and complement mediate immune responses

Cells of the immune system secrete a remarkable number of regulatory and antimicrobial peptides and proteins. We discuss two major groups of molecules that are critical in nonspecific defense responses: cytokines and complement.

Cytokines are important signaling molecules

Cytokines are a large, diverse group of peptides and proteins (most are glycoproteins) that serve as signals and perform regulatory functions. Just as the functions of nonspecific and specific immune responses overlap, the actions of cytokines of these subsystems also overlap. For example, cytokines produced by nonspecific cells such as macrophages can activate lymphocytes involved in specific immune responses.

Cytokines help regulate the intensity and duration of immune responses. They are also important in regulating many other biological processes, such as cell growth, repair, and cell activation. Cytokines bind to specific membrane receptors on target cells. These signaling molecules can act as *autocrine agents,* which affect the very cells that produce them, or as *paracrine agents,* which regulate the activity of nearby cells (see Chapter 48). When produced in large amounts, some cytokines act as endocrine agents (hormones); they circulate in the blood and affect distant tissues. Biologists name the types of cytokines for their function or origin. We discuss several examples, including *interferons, tumor necrosis factors, interleukins,* and *chemokines.*

When infected by viruses or other intracellular parasites (some types of bacteria, fungi, and protozoa), certain cells respond by secreting cytokines called **interferons.** Type I interferons are produced by either macrophages or *fibroblasts,* cells that produce the fibers of connective tissues. Type I interferons inhibit viral replication and activate NK cells that have antiviral actions. Viruses produced in cells exposed to Type I interferons are not very effective at infecting other cells. Interestingly, even though Type I interferons are produced as part of the nonspecific immune response, once released, they can regulate the action of certain cells of the specific immune response. This interaction of nonspecific and specific immune mechanisms is characteristic of the power and complexity of the immune system.

Type II interferon (also called IFN-gamma) is critical in both nonspecific and specific immunity. In nonspecific immunity, Type II interferon stimulates macrophages to destroy tumor cells and host cells that have been infected by viruses. (The interferon activates gene transcription that encodes enzymes needed to produce antimicrobial compounds in lysosomes.)

Since their discovery in 1957, interferons have been the focus of a great deal of research. Pharmaceutical companies now use recombinant DNA techniques to produce large quantities of some interferons. The U.S. Food and Drug Administration (FDA) has approved interferons for treating several diseases, including hepatitis B and hepatitis C, genital warts, a type of leukemia, a type of multiple sclerosis, and AIDS-related Kaposi's sarcoma. Researchers are testing interferons in clinical trials for the treatment of HIV infection and several types of cancer.

Tumor necrosis factor (TNF) stimulates immune cells to initiate an inflammatory response in response to gram-negative bacteria and other pathogens. TNF is secreted mainly by macrophages and by certain lymphocytes called *T cells.* In severe infections, large amounts of TNF are produced. TNF is then circulated in the blood and can have widespread effects. For example, it acts on the hypothalamus, inducing *fever.* Sometimes infection by gram-negative bacteria, such as *Salmonella typhi,* results in the release of large amounts of TNF and other cytokines. This results in a cascade of reactions leading to *septic shock,* a potentially fatal condition that may involve high fever and malfunction of the circulatory system. Thus, cytokines can sometimes have harmful effects.

Interleukins are a diverse group of cytokines secreted mainly by macrophages and lymphocytes. Interleukins are numbered according to their order of discovery. They regulate interactions between white blood cells, such as lymphocytes and macrophages, and other cells. *Interleukin-1 (IL-1)* functions with TNF in mediating inflammation. *Interleukin-12 (IL-12)* stimulates NK cells, as well as T cells, to produce IFN-gamma. Some interleukins have widespread effects. During infection IL-1 can reset the body's thermostat in the hypothalamus, resulting in fever and its symptoms. The overproduction of certain interleukins has been associated with clinical disease, including atherosclerosis.

Chemokines, a large group of cytokines, are signaling molecules that attract, activate, and direct the movement of various cells of the immune system. For example, they regulate the migration of white blood cells from the blood to the tissues. Some chemokines are produced in response to infection and are mediators of the inflammatory response.

Complement leads to the destruction of pathogens

Cytokines produced by phagocytes can activate the *complement system.* **Complement,** so named because it "complements" the

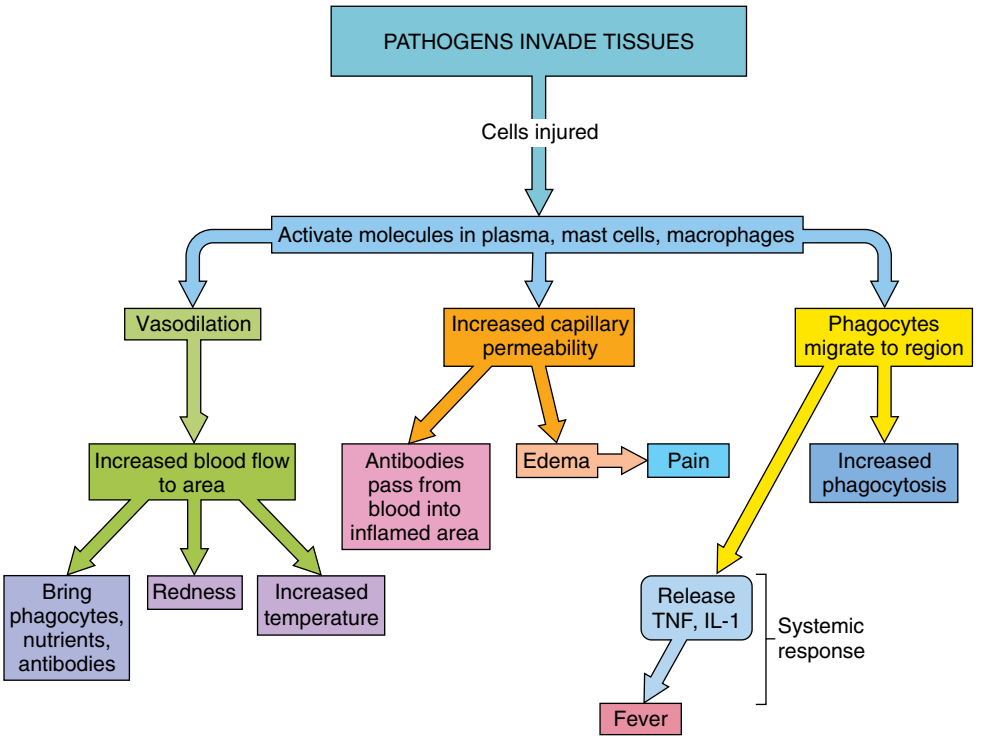

Figure 44-3 ***Animated*** The inflammatory response

action of other defensive responses, consists of more than 20 proteins present in plasma and other body fluids. Similarities in complement proteins in many species, including horseshoe crabs, sea urchins, tunicates, and mammals, suggest that these molecules evolved millions of years ago and have been conserved.

Normally, complement proteins are inactive until the body is exposed to an antigen. Certain pathogens activate the complement system directly. In other cases, the binding of an antigen and antibody stimulates activation. Complement activation involves a cascade of reactions; each component acts on the next in the series. Proteins of the complement system then work to destroy pathogens.

Complement proteins are activated against many antigens, and their actions are nonspecific: They (1) lyse viruses, bacteria, and other cells; (2) coat pathogens, making them less "slippery" so that macrophages and neutrophils phagocytose them more easily; (3) attract white blood cells to the site of infection, a process called *chemotaxis;* and (4) bind to specific receptors on cells of the immune system, stimulating specific actions, such as secreting regulatory molecules and enhancing the inflammatory response.

Inflammation is a protective response

The **inflammatory response,** or *inflammation,* begins immediately after pathogen invasion or physical injury (Fig. 44-3). Tissue injury activates a clotting factor in the blood plasma that turns on three different interconnecting molecular cascades in the plasma, including the clotting cascade. The reactions generate molecules—for example, the peptide *bradykinin*—that mediate the inflammatory process. These plasma mediators dilate blood vessels and increase capillary permeability. Inflammation also activates the complement system.

Many cytokines signal white blood cells to launch the inflammatory response, and some cytokines help regulate the process. For example, large numbers of neutrophils migrate into the inflamed tissue within a few hours of tissue injury or infection. Neutrophils secrete chemokines and other cytokines. Macrophages and **mast cells** stationed in the tissues also respond rapidly to damaged tissue or infection. Mast cells release **histamine,** cytokines, and other compounds that dilate blood vessels in the affected area and increase capillary permeability. Mast cells and macrophages release signaling molecules that attract and activate additional neutrophils. In turn, neutrophils send signals that attract lymphocytes.

The clinical characteristics of inflammation are heat, redness, edema (swelling), and pain. The inflammatory response includes three main processes.

1. *Vasodilation.* Expanded blood vessel diameter brings more blood to the area. The increased blood flow warms the skin and reddens skin that contains little pigment.
2. *Increased capillary permeability.* Fluid and antibodies leave the circulation and enter the tissues. As the volume of interstitial fluid increases, *edema* occurs. The edema, along with the action of certain enzymes in the plasma, causes the pain that characterizes inflammation.
3. *Increased phagocytosis.* Increased blood flow brings large numbers of neutrophils and other phagocytic cells to the infected region. The phagocytes migrate out of the capillaries and into the infected tissues. One of the main functions of inflammation is increased phagocytosis.

Although the inflammatory response begins as a local response, sometimes the entire body becomes involved. **Fever,** a common clinical symptom of widespread inflammation, helps the body fight infection. Elevated body temperature increases phagocytosis and interferes with the growth and replication of microorganisms. Fever breaks down lysosomes, destroying cells infected by viruses. Fever also promotes the activity of certain lymphocytes. A short-term, low fever speeds recovery.

- What processes are involved in the inflammatory response? What types of cells help mediate the inflammatory response?

SPECIFIC IMMUNE RESPONSES

Learning Objectives

4 Distinguish between cell-mediated and antibody-mediated immunity.

5 Describe the principal cells of the immune system, and summarize the function of the major histocompatibility complex.

While nonspecific immune responses destroy pathogens and prevent the spread of infection, the body mobilizes its specific immune responses. It takes several days to activate specific immune responses, but once in gear, these mechanisms are extremely effective. As discussed earlier, specific immune responses are precisely targeted to destroy specific antigens, and they have immunological memory. Two types of specific immune responses are *cell-mediated immunity* and *antibody-mediated immunity.*

Many types of cells are involved in specific immune responses

The primary types of cells of the immune system are shown in Figure 44-4. Two key cell types that participate in specific immune responses are lymphocytes and antigen-presenting cells. Phagocytes and many other cells important in nonspecific immune responses also participate in specific responses. **Eosinophils** are white blood cells that release proteins, including cytokines, from their granules. They also release proteins that are toxic to parasitic worms.

Lymphocytes are the principal warriors in specific immune responses

Three main types of lymphocytes are T lymphocytes, B lymphocytes, and NK cells. As already discussed, NK cells kill virally infected cells and tumor cells. **T lymphocytes,** or **T cells,** are responsible for **cell-mediated immunity.** T cells are the body's cellular soldiers. They travel to the site of infection and attack body cells infected by invading pathogens, as well as foreign cells (such as those introduced in tissue grafts or organ transplants). T cells also destroy cells altered by mutation (cancer cells).

B lymphocytes, or **B cells,** are responsible for **antibody-mediated immunity.** B cells mature into **plasma cells,** which produce specific antibodies. Antibodies bind to specific antigens, neutralizing them or marking them for destruction. Antibody-mediated immunity is one of the body's chief chemical defense strategies.

All lymphocytes develop from stem cells in the bone marrow. B cells complete their development in the adult bone marrow. T cells mature in the **thymus gland** (from which the *T* in their name derives). Large numbers of mature lymphocytes reside in lymph organs, including the spleen, lymph nodes, tonsils, and other lymph tissues strategically positioned throughout the body.

Although T cells and B cells are similar in appearance when viewed with a light microscope, sophisticated techniques such as fluorescence microscopy demonstrate that these cells can be differentiated by their unique cell-surface macromolecules. T cells and B cells have different functions and life histories and tend to locate in (or "home" to) separate regions of the spleen, lymph nodes, and other lymph tissues.

Millions of B cells are produced in the bone marrow daily. Each B cell is genetically programmed to encode a glycoprotein receptor that can bind with a specific type of antigen. When a B cell comes into contact with an antigen that binds to its receptors, the B cell becomes activated. B-cell activation is a complex process that typically requires the participation of a particular type of T cell.

Once activated, a B cell divides rapidly to form a clone of identical cells. The cloned B cells differentiate into plasma cells, which produce antibody. A plasma cell can produce more than 10 million molecules of antibody per hour! The antibody binds to the antigen that originally activated the B cells. Some activated B cells do not become plasma cells but instead become long-living **memory B cells** that continue to produce small amounts of antibody after the body overcomes an infection.

On their way from the bone marrow to the lymph tissues, T cells are processed in the thymus gland. The thymus makes T cells *immunocompetent,* capable of immunological response. As T cells move through the thymus, they divide many times and develop specific surface proteins with distinctive receptor sites. The T-cell population undergoes positive and negative selection. In *positive selection,* T cells are allowed to mature if they recognize self-antigens and bind with foreign antigens.

In *negative selection,* T cells in the thymus that react to self-antigens undergo apoptosis. Immunologists estimate that more than 90% of developing T cells are negatively selected. The remaining T cells differentiate and leave the thymus to take up residence in other lymph tissues or to launch immune responses in infected tissues. By selecting only appropriate T cells, the thymus gland ensures that T cells can distinguish between the body's own molecules and foreign antigens.

Most T cells in the thymus differentiate just before birth and during the first few months of postnatal life. If the thymus is removed before this processing takes place, an animal does not develop cell-mediated immunity. If the thymus is removed after that time, cell-mediated immunity is less seriously impaired.

T cells are distinguished by the **T-cell receptor (TCR),** which recognizes specific antigens. Two main populations of T cells develop in the thymus: T cytotoxic cells and T helper cells. **T cytotoxic (T_C) cells** are also known as *CD8 cells* because they have a glycoprotein designated CD8 on their plasma membrane surface. Known less formally as *killer T cells,* T_C cells recognize and destroy cells with foreign antigens on their surfaces. Among their target cells are virus-infected cells, cancer cells, and foreign tissue grafts.

T helper (T_H) cells, also known as *CD4 cells,* have a surface glycoprotein designated CD4. T_H cells are regulatory cells. They secrete cytokines that activate B cells and macrophages. After an infection, **memory T cells** (both T_C and helper) remain in the body.

Antigen-presenting cells activate T helper cells

Macrophages, dendritic cells, and B cells function as "professional" **antigen-presenting cells** (**APCs**) that display foreign antigens as well as their own surface proteins. APCs are inac-

Key Point

Two main categories of immune system cells are lymphocytes (T cells and B cells) and antigen-presenting cells (macrophages and dendritic cells).

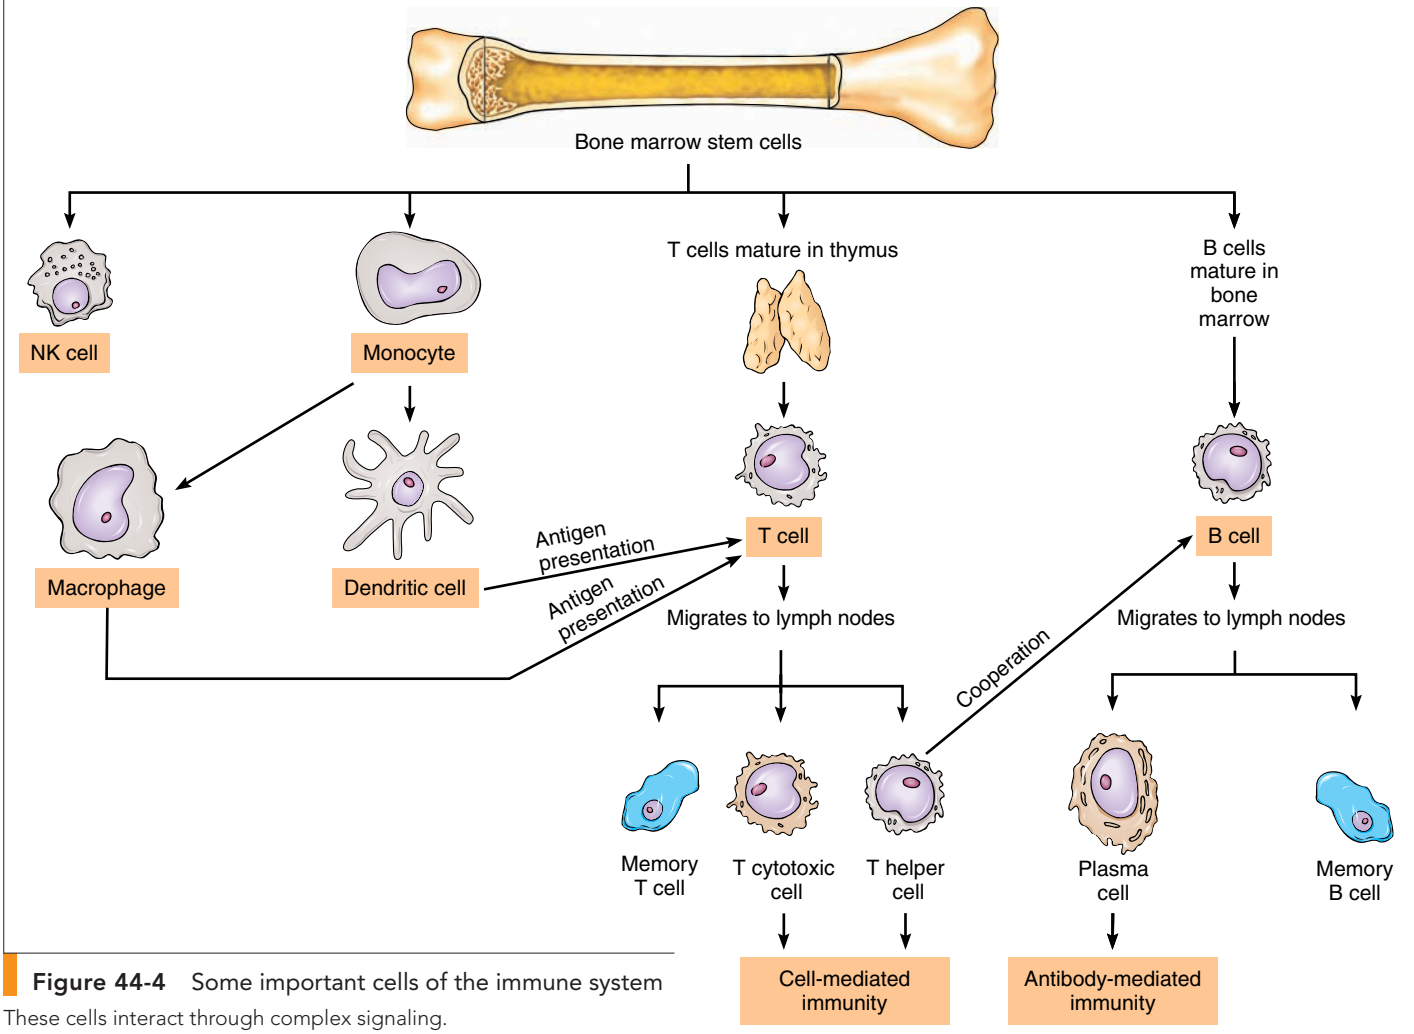

Figure 44-4 Some important cells of the immune system

These cells interact through complex signaling.

tive until their pattern-recognition receptors recognize PAMPs on pathogens. Once activated, an APC ingests the pathogen, and lysosomal enzymes degrade most, but not all, of the bacterial antigens. The APC displays fragments of the foreign antigens on its cell surface in association with a type of self-molecule (class II MHC, discussed later). The activated APC expresses additional signaling molecules, called **co-stimulatory molecules,** along with the displayed antigen. APCs present displayed antigens to T cells.

In addition to their function as APCs, macrophages secrete more than 100 different compounds, including cytokines and enzymes that destroy bacteria. When stimulated by bacteria, macrophages secrete interleukins that activate B cells and certain T cells. Interleukins also promote nonspecific immune responses, such as fever.

Biologists first identified **dendritic cells** in 1868 and then rediscovered them in 1973, but the small numbers of these cells made them hard to study until sophisticated techniques became available in the 1990s. Their name derives from their long cytoplasmic extensions known as *dendrites* (not to be confused with the dendrites of neurons). Like macrophages, they develop from monocytes. Dendritic cells are strategically stationed in all tissues of the body that come into contact with the environment—the skin and the linings of the digestive, respiratory, urinary, and vaginal passageways.

When pathogens infect a tissue, PAMPs activate dendritic cells. Activated dendritic cells capture the pathogens (or their products) by phagocytosis or by receptor-mediated endocytosis (see Chapter 5). Guided by chemokines produced by cells in the lymph nodes and lymph vessels, dendritic cells make their way to the lymph nodes. They mature as they migrate. Mature dendritic cells break down antigens and display the fragments on their cell surface. Co-stimulatory molecules, along with the displayed antigen, attract and activate specific T cells capable of responding to the antigen. Thus, dendritic cells are specialized to process, transport, and present antigens to T cells.

The major histocompatibility complex is responsible for recognition of self

The ability of the vertebrate immune system to distinguish self from nonself depends largely on a cluster of closely linked genes known as the **major histocompatibility complex (MHC).** In humans, the MHC is also called the **HLA (human leukocyte antigen) complex.** The MHC genes are polymorphic (variable). Within the population there are multiple alleles, more than 40 for each locus. As a result, the cell-surface proteins for which they code are generally different in each individual. With so many possible combinations, no two people, except identical twins, are likely to have all the same MHC proteins on their cells. The more closely related two individuals are, the more MHC genes they have in common. Thus, a person's MHC proteins serve as a biochemical "fingerprint."

The MHC genes encode **MHC antigens,** or self-antigens, that differ in chemical structure, function, and tissue distribution. Class I MHC genes encode glycoproteins expressed on the surface of most nucleated cells. These antigens bind with foreign antigens from viruses or other pathogens within the cell to form a foreign antigen–class I MHC glycoprotein complex. The cell displays this complex on its surface and presents it to T_C cells. Thus, any infected cell can function as an antigen-presenting cell and can activate certain T_C cells.

Class II MHC genes encode glycoproteins expressed primarily on "professional" APCs—dendritic cells, macrophages, and B cells. These class II MHC antigens combine with foreign antigen from bacteria, and the cell presents the complex to T_H cells. Class III MHC genes encode many secreted proteins involved in the immune response, including components of the complement system and TNFs.

- What is the function of antigen-presenting cells? Describe two types.
- What are two main types of T cells? What is the function of B cells?

CELL-MEDIATED IMMUNITY

Learning Objective

6 Describe the sequence of events in cell-mediated immunity.

T cells and APCs (mainly dendritic cells and macrophages) are responsible for cell-mediated immunity (Fig. 44-5). T cells destroy cells infected with viruses and cells that have been altered in some way, such as cancer cells. They also destroy the cells of foreign grafts such as a transplanted kidney. There are two general populations of T cells: T_C cells and T_H cells. Each T_C cell expresses the CD8 molecule on its surface, as well as more than 50,000 identical T-cell receptors (TCRs) that bind to one specific type of antigen. Each T_H cell expresses the glycoprotein called CD4. Within each general category of T cell, there are thousands of different antigen specificities that can be recognized. T_C cells recognize antigens presented to them as part of a foreign antigen–class I MHC glycoprotein complex. T_H cells recognize antigens presented to them as part of a foreign antigen–class II MHC glycoprotein complex.

How do T cells know which cells to target? T cells do not recognize antigens unless they are presented properly. When a virus (or other pathogen) infects a cell, some of the viral protein is broken down to peptides and displayed with class I MHC molecules on the cell surface. Only T_C cells with receptors that bind to the specific antigen–MHC class I complex become activated. Generally, fewer than 1 in 10,000 T cells have the same antigen specificity and can respond. T_C cell activation requires at least two signals in addition to the presented antigen: a co-stimulatory signal and an interleukin signal.

Once activated, a T_C cell increases in size and gives rise to a clone of many T_C cells. Activated T_C cells are the effector cells that make up the cell infantry. They leave the lymph nodes and make their way to the infected area, where they destroy target cells within seconds after contact. When a T_C cell combines with antigen on the surface of the target cell, it destroys the cell in much the same way that NK cells destroy their target cells. The T_C secretes perforins and granzymes that perforate the plasma membrane of the target cell and induce it to kill itself by apoptosis. After releasing cytotoxic substances, the T cell disengages itself from its victim cell and seeks out a new target.

The sequence of events in cell-mediated immunity can be summarized as follows:

> Virus invades body cell ⟶ infected cell displays foreign antigen–MHC class I antigen complex ⟶ specific T_C cell activated by this complex ⟶ clone of T_C cells produced ⟶ T_C cells migrate to area of infection ⟶ T_C cells release proteins that stimulate destruction of target cells

T_H cells are activated by the foreign antigen–MHC class II antigen complex displayed on the surface of APCs. Once activated, a T_H cell gives rise to a clone of T_H cells. Some T_H cells attract macrophages to the site of infection and promote the destruction of intracellular pathogens. Others function mainly in promoting antibody-mediated immunity.

- How do T helper cells function in cell-mediated immunity?

ANTIBODY-MEDIATED IMMUNITY

Learning Objectives

7 Summarize the sequence of events in antibody-mediated immunity, including the effects of antigen–antibody complexes on pathogens.

8 Describe the basic structure and function of an antibody, and explain the basis of antibody diversity.

B cells are responsible for antibody-mediated immunity. A given B cell can produce many copies of one specific antibody. Antibody molecules serve as cell-surface receptors that combine with antigens. Only a B cell displaying a matching receptor on its sur-

face can bind a particular antigen. Inside the B cell, the antigen is degraded into peptide fragments. The B cell then displays the peptide fragments together with MHC protein class II on its surface.

In most cases, the activation of B cells involves APCs and T_H cells (Fig. 44-6). T_H cells stimulate B cells to divide and produce antibodies. However, the T_H cell itself must first be activated. T_H cells do not recognize an antigen that is presented alone. The antigen must be presented as part of a foreign antigen–class II MHC complex on the surface of an APC. When an APC displaying a foreign antigen–MHC complex contacts a T_H cell with complementary T-cell receptors, a complicated interaction occurs. Multiple chemical signals are sent back and forth between cells. For example, the APC secretes interleukins, such as IL-1, that activate T_H cells.

B cells serve as APCs to T cells. An activated T_H cell binds with the foreign antigen–MHC complex on the B cell. The T_H cell then releases interleukins, which together with antigen activate the B cell.

Once activated, a B cell divides by mitosis, giving rise to a clone of identical cells (Fig. 44-7). This cell division in response to a specific antigen is known as *clonal selection* (discussed later). The cloned B cells mature into plasma cells that secrete antibodies specific to the antigen that activated the original B cell. It is important to remember that the specificity of the clone is determined *before* the B cell encounters the antigen.

Unlike T cells, most plasma cells do not leave the lymph nodes. Only the antibodies they secrete pass out of the lymph tissues and make their way via the lymph and blood to the infected area. The secreted antibody is a soluble form of the glycoprotein receptor of the activated B cell.

The sequence of events in antibody-mediated immunity can be summarized as follows:

> Pathogen invades body ⟶ APC phagocytoses pathogen ⟶ foreign antigen–MHC complex displayed on APC surface ⟶ T_H cell binds with foreign antigen–MHC complex ⟶ activated T_H cell interacts with a B cell that displays the same antigen ⟶ B cell activated ⟶ clone of B cells ⟶ B cells differentiate, becoming plasma cells ⟶ plasma cells secrete antibodies ⟶ antibodies form complexes with pathogen ⟶ pathogen is destroyed

Some activated B cells do not differentiate into plasma cells but instead become memory B cells (discussed in a later section).

A typical antibody consists of four polypeptide chains

An antibody molecule, also called **immunoglobulin (Ig),** has two main functions: it combines with antigen, and it activates processes that destroy the antigen that binds to it. For example,

Key Point

T cells and APCs are responsible for cell-mediated immunity.

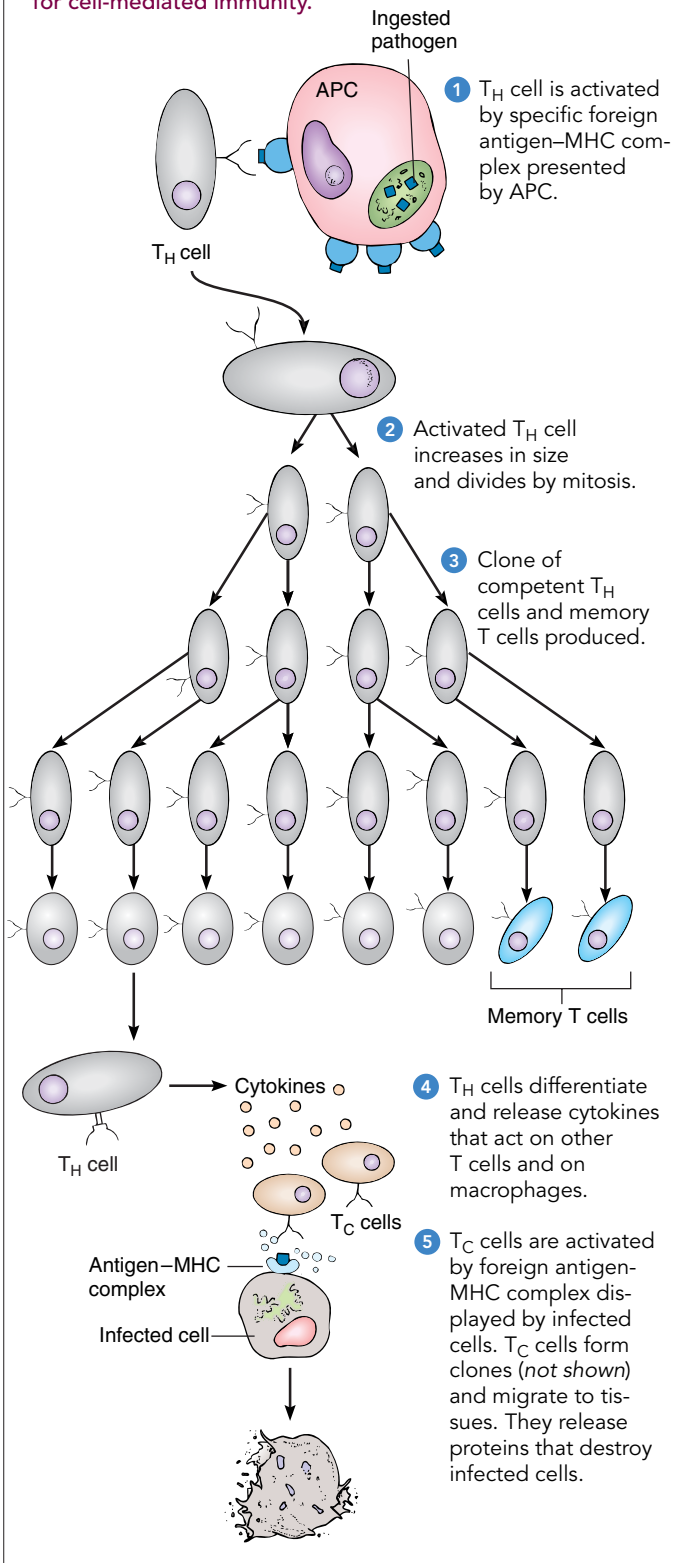

Figure 44-5 ***Animated*** Cell-mediated immunity

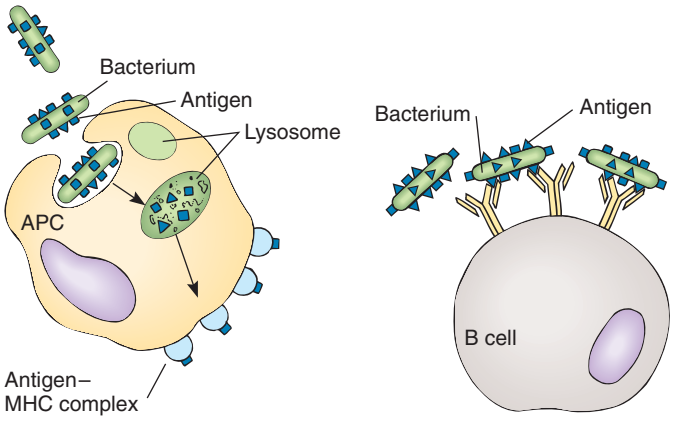
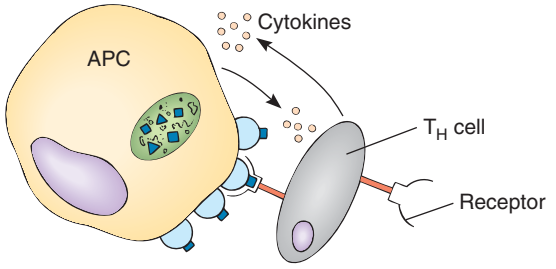
When activated by a foreign antigen–MHC complex presented by an APC and by cytokines, a T_H cell divides and gives rise to a clone of T_H cells. T_C cells are activated by antigens presented on the surfaces of infected cells. T_C cells also form a clone. Both types of T cells migrate to the site of infection. T_H cells release cytokines that stimulate T_C cells and activate macrophages so that they phagocytose pathogens. T_C cells release proteins that destroy infected cells.

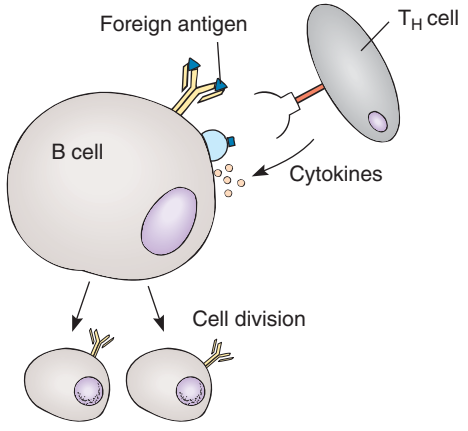


1a APC takes in bacterium, breaks it down, and presents foreign antigens on its surface in combination with MHC class II antigens.

1b B cell independently combines with foreign antigens on surface of bacterium, but B cell is typically not active until stimulated by T_H cells.



2 T_H cells are activated when their receptors combine with foreign antigen–MHC antigen complexes on APC. Signaling takes place via cytokines secreted by both cells.



3 Activated T_H cell recognizes antigen–MHC complex on B cell. T_H cell secretes cytokines that activate B cell that has interacted with foreign antigen. B cell then divides, and subsequent divisions produce clone of identical B cells.

Figure 44-6 ***Animated*** B-cell activation

an antibody may stimulate phagocytosis. Note that an antibody does not destroy an antigen directly; rather, it *labels* the antigen for destruction.

Rodney Porter, of the University of Oxford in England, and Gerald Edelman, of Rockefeller University in New York, clarified the basic structure of the immunoglobulin molecule during the 1960s. Porter used the plant enzyme papain, a protease, to split Ig molecules into fragments. Based on his findings, Porter developed a working model of the structure of the Ig molecule and was the first to suggest that it is Y shaped. These researchers then constructed an accurate model of the antibody molecule. Porter and Edelman were awarded the 1972 Nobel Prize in Medicine for their contributions.

Two fragments of the antibody molecule bind antigen and are referred to as *Fab fragments* (*Fab* stands for *antigen-binding fragment*). The fragment that interacts with cells of the immune system is the *Fc fragment* (*c* indicates that this fragment crystallizes during cold storage). Many cells of the immune system have Fc receptors.

In a Y-shaped antibody molecule, the two arms of the Y, the *Fab,* or *antigen-binding fragments,* bind with antigen (▮ Fig. 44-8). This shape permits the antibody molecule to combine with two antigen molecules, which allows the formation of **antigen–antibody complexes.** The tail of the Y, called the *Fc fragment,* interacts with cells of the immune system, such as phagocytes, or binds with molecules of the complement system.

An antibody molecule consists of four polypeptide chains: two identical long chains, called *heavy chains,* and two identical short chains, called *light chains.* Each chain has a constant region and a variable region. In the **constant (C) region** of the heavy chains, the amino acid sequence is constant within a particular immunoglobulin class. You can think of the C region of the heavy chains as the handle portion of a door key. The C region is the tail of the Y part of the antibody molecule.

The **variable (V) region** has a unique amino acid sequence, like the pattern of bumps and notches on the part of a key that slides into a lock. At its variable regions, the antibody folds three-dimensionally, assuming a shape that enables it to combine with a specific antigen. When they meet, antigen and antibody fit together somewhat like a lock and key. They must fit in just the right way for the antibody to be effective (▮ Fig. 44-9).

The specific part of the antigen molecule that is recognized by an antibody or T-cell receptor is called an **antigenic determinant,** or *epitope.* An antigen may have many antigenic determinants on its surface; some have hundreds. Antigenic determinants often differ from one another, so several different kinds of antibodies can combine with a single antigen. A given antibody can bind with different strengths, or *affinities,* to different antigens. In the course of an immune response, higher-affinity antibodies are generated.

Antibodies are grouped in five classes

Antibodies are grouped in five classes, defined by unique amino acid sequences in the C regions of the heavy chains. The classes are named by using the abbreviation *Ig* for *immunoglobulin* and are designated IgG, IgM, IgA, IgD, and IgE. In humans, about 75% of the circulating antibodies belong to the **IgG** class; these are part of the gamma globulin fraction of the plasma. IgG and **IgM** share some functional properties. Both interact with macrophages and activate the complement system. They defend against many pathogens carried in the blood, including bacteria, viruses, and some fungi. IgM is the first antibody humans make in an im-

Key Point

B cells are responsible for antibody-mediated immunity.

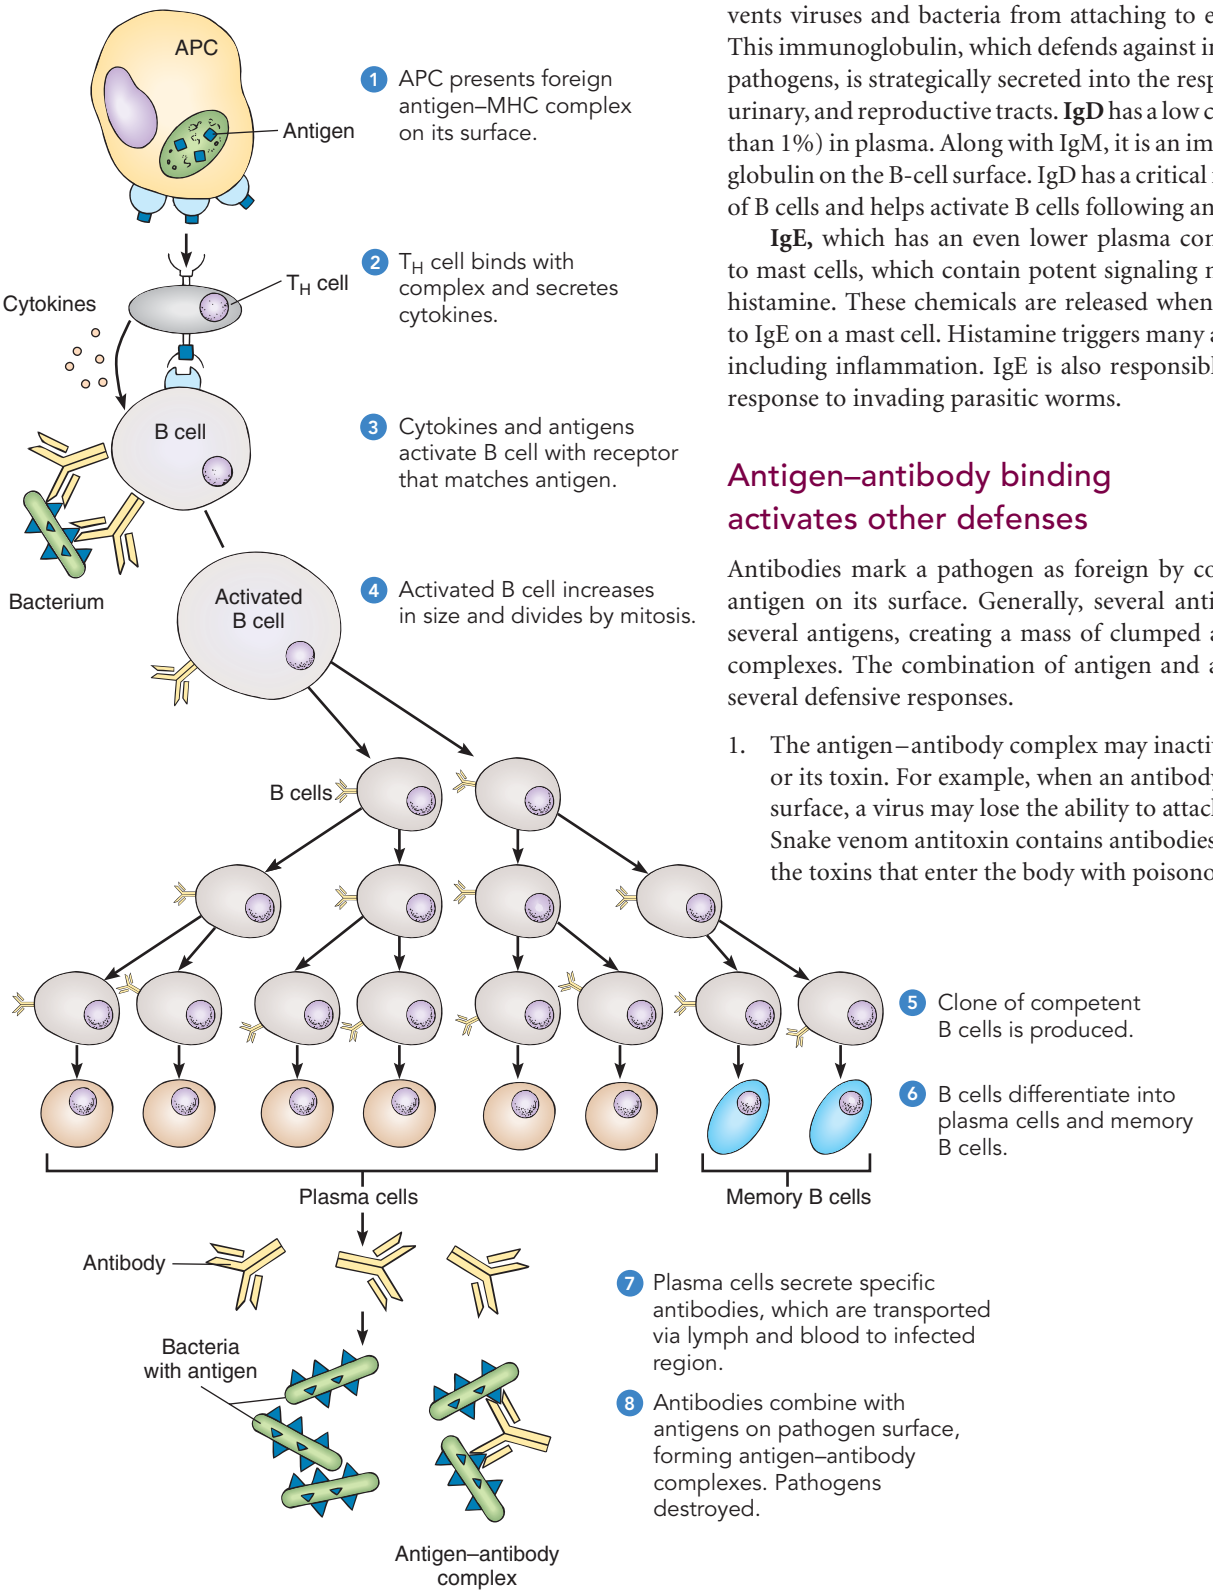


Figure 44-7 ***Animated*** Antibody-mediated immunity

A specific B cell may be activated when a specific antigen binds to immunoglobulin receptors on the B-cell surface. Typically, the B cell also requires cytokine stimulation from nearby T_H cells. Once activated, the B cell divides and produces a clone of B cells. These cells differentiate and become plasma cells that secrete antibodies. The plasma cells remain in the lymph tissues, but the antibodies are transported to the site of infection by the blood or lymph. After the infection has been overcome, memory B cells remain in the tissues.

mune response. IgG is the antibody that crosses the placenta and protects the fetus and, later, the newborn baby.

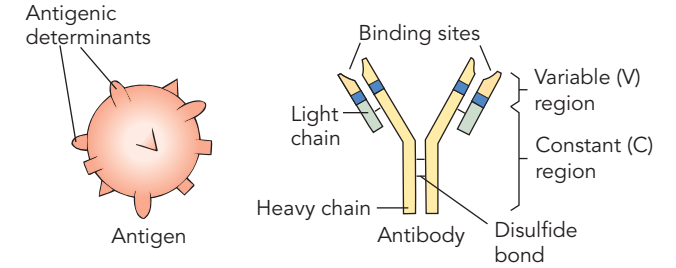
IgA, present in mucus, tears, saliva, and breast milk, prevents viruses and bacteria from attaching to epithelial surfaces. This immunoglobulin, which defends against inhaled or ingested pathogens, is strategically secreted into the respiratory, digestive, urinary, and reproductive tracts. **IgD** has a low concentration (less than 1%) in plasma. Along with IgM, it is an important immunoglobulin on the B-cell surface. IgD has a critical role in maturation of B cells and helps activate B cells following antigen binding.

IgE, which has an even lower plasma concentration, binds to mast cells, which contain potent signaling molecules, such as histamine. These chemicals are released when an antigen binds to IgE on a mast cell. Histamine triggers many allergy symptoms, including inflammation. IgE is also responsible for an immune response to invading parasitic worms.

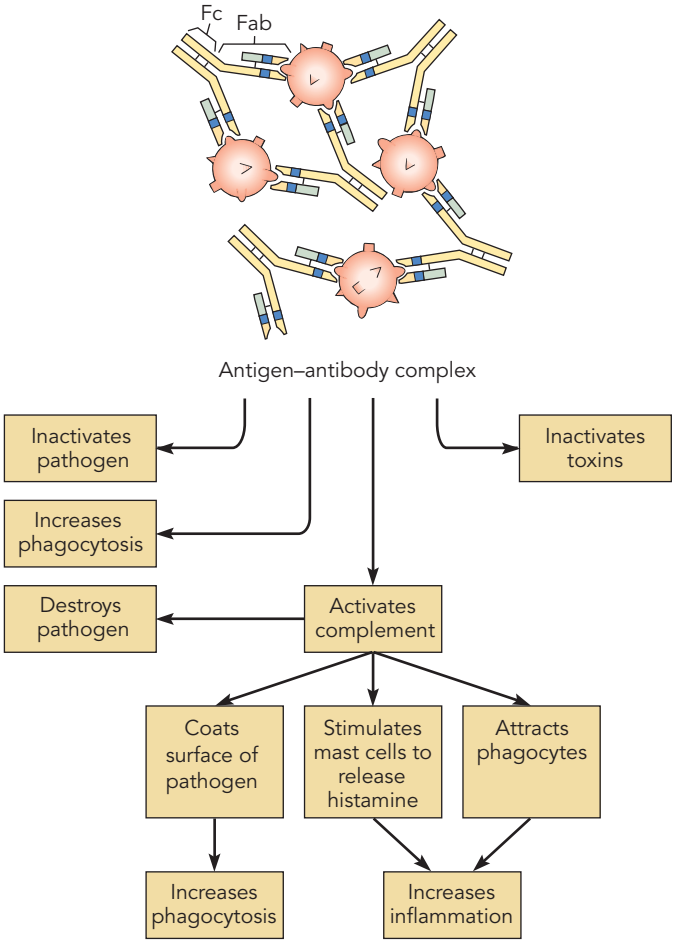
Antigen–antibody binding activates other defenses

Antibodies mark a pathogen as foreign by combining with an antigen on its surface. Generally, several antibodies bind with several antigens, creating a mass of clumped antigen–antibody complexes. The combination of antigen and antibody activates several defensive responses.

1. The antigen–antibody complex may inactivate the pathogen or its toxin. For example, when an antibody attaches to its surface, a virus may lose the ability to attach to a host cell. Snake venom antitoxin contains antibodies that neutralize the toxins that enter the body with poisonous snakebites.



(a) The antibody molecule is composed of two light chains and two heavy chains joined by disulfide bonds. The constant (C) and variable (V) regions of the chains are labeled.



(b) The Fab portion of the antibody binds to antigen. The Fc portion of the molecule binds to a cell of the immune system (*not shown*). Antigen–antibody complexes directly inactivate pathogens and increase phagocytosis. They also activate the complement system.

Figure 44-8 ***Animated*** Antibody structure and function

Antibodies combine with antigens to form antigen–antibody complexes.

2. The antigen–antibody complex stimulates phagocytic cells to ingest the pathogen.
3. Antibodies of the IgG and IgM groups work mainly through the complement system. When antibodies combine with a specific antigen on a pathogen, complement proteins destroy the pathogen. IgG molecules have an Fc fragment that binds Fc receptors; these receptors are expressed on many cells, including macrophages and neutrophils. When an antibody molecule is bound to a pathogen and the Fc portion of the antibody binds with an Fc receptor on a phagocyte, the pathogen is more easily destroyed.

The immune system responds to millions of different antigens

How can the immune system recognize every possible antigen, even those produced by newly mutated viruses never before encountered during the evolution of our species? In the 1950s, the Danish researcher Niels Jerne, of the Basel Institute for Immunology in Basel, Switzerland; David Talmage, of the University of Chicago; and Frank Macfarlane Burnet, of the Walter and Eliza Hall Institute for Medical Research in Melbourne, Australia, developed the **clonal selection** hypothesis. This hypothesis proposes that before a lymphocyte ever encounters an antigen, the

Images not available due to copyright restrictions

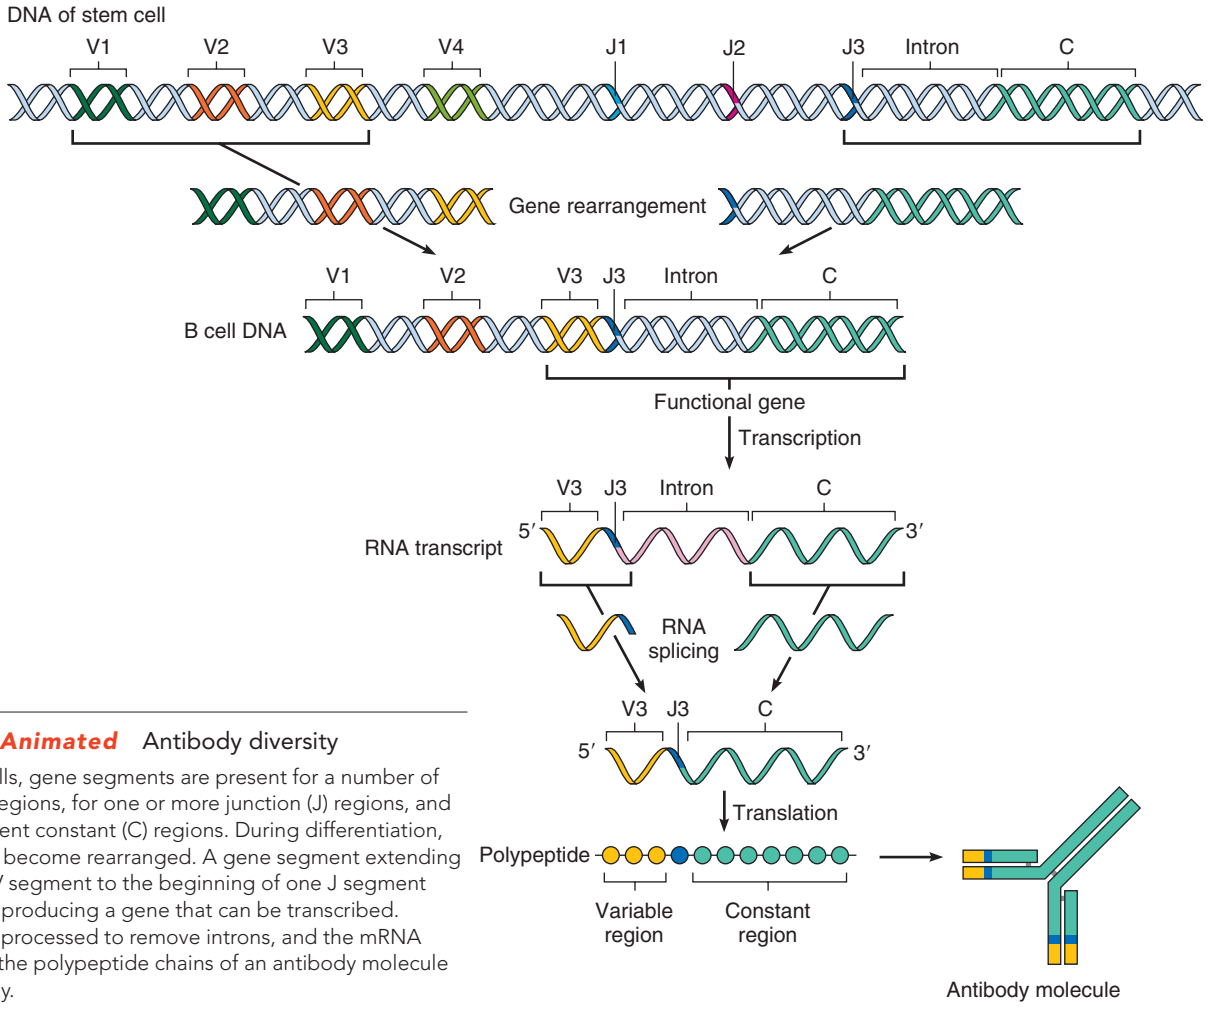


Figure 44-10 ***Animated*** Antibody diversity

In undifferentiated cells, gene segments are present for a number of different variable (V) regions, for one or more junction (J) regions, and for one or more different constant (C) regions. During differentiation, these DNA segments become rearranged. A gene segment extending from the end of one V segment to the beginning of one J segment may be deleted, thus producing a gene that can be transcribed. The RNA transcript is processed to remove introns, and the mRNA is translated. Each of the polypeptide chains of an antibody molecule is produced in this way.

lymphocyte has specific receptors for that antigen on its surface. (Jerne and Burnet later were awarded Nobel prizes in Medicine for their work in immunology.)

When an antigen binds to a matching receptor on a lymphocyte, it activates the lymphocyte, which then gives rise to a clone of cells with identical receptors. A problem with this hypothesis when it was initially proposed was its suggestion that our cells must contain millions of separate antibody genes, each coding for an antibody with a different specificity. Although each human cell has a large amount of DNA, it is not enough to provide a different gene to code for each of the millions of possible specific antibody molecules.

An explanation for how the immune system could have so many different specificities came later. In 1965, W. J. Dreyer, of the Institute of Biochemistry at the University of Zurich, Switzerland; and Joe Claude Bennett, of the University of Alabama at Birmingham, suggested that the C region and the V region of an immunoglobulin are encoded by two separate genes. Their hypothesis was at first rejected by many biologists because it contradicted the prevailing hypothesis that one gene codes for one polypeptide.

The technology needed to test Dreyer and Bennett's hypothesis was not immediately available, and it was not until 1976 that Susumu Tonegawa, of the Massachusetts Institute of Technology, and his colleagues demonstrated that separate genes encode the V and C regions of immunoglobulins. Tonegawa further showed that three separate families of genes code for immunoglobulins and that each gene family contains a large number of DNA segments that code for V regions. Recombination of these DNA segments during the differentiation of B cells is responsible for antibody diversity. Tonegawa was awarded the 1987 Nobel Prize in Medicine for his work, which transformed the emerging science of immunology.

We now understand that in undifferentiated B cells, gene segments are present for a number of different V regions, for one or more junction (J) regions, and for one or more different C regions (Fig. 44-10). Rearrangement of these DNA segments produces an enormous number of potential combinations. Millions of different types of B (and T) cells are produced. By chance, one of those B cells may produce just the right antibody to destroy a pathogen that invades the body. To appreciate the capacity for antibody diversity, consider the diverse combinations of things you create in your everyday life. A familiar example is making an ice-cream sundae. Imagine the varied combinations that are possible using 10 flavors of ice cream, 6 types of sauce, and 15 kinds of toppings.

Researchers have identified additional sources of antibody diversity. For example, the DNA of the mature B cells that codes

for the regions of immunoglobulins mutates very readily. These somatic mutations produce genes that code for slightly different antibodies.

We have used antibody diversity here as an example, but similar genetic mechanisms account for the diversity of T-cell receptors. Although we may actually use only a relatively few types of antibodies or T cells in a lifetime, the remarkable diversity of the immune system prepares it to attack most potentially harmful antigens that may invade the body.

Monoclonal antibodies are highly specific

Before 1975, the only method for obtaining antibodies for medicine or research was immunizing animals and collecting their blood. Then Cesar Milstein and Georges Kohler at the Laboratory of Molecular Biology in Cambridge, England, developed **monoclonal antibodies,** identical antibodies produced by cells cloned from a single cell.

One way to produce monoclonal antibodies in the laboratory is to inject mice with the antigen of interest, for example, an antigen from a particular bacterium. After the mice have produced antibodies to the antigen, their plasma cells are collected. However, these normal plasma cells survive in culture for only a few generations, limiting the amount of antibody that can be produced. In contrast, cancer cells live and divide in tissue culture indefinitely. B cells can be suspended in a culture medium together with lymphoma cells from other mice. (Lymphoma is cancer of lymphocytes.) Then the B cells and lymphoma cells are induced to fuse. They form hybrid cells, known as **hybridomas,** which have properties of the two "parent" cells. Hybridomas can be cultured indefinitely (a cancer cell property) and continue to secrete antibodies (a B-cell property).

Researchers select hybrid cells that are manufacturing the specific antibody needed and then clone them in a separate cell culture. Cells of this clone secrete large amounts of the particular antibody—thus the name *monoclonal antibodies.* Each type of monoclonal antibody is specific for a single antigenic determinant.

Immunologists also use recombinant DNA technology to produce monoclonal antibodies. Because of their purity and specificity, monoclonal antibodies have proved to be invaluable tools in modern biology. For example, a researcher may want to detect a specific molecule present in very small amounts in a mixture. The reaction of that molecule (the antigen) with a specific monoclonal antibody makes its presence known. Monoclonal antibodies are used in similar ways in various diagnostic tests. Home pregnancy tests make use of a monoclonal antibody that is specific for human chorionic gonadotropin (hCG), a hormone produced by a developing human embryo (see Chapters 49 and 50). Several monoclonal antibodies are being used clinically to treat cancer. The drug Herceptin is a monoclonal antibody used in treating a form of breast cancer.

IMMUNOLOGICAL MEMORY

Learning Objectives

9 Describe the basis of immunological memory, and contrast secondary and primary immune responses.

10 Compare active and passive immunity, and give examples of each.

Memory B cells and memory T cells are responsible for long-term immunity. Following an immune response, memory T cells group strategically in many nonlymphatic tissues, including the lung, liver, kidney, and intestine. Many infections occur at such sites, and T cells stationed in those locations can respond quickly. In response to antigen, memory T cells rapidly become T_C cells that produce substances that kill invading cells.

Memory B cells have a "survival gene" that prevents apoptosis, the programmed cell death that is the eventual fate of plasma cells. Memory B cells continue to live and produce small amounts of antibody long after the body has overcome an infection. This circulating antibody is part of the body's arsenal of chemical weapons. If the same pathogen enters the body again, the antibody immediately targets it for destruction. At the same time, specific memory cells are stimulated to divide, producing new clones of plasma cells that produce the same antibody. The presence of circulating antibodies is used clinically to detect previous exposure to specific pathogens. For example, some HIV screening tests measure antibody to the virus that causes AIDS.

A secondary immune response is more effective than a primary response

The first exposure to an antigen stimulates a **primary immune response.** An infection, or an antigen injected into an animal, causes specific antibodies to appear in the blood plasma in 3 to 14 days. After antigen injection, there is a brief *latent period* during which the antigen is recognized and appropriate lymphocytes begin to form clones. A *logarithmic phase* follows, during which the antibody concentration rises rapidly for several days until it reaches a peak (Fig. 44-11). IgM is the principal antibody synthesized during the primary immune response. Finally, there is a *decline phase,* during which the antibody concentration decreases to a very low level.

A second exposure to the same antigen, even years later, results in a **secondary immune response.** Because memory B cells bearing antibodies to that antigen (and also memory T cells with their specific T-cell receptors) persist for many years, the secondary immune response is much more rapid than the primary immune response and has a shorter latent period. Much less antigen is necessary to stimulate a secondary immune response than a primary response, and more antibodies are produced. In addition, the affinity of antibodies is generally much higher. The predominant antibody in a secondary immune response is IgG.

The body's ability to launch a rapid, effective response during a second encounter with an antigen explains why we do not usually suffer from the same infectious disease several times. For example, a person who contracts measles or chickenpox is unlikely

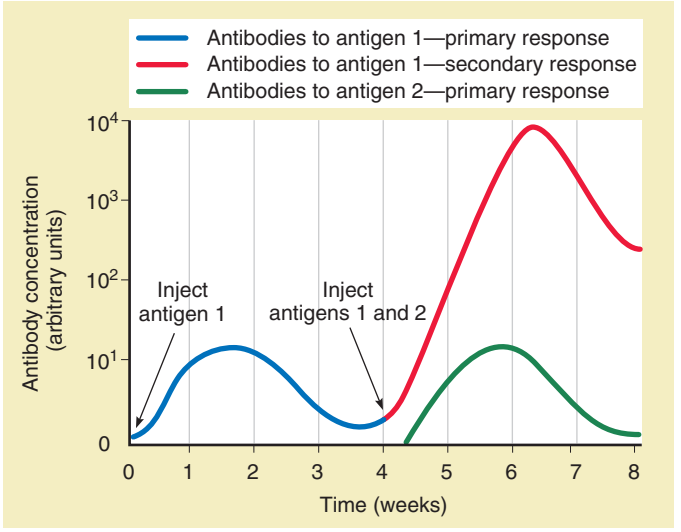

Figure 44-11 ***Animated*** Immunological memory

Antigen 1 was injected at day 0, and the immune response was assessed by measuring antibody levels to the antigen. At week 4, the primary immune response had subsided. Antigen 1 was injected again, together with a new protein, antigen 2. The secondary immune response was greater and more rapid than the primary response. It was also specific to antigen 1. A primary immune response was made to the newly encountered antigen 2.

to become reinfected in the future. When someone is exposed a second time, the immune system responds quickly, destroying the pathogens before they have time to multiply and cause symptoms of the disease. Booster shots of vaccine are given to elicit a secondary immune response, thus reinforcing immunological memory.

You may wonder how a person can get influenza (the flu) or a cold more than once. The reason is that there are many varieties of these viral diseases, each caused by a virus with slightly different antigens. For example, more than 100 different viruses cause the common cold, and new varieties of cold and flu viruses evolve continuously by mutation (a survival mechanism for them), which may result in changes in their surface antigens. Even a slight change may prevent recognition by memory cells. Because the immune system is so specific, each different antigen is treated by the body as a new immunological challenge.

Immunization induces active immunity

We have been considering **active immunity,** immunity that develops following exposure to antigens. Active immunity can be naturally or artificially induced (▮ Table 44-1). If someone with chickenpox sneezes near you and you contract the disease, you develop active immunity naturally. Active immunity can also be artificially induced by **immunization,** that is, by exposure to a *vaccine.* When an effective vaccine is introduced into the body, the immune system actively develops clones of cells, produces antibodies, and develops memory cells.

The first vaccine was prepared in 1796 by British physician Edward Jenner against vaccinia, the cowpox virus. (The term *vaccination* was derived from the name of the cowpox virus.) Jenner's vaccine provided humans with immunity against the deadly disease smallpox, which closely resembles cowpox. Jenner had no knowledge of microorganisms or of immunology, and 100 years passed before French chemist Louis Pasteur began to develop scientific methods for preparing vaccines.

Pasteur showed that inoculations with preparations of attenuated (weakened) pathogens could be used to develop immunity against the virulent (infectious) form of the pathogen. However, not until 20th-century advances in immunology—for example, Burnet's clonal selection theory in 1957 and the discovery of T cells and B cells in 1965—did scientists gain a modern understanding of vaccines. Effective vaccination stimulates the body to launch an immune response against the antigens contained in the vaccine. Memory cells develop, and future encounters with the same pathogen are dealt with rapidly.

Microbiologists prepare effective vaccines in various ways. They can attenuate a pathogen so it loses its ability to cause disease. When pathogens are cultured for long periods in nonhuman cells, mutations adapt the pathogens to the nonhuman host so that they no longer cause disease in humans. This method is used to produce the Sabin polio, measles, mumps, and rubella vaccines. Tetanus and diphtheria vaccines are made from toxins

TABLE 44-1

Active and Passive Immunity

Type of Immunity	When Developed	Development of Memory Cells	Duration of Immunity
Active			
Naturally induced	After pathogens enter the body through natural encounters (e.g., a person with measles sneezes on you)	Yes	Many years
Artificially induced	After immunization with a vaccine	Yes	Many years
Passive			
Naturally induced	After transfer of antibodies from mother to developing baby	No	Few months
Artificially induced	After injection with gamma globulin	No	Few months

secreted by the respective pathogens. The toxin is altered so that it can no longer destroy tissues, but its antigenic determinants are still intact.

Researchers are developing **DNA vaccines** (or RNA vaccines) made from a part of the pathogen's genetic material. The DNA of the pathogen is altered so that it transfers genes that specify antigens. When injected into a patient, the altered DNA is taken up by cells and makes its way to the nucleus. The encoded antigens are manufactured and stimulate both cell-mediated and antibody-mediated immunity. Several DNA vaccines, including vaccines to prevent and treat HIV infection, are in clinical trials.

Passive immunity is borrowed immunity

To provide **passive immunity,** physicians inject people with antibodies actively produced by another organism. The serum or gamma globulin that contains these antibodies is obtained from humans or other animals. Nonhuman serums are less desirable, because nonhuman proteins can act as antigens, stimulating an immune response that may result in serum sickness.

Passive immunity is borrowed immunity. Its effects are temporary whether the immunity is artificially or naturally induced (see Table 44-1). Physicians use artificially induced passive immunity to boost the body's defenses temporarily against a particular disease. For example, when exposed to hepatitis A, a form of viral hepatitis spread through contaminated food or water, people at risk of infection are injected with gamma globulin containing antibodies to the hepatitis pathogen. However, gamma globulin injections offer protection for only a few weeks. Because the body has not actively launched an immune response, it has no memory cells and cannot produce antibodies to the pathogen. Once the injected antibodies are broken down, the immunity disappears.

Pregnant women confer naturally induced passive immunity on their developing babies by manufacturing antibodies for them. These maternal antibodies, of the IgG class, pass through the placenta (the organ of exchange between mother and developing fetus) and provide the fetus and newborn infant with a defense system until its own immune system matures. Babies who are breast-fed continue to receive immunoglobulins, particularly IgA, in their milk.

Review

- What is the basis of immunological memory?
- How is passive immunity different from active immunity?

THE IMMUNE SYSTEM AND DISEASE

Learning Objective

11 Describe the body's response to cancer cells and HIV.

The immune system is generally very effective in defending the body against invading pathogens. However, many factors can impair immune function, including genetic mutations, malnutrition, sleep deprivation, pre-existing disease, stress, and virulent pathogens.

Cancer cells evade the immune system

Cancer is now the second-leading cause of death in Western countries. An estimated one person in three in the United States will develop cancer, and one in five will die of cancer. We have discussed cancer in previous chapters, including Chapters 17 and 38. Here we focus on the interaction between cancer cells and cells of the immune system and on new treatment strategies based on immune mechanisms.

Cancer cells are body cells that have been transformed in a way that alters their normal growth-regulating mechanisms. Every day, a few normal cells may be transformed into precancer cells in each of us in response to the sun's UV rays, X-rays, certain viruses, chemical carcinogens in the environment, and other unknown factors. How does the immune system respond? And why is immune response sometimes ineffective?

Human T cells recognize two main groups of cancer cell antigens: tumor-specific antigens and tumor-associated antigens. *Tumor-specific antigens* are unique to cancer cells. They are induced by certain viruses and by chemical and physical carcinogens, such as ultraviolet light. Most cancer antigens are *tumor-associated antigens,* which are not unique to cancer cells; normal cells express them during fetal development. Some tumor-associated antigens are not expressed after birth, whereas others are expressed at very low levels. High levels stimulate the immune system. Researchers have shown that oncogenes encode tumor-associated antigens (see Chapter 17).

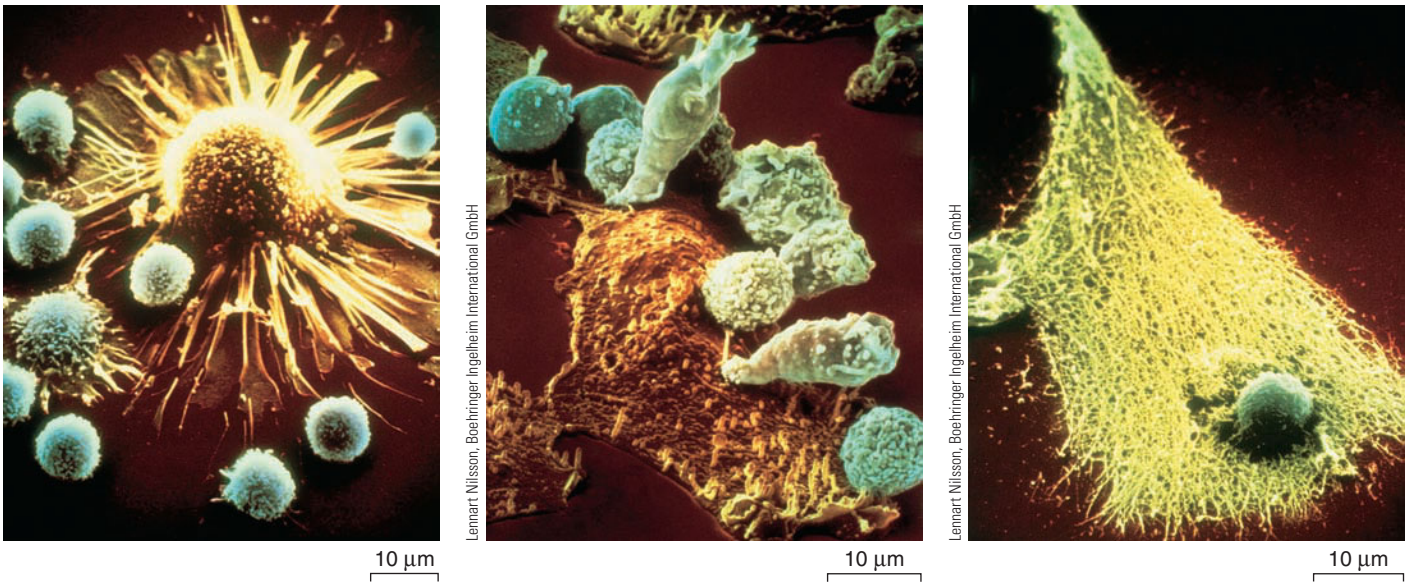
Antigens on cancer cells induce both cell-mediated and antibody-mediated immune responses. NK cells and macrophages destroy cancer cells. Macrophages produce cytokines, including TNFs that inhibit tumor growth. Dendritic cells present antigens to T cells, stimulating them to produce interferons, which have an antitumor effect. T_C cells attack cancer cells directly and also produce interleukins, which attract and activate macrophages and NK cells (Fig. 44-12).

Sometimes cancer cells evade the immune system and multiply unchecked. Some types of cancer cells can block T_C cells. Others dramatically decrease their expression of class I MHC molecules. Recall that T_C cells recognize only antigen associated with class I MHC, so a low level of these molecules prevents tumor destruction. Some cancer cells do not produce co-stimulatory molecules needed to activate T_C cells.

Conventional cancer treatments, such as chemotherapy and radiation, destroy normal cells as well as cancer cells. To treat cancer effectively, treatment strategies must be more specific, or even customized to the particular cancer. For example, cancer researchers are genetically engineering cancer cells to secrete cytokines that would stimulate the patient's immune response.

A few cancer drugs, such as Herceptin, are monoclonal antibodies. Herceptin binds with a growth-factor receptor that is present in excessive numbers on the cells of about 30% of metastatic breast cancers. Herceptin blocks the growth factors that would stimulate proliferation of the cells. More than 50 *angiogenesis inhibitors* are currently being tested. These drugs inhibit the development of blood vessels that tumors need, and although these inhibitors do not cure cancer, they slow its growth.

Researchers are developing cancer vaccines that contain cancer cells or antigens; they stimulate the patient's immune system



(a) An army of T_C cells surrounds a large cancer cell. The T_C cells recognize the cancer cell as nonself because it displays altered or unique antigens on its surface.

(b) Some T_C cells elongate as they chemically attack the cancer cell and break down its plasma membrane.

(c) The cancer cell has been destroyed. Only a collapsed fibrous cytoskeleton remains.

Figure 44-12 Colorized SEMs showing cancer cell destruction

to launch cell-mediated responses to tumor-associated antigens. These vaccines differ from traditional vaccines that are used to destroy pathogens *before* they cause disease. Several kinds of vaccines are being developed, including antigen vaccines, dendritic cell vaccines, DNA vaccines, and tumor cell vaccines.

Scientists make dendritic cell vaccines by taking dendritic cells from a cancer patient and exposing them to antigens from the patient's cancer cells. The combination of dendritic cells and antigens is then injected into the patient. The dendritic cells display the antigens to killer T cells, which then attack the cancer cells. DNA vaccines are made from bits of DNA from a patient's cancer cells. When injected into the patient, the vaccine stimulates increased antigen production. In response, the patient's immune system produces more T cells.

DNA microarrays detect patterns of gene expression in cancer cells. The microarray is a slide or chip that the technician can dot with DNA from thousands of genes (see Fig. 15-13). These genes are used as probes to determine which genes are active in cancer cells. Researchers use microarrays to identify cancer subtypes, information that can help identify and develop the most effective treatments.

Immunodeficiency disease can be inherited or acquired

The absence or failure of some component of the immune system can result in **immunodeficiency disease,** a condition that increases susceptibility to infection. *Inherited* immunodeficiencies have an estimated incidence of 1 per 10,000 births. *Severe combined immunodeficiency syndromes (SCIDs)* are X-linked and autosomal recessive disorders that profoundly affect both cell-mediated immunity and antibody-mediated immunity, resulting in multiple infections. Babies born with SCID typically die by 2 years of age unless they are maintained in a protective bubble until they can be effectively treated, typically with bone marrow transplants.

In *DiGeorge syndrome,* the thymus is reduced or absent and the patient is deficient in T cells. Children born with this disorder are prone to serious viral infections. Treatment involves transplanting bone marrow or fetal thymus tissue.

Researchers use several animal models to study immunodeficiency. For example, the nude mouse (a hairless mutant mouse) does not develop a functional thymus. Because nude mice are deficient in mature T cells, they are used to study the effects of compromised cell-mediated immunity, as well as possible treatments. *Stem cell research* and advances in genetic engineering suggest new approaches to treating immunodeficiency (see Chapters 16 and 17).

Worldwide, the leading cause of *acquired* immunodeficiency in children is protein malnutrition. Lack of protein decreases T-cell numbers and decreases the ability to manufacture antibodies, which in turn increases the risk of contracting opportunistic infections. Another important cause of acquired immunodeficiency is chemotherapy administered to cancer patients.

HIV is the major cause of acquired immunodeficiency in adults

The **human immunodeficiency virus (HIV)** was first isolated in 1983 and was shown to be the cause of **acquired immunodefi-**

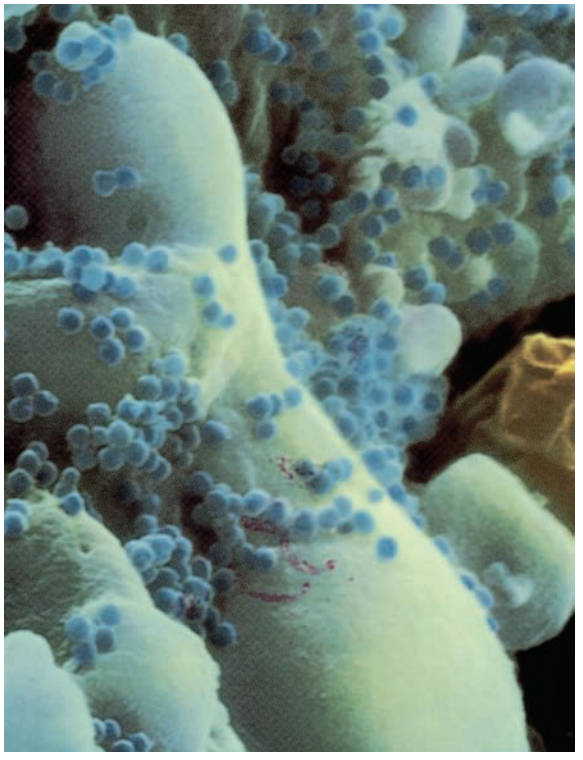
ciency syndrome (AIDS) in 1984. HIV, a retrovirus, has been studied more than any other virus. (Recall from Chapter 24 that a retrovirus is an RNA virus that uses its RNA as a template to make DNA with the help of reverse transcriptase.) Several different strains of the virus are known; HIV-1 is the most virulent form in humans.

The AIDS pandemic has claimed more than 27 million lives. HIV kills more than 3 million people every year, making it the fourth-highest cause of death globally. Epidemiologists estimate that more than 38 million adults and more than 2 million children worldwide are now infected with HIV. The General Assembly of the United Nations has called AIDS a "global emergency" and has outlined measures for mobilizing world resources to combat this disease. HIV/AIDS is more than a medical issue; it is a political, economic, and human rights threat.

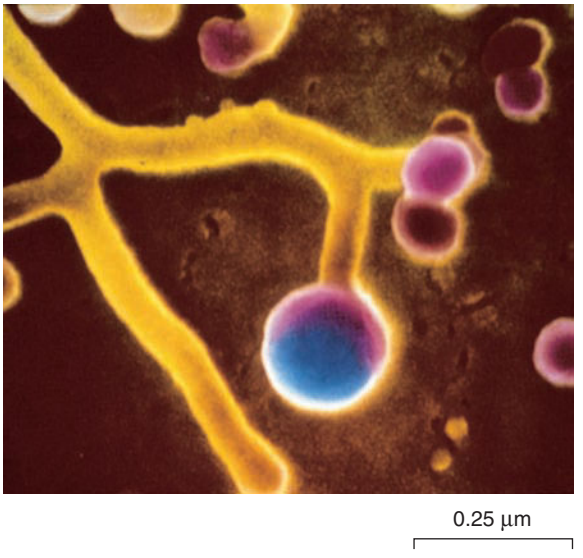
HIV is transmitted mainly during sexual intercourse with an infected person or by direct exposure to infected blood or blood products. Sharing needles and/or syringes (usually for drug injection) with an infected person is a major risk factor. The virus is not spread by casual contact. People do not contract HIV by hugging, casual kissing, or using the same bathroom facilities. Friends and family members who have contact with AIDS patients are not more likely to become infected.

In the United States, 40,000 new HIV infections are occurring each year. Of these new infections, 70% occur in men and 30% in women. Half of all new infections in the United States occur in people 25 years old or younger. Heterosexual contact with infected individuals accounts for more than 75% of HIV infections in women and for an increasing number of cases in both men and women. Use of a latex condom during sexual intercourse provides some protection against HIV transmission, and use of a spermicide containing nonoxynol-9 may provide additional protection.

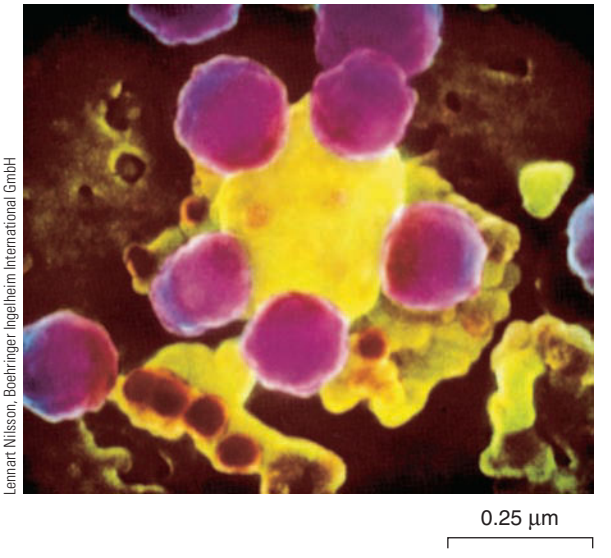
Up to one third of untreated pregnant women infected with HIV will transmit the virus to their babies. HIV can also be transmitted to babies through breastfeeding. Recent drug treatment protocols have reduced the rate of HIV transmission between mother and fetus. Effective blood-screening procedures now



(a) HIV particles attack a T_H cell.



(b) HIV particles budding from the ends of the branched microvilli of a T_H cell.



(c) An even higher magnification of HIV particles budding from a bleb (a cytoplasmic extension broader than a microvillus).

Figure 44-13 HIV infecting a T helper cell

In these colorized SEMs, HIV appears blue. The T helper cell (T_H) appears light green.

safeguard blood bank supplies, markedly reducing the risk of infection by blood transfusion in highly developed countries.

HIV destroys the host immune system

When HIV infects the body, an immune response is launched. Dendritic cells in the mucous membranes at sites of entry appear to be the first cells that HIV targets. When inflammation from another infection is present in the mucosa of the cervix or rectum, large numbers of dendritic cells are present, increasing the risk of HIV infection. Dendritic cells transport HIV from their point of entry to the lymph nodes.

HIV has a protein (gp120) on its outer envelope that attaches to CD4 on the surface of T_H cells, its main target (Fig. 44-13; also see chapter opening photograph). The virus also binds to a second receptor that normally binds chemokines. HIV enters the T_H cell and is reverse-transcribed to form DNA. Its DNA is then incorporated into the host genome. Over time HIV destroys T_H cells, resulting in a dramatic decrease in the T_H cell population. This decrease severely impairs the body's ability to resist infection. T_C cells appear to be the main cells that attack HIV, limiting viral replication and delaying the progress of the disease. Too often, the virus eventually wins the battle.

Although most individuals have no symptoms when first infected, about 15% of infected individuals experience mild flulike symptoms (fever and aching muscles) for a week or so. Some cells infected by HIV are not destroyed, and the virus may continue to replicate slowly for many years. After a time, a progression of symptoms occurs, including swollen lymph glands, night sweats, fever, and weight loss (Fig. 44-14).

In most HIV-infected individuals, the disease eventually progresses to AIDS, the final, lethal stage. By this time, lymph tissue has been destroyed and the blood T_H count has dropped below 200 cells/mm^3. In about one third of AIDS patients, the virus infects the nervous system and causes *AIDS dementia complex*. These patients exhibit progressive cognitive, motor, and behavioral dysfunction that typically ends in coma and death. As a consequence of immunosuppression, many AIDS patients develop and die from serious opportunistic infections or rare forms of cancer, such as Kaposi's sarcoma, a tumor of the endothelial cells lining blood vessels that causes purplish spots on the skin.

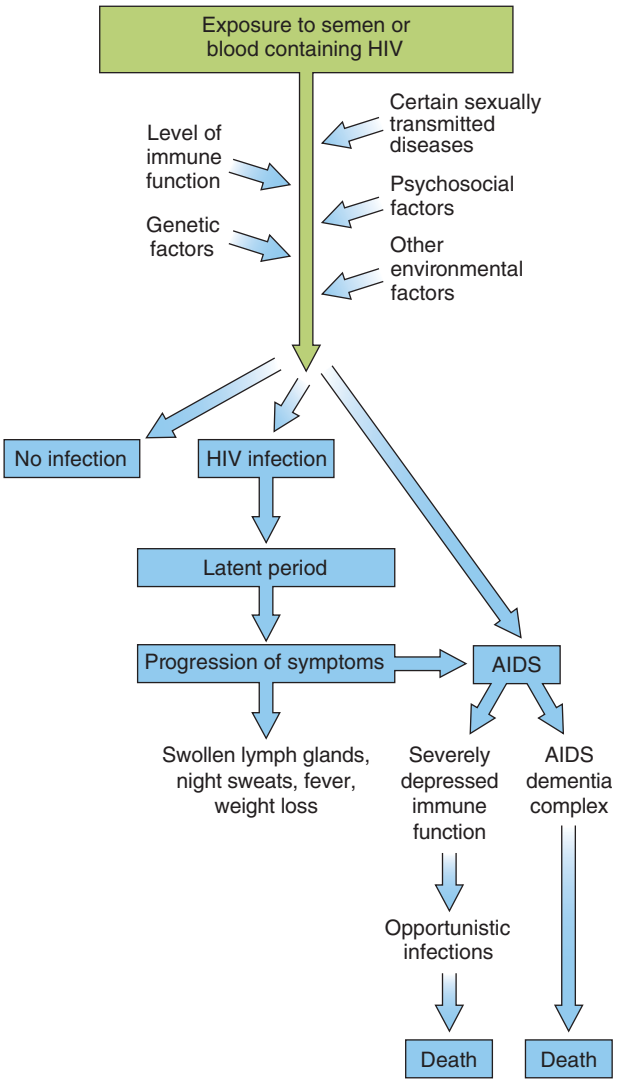


Figure 44-14 ***Animated*** The course of HIV infection

Exposure to semen or blood that contains HIV can lead to HIV infection. The infection is established in lymph nodes and other lymph tissues. During the latent period, chronic infection develops and the virus replicates at a low level. Eventually, viral replication may increase and lead to a progression of symptoms and to AIDS, the final, lethal stage. Although some exposed individuals apparently do not become infected, the risk increases with multiple exposures. Many factors determine whether a person exposed to HIV will develop AIDS.

Researchers are actively working to develop effective treatments

Researchers throughout the world are searching for drugs that will successfully combat the AIDS virus. Because HIV often infects the central nervous system, an effective drug must cross the blood–brain barrier. **AZT** (azidothymidine), the first drug developed to treat HIV infection, can prolong the period prior to the onset of AIDS symptoms. AZT inhibits the action of reverse transcriptase, the enzyme the retrovirus uses to synthesize DNA. As a result, AZT blocks HIV replication. Without producing DNA, the virus cannot incorporate itself into the host cell's DNA. Unfortunately, the reverse transcriptase HIV uses to synthesize DNA makes many mistakes: about 1 in every 2000 nucleotides it incorporates is incorrect. By mutating in this way, viral strains resistant to AZT have evolved.

Protease inhibitors block the viral enzyme protease, resulting in viral copies that cannot infect new cells. Protease inhibitors are used in combination with AZT and other reverse transcriptase inhibitors. Triple-combination treatment has been very effective for many AIDS patients, preventing opportunistic infections and prolonging life. In fact, combination treatment has led to a decline in AIDS incidence and mortality in the United States. Unfortunately, people in many parts of the world cannot afford these expensive drugs, and in impoverished areas, the AIDS epidemic continues to grow. In addition, the emergence of drug-resistant HIV viruses has been a serious problem.

Worldwide containment of the AIDS epidemic will require an effective vaccine that prevents the spread of HIV. Developing

such a vaccine remains a daunting challenge for immunologists. More than 50 vaccines have been developed and tested clinically, but none has proved effective. An effective vaccine would have to counteract HIV's destruction of key cells needed to mount an immune response. Also, because mutations arise at a very high rate, new viral strains with new antigens evolve quickly. A vaccine would not be effective against new antigens and would quickly become obsolete. Some optimism has been generated by an apparently effective vaccine developed against SIV, the simian (monkey) virus that is closely related to HIV.

While immunologists work to develop a successful vaccine and more effective drugs to treat infected patients, massive educational programs have been launched to slow the spread of HIV. Educating the public that having multiple sexual partners increases the risk of AIDS, and teaching sexually active individuals the importance of "safe sex," may help contain the pandemic. Some have suggested that public health facilities should provide free condoms to those who are sexually active and free sterile hypodermic needles to those addicted to intravenous drugs. The cost of these measures would be far less than the cost of medical care for increasing numbers of AIDS patients and the toll in human suffering.

Review

- How does HIV infect the body? How does it affect the body?
- Why is it difficult to develop a vaccine against HIV?

HARMFUL IMMUNE RESPONSES

Learning Objective

12 Summarize the immunological basis of graft rejection, and describe the events that occur during hypersensitivity reactions, including Rh incompatibility, allergic reactions, and autoimmune diseases.

The immune system's ability to distinguish self from nonself sometimes interferes with clinical interventions. For example, efforts to save a patient's life with a blood transfusion or organ transplant can be disastrous if physicians ignore the effects of immune function. Sometimes the immune system malfunctions. **Hypersensitivity** is an exaggerated, damaging immune response to an antigen that is normally harmless, as occurs in an allergic reaction. Inappropriately directed or ineffective immune responses also result in disease states.

Graft rejection is an immune response against transplanted tissue

Skin can be successfully transplanted from one part of the same body to another or from one identical twin to another. However, when skin is taken from one person and grafted onto the body of a non-twin, it is rejected and sloughs off. Why? Recall that tissues from the same individual or from identical twins have identical MHC alleles and thus the same MHC antigens. Such tissues are compatible.

Because there are many alleles for each of the MHC genes, it is difficult to find identical matches. When a tissue or organ is taken from a donor and transplanted to the body of a non-twin host, several of the MHC antigens are likely to be different. The host's immune system regards the graft as foreign and launches an immune response called **graft rejection.** In the first stage of rejection, the *sensitization stage,* T_H cells and T_C cells recognize the antigens. In the second stage, the *effector stage,* T_C cells, the complement system, and cytokines secreted by T_H cells attack the transplanted tissue and can destroy it within a week.

Tissue from donor transplanted into body of recipient ⟶ T_H cells and T_C cells recognize MHC antigens on transplant cells as foreign ⟶ T_C cells launch immune response (graft rejection) ⟶ T_H cells secrete cytokines, and T_C cells destroy transplant cells

Before transplants are performed, tissues from the patient and from potential donors must be typed and matched as closely as possible. Cell typing is somewhat similar to blood typing but is more complex. If all the MHC antigens are matched, the graft has about a 95% chance of surviving the first year. Unfortunately, not many people are lucky enough to have an identical twin to supply spare parts, so perfect matches are difficult to find. Furthermore, some organs, such as the heart, cannot be spared. Most organs to be transplanted, therefore, are removed from unrelated donors, often from patients who have just died.

To prevent graft rejection in less compatible matches, physicians use anti-rejection drugs and/or radiation to suppress the immune system. Unfortunately, these treatments make the transplant patient more vulnerable to pneumonia or other infections and increase the risk of certain types of cancer. If the patient survives the first few months, immunosuppressant drug dosages are reduced. Researchers are developing specific immunosuppression techniques, monoclonal antibodies that will target the specific lymphocytes that cause graft rejection.

Within the United States, thousands of patients are in need of organ transplants. Because the number of human donors does not meet this need, investigators are developing techniques for transplanting animal tissues and organs to humans. Challenges include risks of transmitting animal diseases to humans and graft rejection. Researchers are developing methods for genetically engineering pigs and other animals so that they do not produce antigens that stimulate immune responses in human recipients. These animals could then be cloned and used as donors of hearts, kidneys, and other organs. Effective artificial organs are also being developed.

The body has a few immunologically privileged locations where foreign tissue is accepted. For example, corneal transplants are highly successful because the cornea has almost no associated blood or lymphatic vessels and is thus out of reach of most lymphocytes. Furthermore, antigens in the corneal graft probably would not find their way into the circulatory system and therefore could not stimulate an immune response.

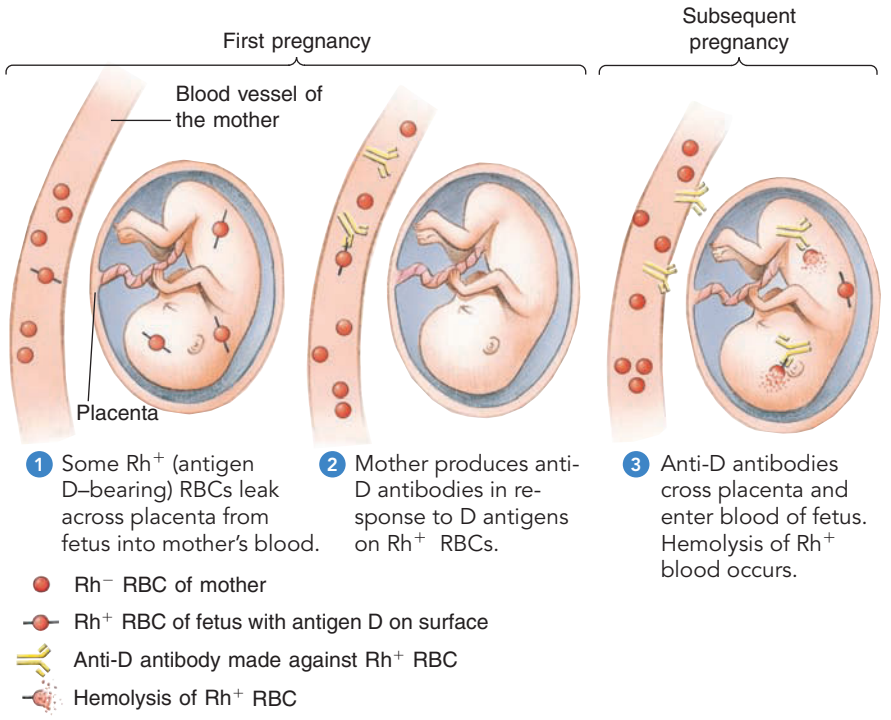

Figure 44-15 ***Animated*** Rh incompatibility

When an Rh-negative woman produces Rh-positive offspring, her immune system can be sensitized. In subsequent pregnancies she may produce anti-D antibodies that cross the placenta and destroy fetal red blood cells.

Rh incompatibility can result in hypersensitivity

Named for the rhesus monkeys in whose blood it was first found, the Rh system consists of more than 40 kinds of Rh antigens, each referred to as an **Rh factor.** By far the most important of these factors is *antigen D.* About 85% of U.S. residents who are of Western European descent are Rh positive—they have antigen D on the surfaces of their red blood cells (in addition to the antigens of the ABO system and other blood group antigens). The 15% or so of this population who are Rh negative have no antigen D. Unlike the situation discussed in Chapter 11 for the ABO blood group, Rh-negative individuals do not naturally produce antibodies against antigen D (anti-D). However, they produce anti-D antibodies if they are exposed to Rh-positive blood. The allele coding for antigen D is dominant to the allele for the absence of antigen D. Hence, Rh-negative people are homozygous recessive, and Rh-positive people are heterozygous or homozygous dominant.

Although several kinds of maternal-fetal blood type incompatibilities are known, **Rh incompatibility** is the most serious (Fig. 44-15). If a woman is Rh negative and the father of the fetus she is carrying is Rh positive, the fetus may also be Rh positive, having inherited the D allele from the father. Ordinarily no mixing of maternal and fetal blood occurs; nutrients, oxygen, and other substances are exchanged between these two circulatory systems across the placenta. However, late in pregnancy or during the birth process, a small quantity of blood from the fetus may pass through a defect in the placenta.

The fetus's red blood cells, which bear antigen D, activate the mother's immune system, stimulating B cells to produce antibodies to antigen D. If the woman becomes pregnant again, she produces anti-D antibodies that cross the placenta and enter the fetal blood. They combine with antigen D molecules on the surface of the fetal red blood cells, causing hemolysis (cells rupture and release hemoglobin into the circulation). The ability to transport oxygen is reduced, and breakdown products of the released hemoglobin damage organs, including the brain. In extreme cases of this disease, known as **erythroblastosis fetalis,** so many fetal red blood cells are destroyed that the fetus may die.

When Rh-incompatibility problems are suspected, fetal blood can be exchanged by transfusion before birth, but this is a risky procedure. More commonly, Rh-negative women are treated just after childbirth (or at termination of pregnancy by miscarriage or abortion) with a preparation of anti-D antibodies known as RhoGAM. These antibodies clear the Rh-positive fetal red blood cells from the mother's blood very quickly, minimizing the chance for her own white blood cells to become sensitized and develop memory cells. The antibodies are also soon eliminated from her body. As a result, if she becomes pregnant again, her blood does not contain the anti-D that could harm the developing fetus.

Allergic reactions are directed against ordinary environmental antigens

About 20% of the U.S. population is plagued by an allergic disorder, such as allergic asthma or hay fever. A predisposition toward these disorders appears to be inherited. In **allergic reactions,** hypersensitivity results in the manufacture of antibodies against mild antigens, called **allergens,** that normally do not stimulate an immune response. Common environmental agents, such as house-dust mites, roach feces, pet dander, and pollen, can trigger allergic reactions in some individuals. In many kinds of allergic reactions, distinctive IgE immunoglobulins are produced.

Let us examine a common allergic reaction, a hay fever response to ragweed pollen (Fig. 44-16). 1 Exposure to pollen causes *sensitization.* Macrophages degrade the allergen and present fragments of it to T cells. The activated T cells then stimulate B cells to become plasma cells and produce pollen-specific IgE. 2 These antibodies attach to receptors on mast cells. The Fc end of each IgE molecule attaches to a mast cell receptor; its V region is free to combine with the ragweed pollen allergen. 3 When a sensitized, allergic person inhales the microscopic pollen, 4 allergen molecules rapidly attach to the IgE on sensitized mast cells.

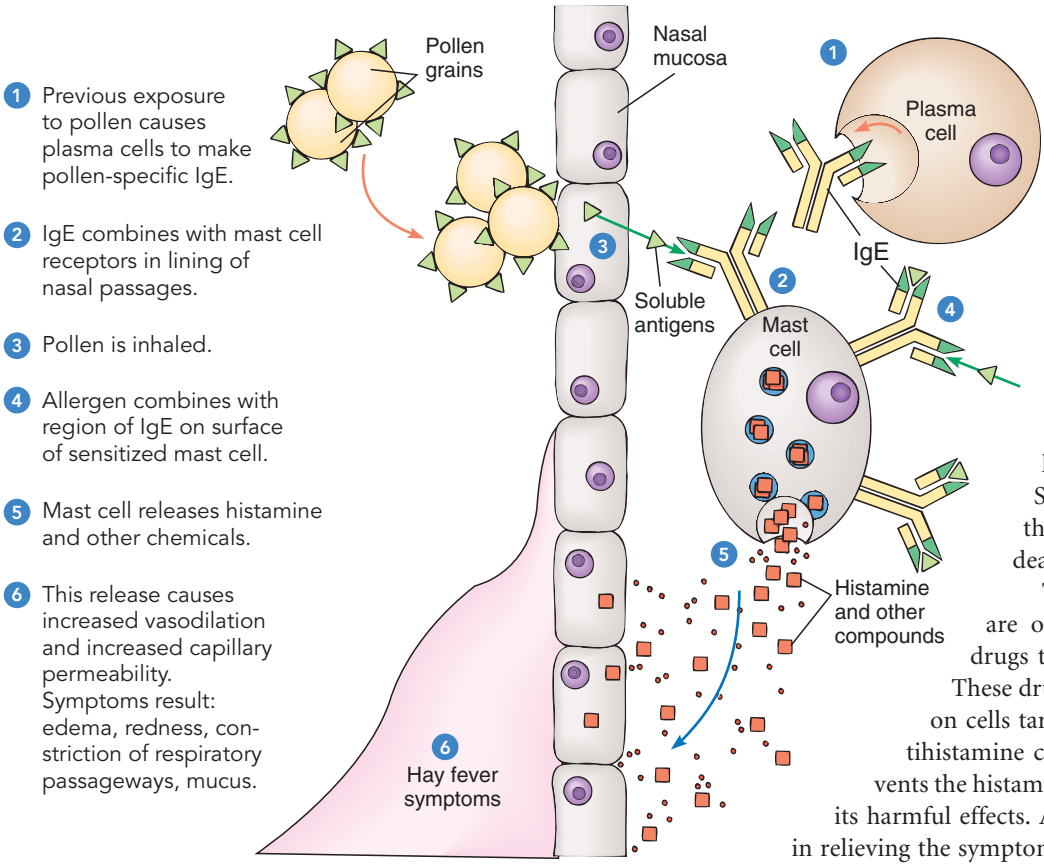

Figure 44-16 An allergic reaction

Pollen causes a common type of allergic reaction in many people.

5 This binding of allergen with IgE antibody stimulates the mast cell to release granules filled with histamine and other molecules that cause inflammation. 6 Blood vessels dilate, and capillaries become more permeable, leading to edema and redness. Such responses cause the nasal passages to become swollen and irritated. A runny nose, sneezing, watery eyes, and a general feeling of discomfort are common.

A prolonged allergic response occurs when neutrophils are attracted by chemical compounds released by the mast cells. Neutrophils migrate to the inflamed area and release compounds that prolong the allergic reaction.

In **allergic asthma,** an allergen–IgE response occurs in the bronchioles of the lungs. Mast cells release substances that cause smooth muscle to contract, and the airways in the lungs sometimes constrict for several hours, making breathing difficult. An antibody to IgE is being clinically tested as a treatment for allergic asthma.

Certain foods or drugs act as allergens in some people, causing a reaction in the walls of the digestive tract that leads to discomfort and diarrhea. The allergen may be absorbed and cause mast cells to release granules elsewhere in the body. When the allergen–IgE reaction takes place in the skin, the histamine released by mast cells causes the swollen red welts called **hives.**

Systemic anaphylaxis is a dangerous allergic reaction that can occur when a person develops an allergy to a specific drug, such as penicillin; to compounds in the venom injected by a stinging insect; or even to certain foods. Within minutes after the substance enters the body, a widespread allergic reaction takes place. Mast cells release large amounts of histamine and other compounds into the circulation that cause extreme vasodilation and capillary permeability. So much plasma may be lost from the blood that circulatory shock and death can occur within a few minutes.

The symptoms of allergic reactions are often treated with **antihistamines,** drugs that block the effects of histamine. These drugs compete for the same receptors on cells targeted by histamine. When the antihistamine combines with the receptor, it prevents the histamine from binding and thus prevents its harmful effects. Antihistamines are useful clinically in relieving the symptoms of hives and hay fever. They are not completely effective, because mast cells release molecules other than histamine that also cause allergic symptoms.

In an autoimmune disease, the body attacks its own tissues

During lymphocyte development, self-tolerance (self-recognition) is established so that lymphocytes do not attack tissues of their own body. However, some lymphocytes remain that have the potential to be *autoreactive,* that is, to launch an immune response against self tissues. Such autoreactivity can lead to a form of hypersensitivity known as *autoimmunity,* or **autoimmune disease,** in which immune cells react immunologically against the body's own cells. Some of the diseases that result from such failure in self-tolerance are rheumatoid arthritis, systemic lupus erythematosus (SLE), insulin-dependent diabetes, scleroderma, and multiple sclerosis.

In autoimmune diseases, antibodies and T cells attack the body's own tissues. In **rheumatoid arthritis,** T cells in the area of inflammation produce a cytokine that promotes inflammation. In addition, antibodies to a joint protein may generate antigen–antibody complexes that are deposited in the small joints. In **multiple sclerosis,** an autoimmune disease of the central nervous system, T_H cells attack self myelin antigens. MRI scans show the loss of myelin sheaths in multiple areas around axons in the brain and spinal cord that are normally myelinated. Scar tissue forms and compromises the ability of these damaged neurons to transmit signals.

Genetic risk factors are important in autoimmune diseases. Mutations that cause abnormal apoptosis or inadequate clearing of dead cells may result in danger signals that activate the immune system. Another important factor is that viral or bacterial infection often precedes the onset of an autoimmune disease. Some pathogens have evolved a tactic known as *molecular mimicry.* They trick the body by producing molecules that look like self molecules. For example, an adenovirus that causes respiratory and intestinal illness produces a peptide that mimics myelin protein. When the body launches responses to the adenovirus peptide, it may also begin to attack the similar self molecule, myelin.

To maintain homeostasis and health, the numerous types of cells, regulatory and signaling molecules, and the complex actions of the immune system must be carefully regulated. Specific T cells and B cells proliferate and respond to challenges by pathogens, but after an effective immune response the expanded populations of T cells and B cells must be decreased to normal numbers. Cells that are no longer needed die by apoptosis. Overactivation of critical components can result in inflammation and autoimmune disease. Underactivation allows pathogens to cause serious disease. Either situation can lead to death.

Review

- What is the immunological basis for graft rejection?
- What immunological events take place in a common type of allergic reaction, such as hay fever?
- What is an autoimmune disease? Give two examples.

SUMMARY WITH KEY TERMS

Learning Objectives

1 Distinguish between nonspecific and specific immune responses (page 945).

- **Immune responses** are the body's defensive responses against **pathogens,** toxins, and other harmful agents. In immune responses, the body recognizes foreign or dangerous macromolecules and responds to eliminate them. **Nonspecific immune responses** provide general and immediate protection against pathogens, some toxins and drugs, and cancer cells.
- **Specific immune responses** target distinct antigens, molecules recognized as foreign or dangerous by cells of the immune system. When it encounters antigens, the immune system produces **antibodies,** highly specific proteins that recognize and bind to specific antigens. Another defining feature of specific immunity is **immunological memory,** that is, the system "remembers" foreign or dangerous molecules and responds more strongly to repeated encounters with the same molecules.

2 Compare, in general terms, the immune responses of invertebrates and vertebrates (page 945).

- Invertebrates depend on nonspecific immune responses, such as physical barriers (cuticle, skin); **phagocytosis;** and **antimicrobial peptides,** soluble molecules that destroy pathogens.
- Vertebrates use both nonspecific and specific immune responses.

3 Describe nonspecific immune responses, including physical and chemical barriers; recognition by Toll-like receptors; the actions of cells, such as phagocytes and natural killer cells; cytokines and the proteins that make up the complement system; and the inflammatory response (page 946).

- Nonspecific immune responses include physical barriers, such as the skin and the mucous linings of the respiratory and digestive tracts. Antimicrobial peptides are produced by epithelial membranes.
- When pathogens break through these first-line defenses, other nonspecific defenses are activated by **Toll-like receptors,** cell-surface receptors on phagocytes and certain other types of cells. Toll-like receptors recognize certain common molecular features of classes of pathogens called **pathogen-associated molecular patterns,** or **PAMPs.**
- **Phagocytes,** including **neutrophils** and **macrophages,** destroy bacteria. **Natural killer (NK) cells** destroy cells infected with viruses and foreign or altered cells such as tumor cells.
- **Cytokines** are signaling proteins that regulate interactions between cells. Important groups are interferons, tumor necrosis factors, interleukins, and chemokines. **Interferons** inhibit viral replication and activate natural killer cells. **Tumor necrosis factor (TNF)** stimulates immune cells to initiate an inflammatory response. **Interleukins** help regulate interactions between lymphocytes and other cells of the body, help mediate inflammation, and can mediate fever. **Chemokines** attract, activate, and direct the movement of certain cells of the immune system.
- **Complement** proteins lyse the cell wall of pathogens; coat pathogens, thereby enhancing phagocytosis; and attract white blood cells to the site of infection. These actions enhance the inflammatory response.
- When pathogens invade tissues, they trigger an **inflammatory response,** which includes three main processes: vasodilation, which brings more blood to the area of infection; increased capillary permeability, which allows fluid and antibodies to leave the circulation and enter the tissues; and increased phagocytosis. In response to infection, **mast cells** release **histamine** and other compounds that cause vasodilation and increased capillary permeability.

ThomsonNOW™ Watch immune responses, including the inflammatory response, by clicking on the figures in ThomsonNOW.

4 Distinguish between cell-mediated and antibody-mediated immunity (page 950).

- In **cell-mediated immunity,** specific T cells are activated; T cells release proteins that destroy cells infected with viruses or other intracellular pathogens.
- In **antibody-mediated immunity,** specific B cells are activated; B cells multiply and differentiate into plasma cells, which produce antibodies.

5 Describe the principal cells of the immune system, and summarize the function of the major histocompatibility complex (page 950).

- Two main types of cells important in specific immune responses are lymphocytes and antigen-presenting cells. Lymphocytes develop from stem cells in the bone marrow. **T cells** are lymphocytes responsible for cell-mediated immunity. The **thymus gland** confers immunocompetence on T cells by making them capable of distinguishing between self and nonself. Three types of T cells are **T cytotoxic cells (T_C cells), T helper cells (T_H),** and **memory T cells.** T cells are distinguished by their **T-cell receptors (TCRs).**
- **B cells** are lymphocytes responsible for antibody-mediated immunity. B cells differentiate into **plasma cells,** which produce antibodies. Some activated B cells become **memory B cells,** which continue to produce antibodies after an infection has been overcome.
- **Antigen-presenting cells (APCs),** including dendritic cells, macrophages, and B cells, display foreign antigens as well as their own surface proteins. **Dendritic cells** are located in the skin and other tissues of the body that interact with the environment. They are specialized to process, transport, and present antigens.
- Immune responses depend on the **major histocompatibility complex (MHC),** a group of genes that encode MHC proteins. Class I MHC genes encode self antigens, glycoproteins expressed on the surface of most nucleated cells. Class II MHC genes encode glycoproteins expressed on APCs of the immune system. Class III MHC genes encode components of the complement system and TNFs.

6 Describe the sequence of events in cell-mediated immunity (page 952).

- In cell-mediated immunity, specific T cells are activated by a foreign antigen–MHC complex on the surface of an infected cell. A co-stimulatory signal and interleukins are also required. Activated T_C cells multiply and give rise to a clone. These cells migrate to the site of infection and destroy pathogen-infected cells. Activated T_H cells give rise to a clone of T_H cells, which secrete cytokines that activate B cells and macrophages.

7 Summarize the sequence of events in antibody-mediated immunity, including the effects of antigen–antibody complexes on pathogens (page 952).

- In antibody-mediated immunity, B cells are activated when they combine with antigen. Activation requires both an APC (such as a dendritic cell or macrophage) that has a foreign antigen–MHC complex displayed on its surface and a T_H cell that secretes interleukins.
- When activated B cells multiply, they give rise to clones of cells. The cloned cells differentiate and form plasma cells. Plasma cells produce specific antibodies, called **immunoglobulins (Ig),** in response to the specific antigens that activated them. An antibody combines with a specific antigen to form an **antigen–antibody complex,** which may inactivate the pathogen, stimulate phagocytosis, or activate the complement system.

ThomsonNOW™ See cell-mediated and antibody-mediated immunity by clicking on the figures in ThomsonNOW.

8 Describe the basic structure and function of an antibody, and explain the basis of antibody diversity (page 952).

- In a Y-shaped antibody, the two arms combine with antigen. An antibody molecule consists of four polypeptide chains: two identical heavy chains and two shorter light chains. Each chain has a **constant (C) region** and a **variable (V) region.**
- Rearrangement of DNA segments during the differentiation of B cells is the main factor responsible for antibody diversity; millions of different types of B (and T) cells are produced.

ThomsonNOW™ Learn more about antibody structure, function, and diversity by clicking on the figures in ThomsonNOW.

9 Describe the basis of immunological memory, and contrast secondary and primary immune responses (page 958).

- After an infection, memory B cells and memory T cells remain in the body. These cells are responsible for long-term immunity.
- The first exposure to an antigen stimulates a **primary immune response.** A second exposure to the same antigen evokes a **secondary immune response,** which is more rapid and more intense than the primary response.

10 Compare active and passive immunity, and give examples of each (page 958).

- **Active immunity** develops as a result of exposure to antigens; it may occur naturally after recovery from a disease or can be artificially induced by immunization with a vaccine.
- **Passive immunity** is a temporary condition that develops when an individual receives antibodies produced by another person or animal.

11 Describe the body's response to cancer cells and HIV (page 960).

- NK cells, macrophages, T cells, and other cells of the immune system recognize antigens on cancer cells and launch an immune response against them. Cancer cells evade the immune system by blocking T_C directly or by decreasing the class I MHC molecules on T_C cells.
- **Acquired immunodeficiency syndrome (AIDS)** is caused by the **human immunodeficiency virus (HIV),** a retrovirus. HIV destroys T helper cells, severely impairing immunity and placing the patient at risk for opportunistic infections.

12 Summarize the immunological basis of graft rejection, and describe the events that occur during hypersensitivity reactions, including Rh incompatibility, allergic reactions, and autoimmune diseases (page 964).

- Transplanted tissues have MHC antigens that stimulate **graft rejection,** an immune response in which T cells destroy the transplant.
- When an Rh-negative woman gives birth to an Rh-positive baby, she may develop anti-D antibodies. **Rh incompatibility** can then occur in future pregnancies.
- In an **allergic reaction,** an **allergen** stimulates the production of IgE, which combines with receptors on mast cells. The mast cells release histamine and other molecules that cause inflammation and other symptoms of allergy. **Systemic anaphylaxis** is a rapid, widespread allergic reaction that can lead to death.
- In **autoimmune diseases,** the body reacts immunologically against its own tissues.

TEST YOUR UNDERSTANDING

1. A molecule recognized as foreign by cells of the immune system is a(an) (a) antibody (b) antigen (c) immunoglobulin (d) interferon (e) cytokine

2. Nonspecific (innate) immune responses include (a) inflammation (b) antigen–antibody complexes (c) immunoglobulin action (d) complement and memory T cells (e) memory B cells

3. Invertebrate defense responses include (a) phagocytosis (b) antimicrobial peptides (c) ability to distinguish between self and nonself (d) a, b, and c (e) a and c

4. Cytokines (a) are regulatory Toll-like receptors (b) prevent the inflammatory response (c) include interferons and interleukins (d) are immunoglobulins (e) include interleukins and complement proteins

5. Which of the following is *not* an action of complement? (a) enhances phagocytosis (b) enhances inflammatory response (c) coats pathogens (d) lyses viruses (e) stimulates allergen release

6. Which of the following cells are antigen-presenting cells? (a) NK cells and monocytes (b) macrophages and plasma cells (c) dendritic cells and macrophages (d) mast cells and B cells (e) memory T cells and memory B cells

7. Which of the following cells are especially adept at destroying tumor cells? (a) NK cells (b) plasma cells (c) neutrophils (d) B cytotoxic cells (e) mast cells

8. Which of the following cells become immunologically competent after processing in the thymus gland? (a) NK cells (b) T cells (c) macrophages (d) B cells (e) plasma cells

9. Cells that have a surface marker called CD4 are (a) NK cells (b) T cytotoxic cells (c) T helper cells (d) B cells (e) plasma cells

10. The major histocompatibility complex (MHC) (a) encodes a group of cell-surface proteins (b) encodes certain antibodies (c) encodes Toll-like receptors (d) inhibits complement release from macrophages (e) consists of Y-shaped molecules

11. Which sequence most accurately describes antibody-mediated immunity?

    1. B cell divides and gives rise to clone 2. antibodies produced 3. cells differentiate and form plasma cells 4. activated T helper cell interacts with B cell displaying same antigen complex 5. B cell activated

    (a) 1, 2, 3, 4, 5 (b) 3, 2, 1, 4, 5 (c) 4, 5, 3, 2, 1 (d) 4, 5, 1, 3, 2 (e) 4, 3, 1, 2, 5

12. A typical antibody (a) is activated by APCs (b) has four identical heavy chains and four identical light chains (c) has IgG and IgD components (d) suppresses phagocyte actions (e) has a Y shape

13. Immunoglobulin A (a) recognizes pathogen-associated molecular patterns (b) combines with NK cells (c) prevents pathogens from attaching to epithelial surfaces (d) is found mainly on B-cell surfaces (e) is found mainly on T cells

14. When a person is exposed to the same antigen a second time, the response is (a) a secondary immune response (b) a more rapid response (c) a response mediated by dendritic cells (d) a, b, and c (e) a and b

15. Graft rejection (a) is an example of passive immunity (b) occurs in mild form after immunization (c) generates monoclonal antibodies (d) does not occur when tissue is transplanted from one identical twin to the other (e) is initiated by the thymus gland

16. In an allergic reaction, (a) the body is immunodeficient (b) an allergen binds with IgE (c) T helper cells release histamine (d) allergen stimulates graft rejection (e) mast cells are deactivated

17. HIV (a) is a retrovirus (b) destroys T cytotoxic cells (c) is attacked mainly by B cells (d) a, b, and c (e) none of the preceding

CRITICAL THINKING

1. Specificity, diversity, and memory are key features of the immune system. Giving specific examples, explain how each of these features is important.

2. Macrophages can be selectively destroyed in the body by the administration of a certain chemical. What would be the effects of such a loss of macrophages? Which do you think would have a greater effect on the immune system, loss of macrophages or loss of B cells?

3. What are the advantages of having MHC antigens? Disadvantages? What do you think would be the consequences of not having them?

4. A playmate in kindergarten exposes John and Jack to measles. John has been immunized against measles, but Jack has not received the measles vaccine. How are their immune responses different? Five years later, John and Jack are playing together when Judy, who has just been diagnosed with measles, sneezes on both of them. Compare their immune responses.

5. Imagine that you are a researcher developing new HIV treatments. What approaches might you take? What public policy decisions would you recommend that might help slow the spread of AIDS while new treatments or vaccines are being developed?

6. **Evolution Link.** Fishes have only one antibody class, IgM. Amphibians have two classes, and the number increases to five main classes in mammals. Hypothesize an adaptive advantage of having a greater variety of antibody groups.

Gas Exchange

Skip Moody/Dembinsky Photo Associates

Ventilation. The white-tailed deer (*Odocoileus virginanus*) and other terrestrial vertebrates ventilate their lungs by breathing air.

KEY CONCEPTS

Air has a higher concentration of molecular oxygen than water does, and animals require less energy to move air than to move water over a gas exchange surface; adaptations in terrestrial animals protect their respiratory surfaces from drying.

Adaptations for gas exchange include a thin, moist body surface; gills in aquatic animals; and tracheal tubes and lungs in terrestrial animals.

In mammals, oxygen and carbon dioxide are exchanged between alveoli and blood by diffusion; the pressure of a particular gas determines its direction and rate of diffusion.

Respiratory pigments combine with oxygen and transport it. Almost all of the oxygen in vertebrate blood is transported as oxyhemoglobin; carbon dioxide is transported mainly as bicarbonate ions.

Most animal cells require a continuous supply of oxygen for cellular respiration. Some cells, such as mammalian brain cells, may be damaged beyond repair if their oxygen supply is cut off for only a few minutes. To stay alive, animals must take in oxygen and release excess carbon dioxide. The exchange of gases between an organism and its environment is known as **respiration.**

Two phases of respiration are organismic and cellular respiration. During **organismic respiration,** oxygen from the environment is taken up by the animal and delivered to its individual cells. At the same time, carbon dioxide generated during cellular respiration is excreted into the environment. In **aerobic cellular respiration,** which takes place in mitochondria, oxygen is essential because it serves as the final electron acceptor in the mitochondrial electron transport chain (see Chapter 8). Carbon dioxide is a metabolic waste product of cellular respiration.

In small, aquatic organisms, such as sponges, hydras, and flatworms, gas exchange occurs entirely by simple **diffusion,** the passive movement of particles (atoms, ions, or molecules) from a region of higher concentration to a region of lower concentration, that is, down a concentration gradient. Most cells are in direct contact with the environment. Dissolved oxygen from the surrounding water diffuses into the cells, whereas carbon dioxide diffuses out of the cells and into the water. No specialized respiratory structures are needed.

Oxygen diffuses through tissues slowly, however. In an animal more than about 1 mm thick, oxygen cannot diffuse quickly enough through layers of cells to support life. Specialized respira-

tory structures, such as gills or lungs, are required to deliver oxygen to the cells or to a transport system and to facilitate excretion of carbon dioxide. Such respiratory systems, working with circulatory systems, provide the efficient intake and transport of oxygen necessary to support high metabolic rates. Animals with lungs carry on *ventilation* by breathing air (see photograph). ■

ADAPTATIONS FOR GAS EXCHANGE IN AIR OR WATER

Learning Objective

1 Compare the advantages and disadvantages of air and water as mediums for gas exchange, and describe adaptations for gas exchange in air.

Gas exchange in air has certain advantages over gas exchange in water. Air contains a much higher concentration of molecular oxygen than water does. In addition, oxygen diffuses much faster through air than through water. Another advantage is that less energy is needed to move air than to move water over a gas exchange surface, because air is less dense and less viscous. A problem with gas exchange in air is the threat of desiccation. Animals that respire in air struggle continuously with water loss.

Gills are adapted for gas exchange in water, and the tracheal tubes of insects and lungs of vertebrates are respiratory structures adapted for gas exchange in air. Respiratory surfaces must be kept moist because oxygen and carbon dioxide are dissolved in the fluid that bathes the cells of the respiratory surfaces. Whether an animal makes its home on land or water, gas exchange takes place across a moist surface.

Adaptations have evolved that keep respiratory surfaces moist and minimize desiccation. For example, the lungs of air-breathing vertebrates are located deep within the body, not exposed as gills are. Air is humidified and brought to body temperature as it passes through the upper respiratory passageways, and expired air must again pass through these airways (providing opportunity for retaining water) before leaving the body. These adaptations protect the lungs from the drying and cooling effects of air.

Review

- What are some advantages of gas exchange in air over gas exchange in water?

TYPES OF RESPIRATORY SURFACES

Learning Objective

2 Describe the following adaptations for gas exchange: body surface, tracheal tubes, gills, and lungs.

Not only must respiratory structures be moist but they must also have thin walls through which diffusion can easily occur. Respiratory structures are generally richly supplied with blood vessels to facilitate transport and exchange of respiratory gases. Four main types of respiratory surfaces have evolved in animals: the animal's own body surface, tracheal tubes, gills, and lungs (Fig. 45-1). Some animals use a combination of these adaptations.

Most respiratory systems carry on **ventilation,** that is, they actively move air or water over their respiratory surfaces. If the air or water supplying oxygen to the cells can be continuously renewed, more oxygen will be available. Sponges do this with flagella, setting up a current of water through the channels of their bodies. Most fishes gulp water, which then passes over their gills. Terrestrial vertebrates have lungs and breathe air. When mammals breathe, the diaphragm and other muscles move air in and out of the lungs.

The body surface may be adapted for gas exchange

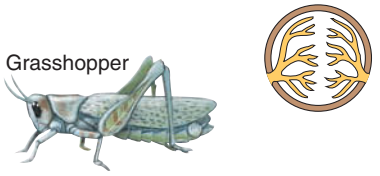
Gas exchange occurs through the entire body surface in many animals, including nudibranch mollusks, most annelids, and some amphibians. These animals are small, with a high surface area–to-volume ratio. They also have a low metabolic rate that requires smaller quantities of oxygen per cell. In aquatic animals, the body surface is kept moist by the surrounding water. In terrestrial animals, the body secretes fluids that keep its surface moist. Many animals that exchange gases across the body surface also have gills or lungs.

Tracheal tube systems deliver air directly to the cells

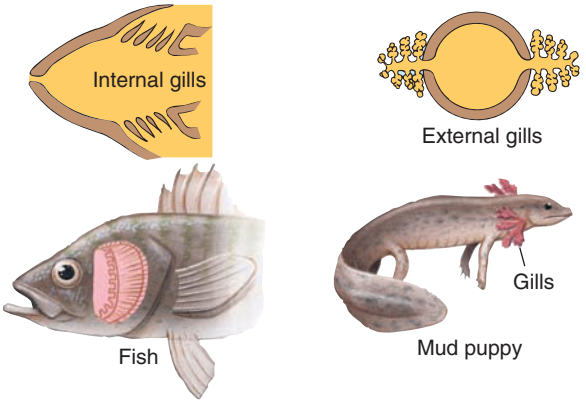
The relatively inefficient open circulatory system of arthropods cannot supply these active animals with enough oxygen. They need a specialized respiratory system. In insects and some other arthropods (such as chilopods, diplopods, some mites, and some spiders), the respiratory system is a network of **tracheal tubes,** also called **tracheae** (Fig. 45-2). Air enters the tracheal tubes through a series of up to 20 tiny openings called **spiracles** along the body surface. In some insects, especially large, active ones, muscles help ventilate the tracheae by pumping air in and out of the spiracles. For example, the grasshopper draws air in through the first four pairs of spiracles when the abdomen expands. Then the abdomen contracts, forcing air out through the last six pairs of spiracles.

Once inside the body, the air passes through a system of branching tracheal tubes, which extend to all parts of the animal. The tracheal tubes terminate in microscopic, fluid-filled tracheoles. Gases are exchanged between this fluid and the body cells. The tracheal system supplies enough oxygen to support the high metabolic rates required by many insects.

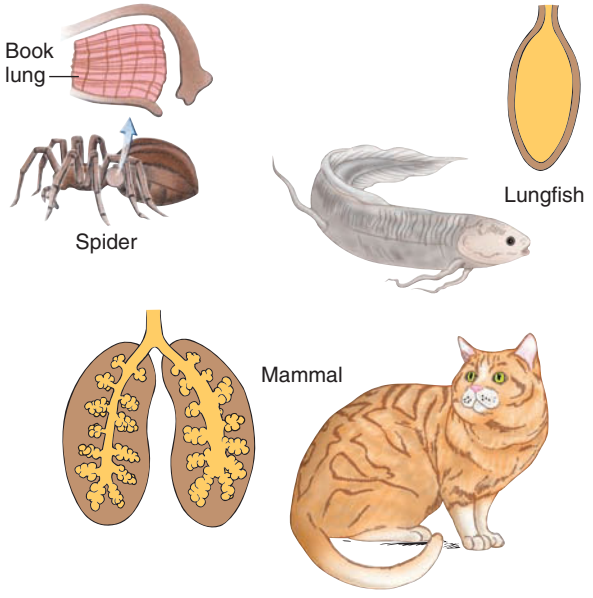
(a) Body surface. Small, multicellular animals exchange gases through the body surface.



(b) Tracheal tubes. Insects and some other arthropods exchange gases through a system of tracheal tubes, or tracheae.



(c) Gills. Most aquatic animals exchange gases through gills, thin structures that extend from the body. Gills can be internal or external.



(d) Lungs. Lungs are adaptations for terrestrial gas exchange.

Gills are the respiratory surfaces in many aquatic animals

Found mainly in aquatic animals, **gills** are moist, thin structures that extend from the body surface. They are supported by the buoyancy of water but tend to collapse in air. In many animals, the outer surface of the gills is exposed to water, whereas the inner side is in close contact with networks of blood vessels.

Sea stars and sea urchins have **dermal gills** that project from the body wall. Their ciliated epidermal cells ventilate the gills by beating a stream of water over them. Gases are exchanged between the water and the coelomic fluid inside the body by diffusion through the gills.

Various types of gills are found in some annelids, aquatic mollusks, crustaceans, fishes, and amphibians. Mollusk gills are folded, providing a large surface for respiration. In clams and other bivalve mollusks and in simple chordates, gills may also be adapted for trapping and sorting food. The rhythmic beating of cilia draws water over the gill area, and food is filtered out of the water while gases are exchanged. In mollusks, gas exchange also takes place through the mantle.

In chordates, gills are usually internal. A series of slits perforates the pharynx, and the gills lie along the edges of these gill slits (see Fig. 31-4). In bony fishes, the fragile gills are protected by an external bony plate, the **operculum.** In some fishes, movements of the jaw and operculum help pump water rich in oxygen through the mouth and across the gills. The water leaves through the gill slits.

Each gill in the bony fish consists of many **gill filaments,** which provide an extensive surface for gas exchange (Fig. 45-3a and b). The filaments extend out into the water, which continuously flows over them. A capillary network delivers blood to the gill filaments, facilitating diffusion of oxygen and carbon dioxide between blood and water. This system is extremely efficient because blood flows in a direction opposite to the movement of the water. This arrangement, called a **countercurrent exchange system,** maximizes the difference in oxygen concentration between blood and water throughout the area where the two remain in contact (Fig. 45-3c).

If blood and water flowed in the *same* direction, that is, *concurrent exchange,* the difference between the oxygen concentrations in blood (low) and water (high) would be very large initially and very small at the end (Fig. 45-3d). The oxygen concentration in the water would decrease as the concentration in the blood increased. When the concentrations in the two fluids became equal, an equilibrium would be reached, and the net diffusion of oxygen would stop. Only about 50% of the oxygen dissolved in the water could diffuse into the blood.
